The conformational conversion of the cellular prion protein (PrPC) into a misfolded, aggregated and infectious scrapie isoform is associated with prion disease pathology and neurodegeneration. Despite the significant number of experimental and theoretical studies the molecular mechanism regulating this structural transition is still poorly understood. Here, via Nuclear Magnetic Resonance (NMR) methodologies we investigate at the atomic level the mechanism of the human HuPrP(90–231) thermal unfolding and characterize the conformational equilibrium between its native structure and a β-sheet-enriched intermediate state, named β-PrPI. By comparing the folding mechanisms of metal-free and Cu²⁺-bound HuPrP(23–231) and HuPrP(90–231) we show that the coupling between the N- and C-terminal domains, through transient electrostatic interactions, is the key molecular process in tuning long-range correlated μs–ms dynamics that in turn modulate the folding process. Moreover, via thioflavin T (ThT)-fluorescence fibrilization assays we show that β-PrPI is involved in the initial phases of PrP fibrillation, overall providing a clear molecular description of the initial phases of prion misfolding. Finally, we show by using Real-Time Quaking-Induced Conversion (RT-QuIC) that the β-PrPI acts as a seed for the formation of amyloid aggregates with a seeding activity comparable to that of human infectious prions.

**Introduction**

Prions are fatal pathogenic infectious agents responsible for neurodegenerative diseases collectively known as prion diseases or transmissible spongiform encephalopathies (TSEs). Prion diseases are characterized by spongiform vacuolation of the brain and nerve cells, accompanied by a wide variety of symptoms such as loss of balance, muscle rigidity, and difficulties in speech. Prions are highly contagious and can persist in the environment for long periods.

Prions are composed of a protein called PrP, which is present in the brain and the peripheral nervous system. PrP is a glycoprotein, meaning it has a sugar component attached to it. PrP has a dual role: it helps maintain the structure of the cell membrane and is involved in cell signaling.

PrP is normally present in the brain and is responsible for maintaining cellular homeostasis. However, when PrP is misfolded, it can cause prion diseases. PrP misfolding leads to the formation of amyloid fibrils, which are abnormal protein aggregates that cause damage to brain cells.

Amyloid fibrils are long, filamentous structures that are composed of a protein called amyloid fibril. Amyloid fibrils are involved in the formation of plaques, which are deposits of misfolded protein seen in the brain of individuals with prion diseases.

**PrPC**

PrPC is a glycoprotein that is expressed in the brain and the peripheral nervous system. It is composed of 231 amino acids and has a molecular weight of 30,000 Da. PrPC is involved in a variety of cellular processes, including synaptic plasticity, neuronal growth and differentiation, and copper homeostasis.

**β-PrPI**

β-PrPI is a β-sheet-enriched intermediate involved in amyloid fibrillar assembly of human prion protein. It is formed through the conformational conversion of the cellular prion protein (PrPC) into a misfolded, aggregated and infectious scrapie isoform. β-PrPI is involved in the initial phases of PrP fibrillation, overall providing a clear molecular description of the initial phases of prion misfolding.

**β-PrPI acts as a seed for the formation of amyloid aggregates**

β-PrPI acts as a seed for the formation of amyloid aggregates with a seeding activity comparable to that of human infectious prions. This suggests that β-PrPI could be a potential target for prion disease therapies.

(α1, α2 and α3) and a short antiparallel β-sheet (β1–β2). The longest helices, α2 and α3, which are covalently linked through a disulphide bridge, form a V-shaped arrangement on which the β-sheet and α1 are anchored. The N-terminal domain (residues 23–126) is intrinsically disordered and contains two charged clusters (CC1, residues 24–30, and CC2, residues 101–110), the octarepeat region (OR, residues 59–90), the non-octarepeat region (non-OR, residues 91–110) and a hydrophobic domain (HD) (residues 111–126) containing a palindromic sequence motif (residues 113–120) (ESI Fig. 1A and B†) known to be able to initiate prion conversion. The N-terminal moiety of PrP© can bind Cu2+ with high affinity at four sites in the OR region and with lower affinity at two sites in the adjacent non-OR region. Recent studies, using biochemical and biophysical techniques, have shown that the flexible N-terminal domain and the C-terminal globular domain may interact with each other in a highly regulated modality playing a crucial role in the physiological and pathological functions of both prion protein and prions. In particular, as demonstrated by dynamic light scattering measurements, this cis interaction is principally dependent on charge complementarity between the positively charged residues of the N-terminal polyanionic region and negatively charged amino acids of helix 3. Additionally, other previous studies have shown that the binding to metal ions, such as Cu2+ and Zn2+, modulates the inter-domain coupling by inducing a specific interaction between the two domains. The misfolding of PrP© into PrP© may occur due to genetic mutations enhancing the aggregation propensity of the protein or through infection by seeding through PrP© forms, which then act as templates for PrP©–PrP© autocatalytic conversion. Nonetheless, most reported prionopathies are the result of spontaneous conversion of PrP© into PrP© whose mechanism has not yet been elucidated, although several in vitro and computational studies indicate high PrP© conformational flexibility as a crucial factor in causing aggregation. The capability of PrP© to populate partially unfolded forms (PUFs) in equilibrium with the native state appears to be an essential step toward conversion to the β-structured toxic oligomers and successively to the fibrillar insoluble forms. In earlier studies, no PUFs were detected in hydrogen–deuterium exchange NMR analysis of human and Syrian hamster prion proteins. However, folding intermediates were successively detected in kinetic studies of HuPrP at pH 5.5, as well as of pathogenic variants of ovine PrP, but not in similar folding analysis of mouse PrP at pH 7.0. Indeed, structural characterization of PrP PUFs has been recently performed under conditions in which the PrP native state is destabilized, at lower pH and/or in the presence of denaturants. Moreover, a recent study has underlined that the N-terminal domain confers to the full-length mouse PrP, MoPrP(23–230), a higher chemical stability with respect to truncated MoPrP(89–230) and allows a completely reversible cooperative process of the protein thermal unfolding. Conversely, MoPrP(89–230) thermal unfolding is irreversible and characterized by an intermediate state. In spite of this wealth of knowledge, an exhaustive investigation at the atomic level of the molecular determinants controlling the prion protein unfolding process, including a high-resolution structural and dynamics characterization of prion protein intermediate states, is still missing. To obtain a detailed structural description of the human PrP full-length, HuPrP(23–231) and truncated HuPrP(90–231) conformational equilibria we use Circular Dichroism (CD) and NMR spectroscopy to follow their thermal unfolding. In particular, we explore at the atomic level the structural-dynamics features of the intermediate state (β-PrPI) that HuPrP(90–231) forms at 61 °C and pH 5.5 showing that, in the regions surrounding the β-sheet and α1 helix, though preserving the three native z-helices, it samples conformations with a significant tendency to increase the β-sheet folding with respect to the native state. Additionally, we provide an atomic resolution picture of the molecular mechanism by which the N-terminal domain regulates the folding process of the full-length HuPrP also highlighting how copper binding alters the prion protein folding energy landscape. Furthermore, by combining NMR relaxation dispersion and thermal unfolding data, we show that HuPrP(90–231) at pH 5.5 and 25 °C is in conformational equilibrium with a PUF that is significantly similar to the folding intermediate detected during the thermal denaturation. By means of thioflavin T (ThT) fluorescence experiments, we also show that truncated HuPrP forms amyloid fibrils more rapidly at 61 °C than at 25 °C, indicating that the documented folding intermediate plays a key role in seeding amyloid growth with a seeding activity similar to that of the pathogenic scrapie form, as revealed by RT-QuIC experiments. Finally, our study outlines a theoretical model that may be common with other multi-domain proteins, in which domain coupling regulates dynamic folding.

Results
The N-terminal domain controls the folding mechanism of human PrP©
We carried out CD thermal unfolding experiments on HuPrP(23–231) and HuPrP(90–231) at pH 6.8 and 5.5 using different protein concentrations ranging from 10 to 80 μM (only for measurements at pH 5.5) (ESI Fig. 2†); the latter pH value has been reported to facilitate PrP© to PrP© conversion and it represents the pH environment of endosomes in which the prion protein misfolding occurs. At low concentration (10 μM), full-length HuPrP shows a single sigmoidal cooperative thermal unfolding with a midpoint transition temperature (Tm) of 69 ± 2 and 59 ± 1 °C at pH 5.5 and 6.8, respectively (ESI Fig. 2 and ESI Table 1†). Differently, the truncated form HuPrP(90–231) at pH 5.5 exhibits a more complex thermal unfolding curve that can be described as the convolution of two transition states, the first having a Tm of 52 ± 1 °C and the second 74 ± 2 °C (ESI Fig. 2 and ESI Table 1†). At pH 6.8, the thermal profile shows two closer transitions, the first centred at 56 ± 3 °C and the second at 70 ± 1 °C (ESI Fig. 2 and ESI Table 1†). Then, we checked the unfolding reversibility by analysing the CD spectra of the HuPrP(23–231) and HuPrP(90–231) prion protein samples that were cooled to 25 °C after heating to 90 °C. At pH 5.5, for HuPrP(23–231) and HuPrP(90–231) the CD spectrum acquired after cooling down to 25 °C is very similar to the native protein.
spectrum (ESI Fig. 2 and 3†) prior to thermal unfolding with a reversibility of 100 and 97%, respectively (ESI Table 2†). In contrast, at pH 6.8 for HuPrP(23–231) and HuPrP(90–231) the CD spectrum acquired after cooling the heat-denatured sample is slightly different to that of the native protein indicating that the thermal unfolding is partially irreversible with a reduction of the reversibility of ~20% (ESI Table 2†). Therefore, to assess whether the cause of this irreversibility is aggregation of the heat-unfolded polypeptide, we performed CD thermal unfolding measurements at increasing protein concentrations (ESI Table 1†) and we evaluated the existence of oligomers and/or large aggregates in solution by comparing the aggregation index (A.I.) (ESI Table 2†) calculated before and after thermal denaturation. Interestingly, we observed that (i) the thermal unfolding process of HuPrP(23–231) and HuPrP(90–231) at both pH values is concentration independent (ESI Fig. 2 and ESI Tables 1 and 2†), (ii) the A.I. values (ESI Table 2†) obtained after cooling the heat-denatured samples are below 10 and (iii) in all cases the $\theta_{222}/\theta_{210}$ ratio (ESI Table 2†) calculated at 25 °C before and after melting is 0.9 which is similar to that determined using the ellipticity values predicted from the NMR structure ($\theta_{222}/\theta_{210} = 1.0$) (PDB ID: 2LSB). Overall, under our experimental conditions the partial reversibility is due to loss of material and/or due to the formation of aggregates. However, as revealed by the thermal unfolding curves observed at different protein concentrations, as well as the melting temperatures and $\theta_{222}/$

Fig. 1  NMR thermal unfolding of the C-terminal HuPrP domain. (A) Series of $^1$H–$^{15}$N HSQC NMR spectra of HuPrP(90–231) as a function of temperature for selected residues (Gly$^{131}$, Thr$^{199}$, Ile$^{139}$, Phe$^{241}$). Temperature increase is indicated by a gradual change in the color of the resonances from light cyan (15 °C) to red (61 °C). (B) Plot of normalized chemical shifts against temperature for 10 representative Hα protons showing mean-like behaviour in the 15–61 °C range. (C) $^1$H–$^{15}$N HSQC spectrum of HuPrP(90–231) acquired at 600 MHz at 61 °C and pH 5.5. (D) $^1$H–$^{15}$N HSQC spectrum of the unfolded HuPrP(90–231) at 61 °C. The NMR spectrum was reconstructed (see the ESI†) using the random coil $^1$H and $^{15}$N chemical shifts predicted for HuPrP(90–231) at 61 °C and pH 5.5 through a specific algorithm suitable for IDPs (Intrinsically Disordered Proteins). (E–G) Ribbon drawing representation of the HuPrP(90–231) NMR structure showing the thermal stability for HN (E), Hα (F) and both (G) protons mapped on their corresponding heavy atoms. The inset indicates the $T_m$ scale. The $T_m$ histogram is also reported.
θ_{219} ratios, for all investigated prion protein samples the unfolding process is not influenced by the formation of a small amount of soluble aggregates which in turn may be involved in precipitation processes. Moreover, CD results support that even in HuPrP the N-terminal domain plays a key role in the thermodynamic stability of the protein and that its absence induces a more complex thermal unfolding, particularly at pH 5.5. To further understand the role of the N-terminal domain in the HuPrP stability, we recorded NMR high-resolution spectra of prion protein folding processes (Fig. 1) of HuPrP(23–231) and HuPrP(90–231) at pH 5.5 by acquiring a series of two-dimensional $^1$H/$^15$N and $^1$H/$^13$C HSQCs between 5 and 80 °C at intervals of 5 °C (with 2 °C intervals in the range 55–75 °C). In both cases, in the $^1$H/$^15$N HSQC spectra, the position of many peaks shifts over the temperature range preceding the first thermal transition, which is indicative of fast amide proton exchange. In the $^1$H/$^15$N HSQC of the full-length HuPrP most residues disappeared at around 57 °C and reappeared at 75 °C with typical unfolded chemical shift dispersion (ESI Fig. 4A and B†). This behaviour indicates that HuPrP(23–231) is characterized by a cooperative two-state thermal unfolding with folding/unfolding conformational exchanges in the micro–millisecond timescale.14,45 Conversely, for the truncated HuPrP, most of the residues exhibit a curved temperature response for the $^1$H and $^15$N resonances suggesting a multi-state process (Fig. 1A and B) that could be resolved in the $^1$H/$^13$C range.

Residues exhibiting $^1$H/$^13$C chemical shifts greater than the Standard Deviation (SD) were mainly observed within the β-strand/α-helix (Gly131-Gly142) and in the loop regions flanking the β2 strand (Pro158-Ser170); the helical content for the three α-helices shows a decrease of ~10% (Fig. 2A and B). Moreover, the Cα and Cβ chemical shift analysis of cysteines (Cys214, Cys179) (ESI Fig. 6†) and the amide temperature coefficients ($\Delta\delta_{NH}/\Delta T$(ppb K$^{-1}$)) (Fig. 2C) indicates that the β-PrPI is stabilized by the permanence of the disulphide bridge and by the conservation of a large part of the native hydrogen bond network that is essential for preserving the three α-helices (Fig. 2A–C). Additionally, we explored the fast ps–ns motions of the folding intermediate state at 61 °C by estimating the model-free order parameters ($S^2$) for the backbone amide group from the backbone chemical shifts using the Random Coil Index (RCI) approach.49 To verify the ability of the assigned backbone resonances of quantifying protein flexibility we predicted $S^2$ values for HuPrP(90–231) at 25 °C and then we compared them to the order parameters estimated from $^15$N NMR relaxation measurements (ESI Fig. 7†). As reported in ESI Fig. 8A–C,† the model-free order parameters obtained applying the RCI method provide for the residues located within secondary structure elements an accurate description of fast ps–ns backbone motions. In the case of the β-PrPI intermediate state, according to the structural data, the $S^2$ values predicted from backbone chemical shifts (ESI Fig. 5B†) show that HuPrP(90–231) at 61 °C largely maintains a discrete structural rigidity in the ps–ns timescale.

**Structural and dynamics features of the prion protein β-sheet enriched intermediate state (β-PrPI)**

We assigned and analysed the backbone chemical shifts for $^1$H, $^15$N and $^13$C nuclei, which are sensitive probes for protein local structure.46–48 When we compared the NMR spectra (eqn (1) in Methods) of truncated HuPrP acquired at 25 °C and 61 °C (ESI Fig. 4A–E and ESI Fig. 5A and B†) significant chemical shift differences greater than the Standard Deviation (SD) were mainly observed within the β1 strand (Tyr128-Leu150) and the nearby loop (Gly131-Phe141), the N-terminus of the α1 helix (Glu146, Tyr150), the β2 strand (Val161-Tyr163) and the following loop (Arg164-Gln172), the N-terminus of the α2 helix (Gln172-Phe175) and the C-terminus of the α3 helix (Asp178, Val183) (ESI Fig. 5A and B†). Significant perturbations were observed for the residues located in the hydrophobic domain (His111-Gly129) and in the turn between z2 and z3 (Thr193-Glu200). The residues from the α2 and α3 helices flanking the disulphide bridge showed small chemical shift differences indicating that these regions are almost unaffected. These results suggest that the main structural differences between the native and the intermediate β-PrPI state are localized in the region around the two native β strands and the α1 helix and that these structural rearrangements slightly perturb only the structure of the edges of adjacent α2 and α3 helices. To identify the secondary structure changes induced by this conformational transition, the Cα secondary chemical shifts at 25 °C (ESI Fig. 4D and E†) and at 61 °C (ESI Fig. 5B†) have been compared. After that, we compared the secondary structure populations between the native and the β-PrPI state finding that in the intermediate state there is a β-sheet population increase of 30% in the region between the β1 strand/α1 helix (Gly131-Gly142) and in the loop regions flanking the β2 strand (Pro158-Ser170); the helical content for the three α-helices shows a decrease of ~10% (Fig. 2A and B). Moreover, the Cα and Cβ chemical shift analysis of cysteines (Cys214, Cys179) (ESI Fig. 6†) and the amide temperature coefficients ($\Delta\delta_{NH}/\Delta T$(ppb K$^{-1}$)) (Fig. 2C) indicates that the β-PrPI is stabilized by the permanence of the disulphide bridge and by the conservation of a large part of the native hydrogen bond network that is essential for preserving the three α-helices (Fig. 2A–C). Additionally, we explored the fast ps–ns motions of the folding intermediate state at 61 °C by estimating the model-free order parameters ($S^2$) for the backbone amide group from the backbone chemical shifts using the Random Coil Index (RCI) approach.49 To verify the ability of the assigned backbone resonances of quantifying protein flexibility we predicted $S^2$ values for HuPrP(90–231) at 25 °C and then we compared them to the order parameters estimated from $^15$N NMR relaxation measurements (ESI Fig. 7†). As reported in ESI Fig. 8A–C,† the model-free order parameters obtained applying the RCI method provide for the residues located within secondary structure elements an accurate description of fast ps–ns backbone motions. In the case of the β-PrPI intermediate state, according to the structural data, the $S^2$ values predicted from backbone chemical shifts (ESI Fig. 5B†) show that HuPrP(90–231) at 61 °C largely maintains a discrete structural rigidity in the ps–ns timescale.

**Identification of the key residues regulating the inter-domain coupling**

The structural mechanisms underlying the different folding behaviours observed in full-length and truncated HuPrP were assessed by means of backbone ($^1$H/$^15$N/$^13$C) chemical shift
Fig. 2 Structural details of the HuPrP(90–231) conformational intermediate state. (A and B) Mapping of the SSP scores onto the representative NMR structure of HuPrP(90–231). The α-helix and β-strand populations are reported in red and blue, respectively. The insets report the increase and the reduction of β-sheet and α1 helix populations, respectively. The disulphide bridge, formed by Cys179 and Cys214, is also reported as a yellow stick. (C) Normalized distribution of $^{1}H N$ temperature coefficient values ($\Delta \delta_{HN}/\Delta T$) for each of the three α-helices of the β-PrP intermediate state.
perturbation mapping (eqn (1) in Methods). Removal of the N-terminal domain results in substantial changes in the $^1$H–$^{15}$N and $^1$H–$^{13}$C HSQC correlation spectra (ESI Fig. 9A and B, ESI Fig. 4A and C, and ESI Fig. 10A–F). Larger chemical shift perturbations ($\Delta_{D_{H,N,C}}$) were observed for His$^{111}$, Met$^{129}$, Pro$^{137}$, Asn$^{159}$, Asp$^{178}$, Gly$^{195}$ and several residues located in the $\alpha_3$ helix (Val$^{209}$, Gln$^{212}$, Cys$^{214}$, Ser$^{222}$-Tyr$^{226}$). Important small differences were observed for a large number of residues homogeneously distributed on the globular domain surface (ESI Fig. 9A†). Notably, the perturbed residues do not create a continuous patch on the surface; they are mainly localized around negatively charged residues (Fig. 3A) and close to the disease-linked mutation sites (ESI Fig. 11A–C†). Considering N-terminal domain richness in positively charged residues (Fig. 3A), these results strongly support previous studies which suggest that the two domains cross-talk through transient electrostatic interactions. To fully address this crucial point and to identify the key amino acids of the globular domain governing the inter-domain coupling we compared the chemical shift variations observed for the full-length and truncated

---

The OR region is also indicated as a light blue box. (lower) C-terminal domain electrostatic surface potential, HuPrP(90–231), at pH 5.5 depicted from electropositive (blue; 10 kcal mol$^{-1}$) to electronegative (red; –10 kcal mol$^{-1}$). The negatively charged residues are indicated. (B) Comparison of $^1$H–$^{15}$N HSQC NMR spectra used to detect the chemical shift variations for HuPrP(90–231) (blue) and HuPrP(23–231) (red) upon addition of 50 and 200 mM NaCl. (C) $\Delta_{D_{H,N}}$ values calculated for 50 and 200 mM plotted versus the primary sequence. The cyan and light green lines indicate the average value for 50 and 200 mM, respectively. (D) Mapping of the residues showing significant HN and N chemical shift changes upon addition of 50 and 200 mM NaCl, respectively.
Fig. 4  Copper binding effects on the prion protein unfolding mechanisms. (A) $^{1}H$–$^{15}N$ signal intensity changes shown as a fraction of the starting values for the addition of 1, 4 and 6 equivalent(s) of Cu$^{2+}$. $I_0$ and $I$ are intensities of $^{1}H$–$^{15}N$ cross-peaks of HuPrP(23–231) in the absence and presence of Cu$^{2+}$. (B) CSPs of HuPrP(23–231) upon binding to 1 and 4 equivalent(s) of Cu$^{2+}$ mapped onto the NMR structure of the C-terminal domain in two orientations. Residues for which CSP$_{HN,N}$ > mean + SD are shown in light green and orange for HuPrP(23–231)/Cu$^{2+}$ (1 : 1) and (1 : 4), respectively. In the case of HuPrP(23–231)/Cu$^{2+}$ (1 : 6) the residues for which the HN/N signals are not detected are reported as violet. (C) $\delta_{C\alpha}$ secondary chemical shifts observed for the copper induced intermediate state for HuPrP(23–231) upon binding to 1 and 4 equivalent(s) Cu$^{2+}$. The $\delta_{C\alpha}$ secondary chemical shifts related to the β-PrP intermediate state are also reported (light grey). (D) Mapping of the SSP scores obtained...
HuPrP upon addition of increasing amounts of sodium chloride (eqn (4) in Methods) (Fig. 3B). In the presence of 50 mM NaCl, significant chemical shift perturbations were observed for residues surrounding Glu146, Asp147, Glu152, Asp178, Glu196, Glu200 and Asp202 (Fig. 3C and D). Interestingly, upon increase of the NaCl concentration to 200 mM we observed substantial chemical shift variations for additional residues neighbouring Asp144, Glu207, Glu219 and Glu221 (Fig. 3C and D). Overall, NMR structural data clearly show that the inter-domain coupling is regulated by two patches: patch1 is formed by the acidic residues positioned in the α2 and α3 helices and it represents the primary anchor point for the N-terminal domain (Fig. 3D); patch2 is mainly composed of the negatively charged residues surrounding the α1 helix and it contributes to stabilizing the transient electrostatic inter-domain coupling (Fig. 3D). In this scenario, we hypothesized that the N-terminal domain might regulate the folding mechanism of the full-length HuPrP, avoiding the formation of intermediate states by altering the secondary and/or tertiary structure of the C-terminal domain. Thus, we first compared the Hz and Cα secondary chemical shifts of the full-length HuPrP with those of the truncated form (ESI Fig. 9B†), showing that the N-terminal domain does not affect the secondary structure organization of the globular domain. Then, we investigated the effect of the N-terminal domain on the HuPrP(90–231) tertiary structure by fitting the backbone chemical shifts measured for the full-length protein to the corresponding shift values observed for the globular domain (eqn (2) in Methods and ESI Fig. 10C and D†) and to the shifts predicted from the NMR structure of the globular domain (eqn (3) in Methods and ESI Fig. 10E and F†). The evaluation of the QΔ and Q factor values (ESI Fig. 10C–F†) clearly show that the N-terminal domain transiently interacts with the C-terminal globular domain without altering the tertiary organization of the latter.

Effect of copper binding on the full-length prion protein folding processes

Prompted by previous results showing that in the full-length prion protein the cis inter-domain coupling is mediated by Cu\textsuperscript{2+} binding,\textsuperscript{28,29} we carried out an atomic resolution description of the copper binding effects on the single sigmoidal cooperative unfolding mechanism observed for full-length HuPrP. First, the identification of the metal binding sites of HuPrP(23–231) was assessed by means of backbone \textsuperscript{1}H/\textsuperscript{15}N chemical shift perturbation mapping and by evaluating the reduction of the height of NMR signals upon addition of 1, 4 and 6 equivalent(s) of the paramagnetic copper ion (Fig. 4A and B). At low 1 molar equivalent of Cu\textsuperscript{2+} the signal intensity ratios (Fig. 4A and B) indicate that the OR region binds the metal ion by a multiple histidine Cu\textsuperscript{2+}-binding mode. At 4 molar equivalents of Cu\textsuperscript{2+} (Fig. 4A and B) the intensity ratio profile shows that in addition to the OR-region the Cu\textsuperscript{2+}-binding involves both His\textsuperscript{96} and His\textsuperscript{111}. Furthermore, in agreement with previous studies performed at 37 °C,\textsuperscript{29} substantial intensity ratio reduction due to the copper paramagnetic relaxation effect (PRE) is observed at three distinct regions (i.e. (i) Ile\textsuperscript{138}-Gly\textsuperscript{142}, (ii) Asn\textsuperscript{173}, Val\textsuperscript{180} and (iii) Met\textsuperscript{206}-Glu\textsuperscript{211}) of the globular domain, even in the presence of 1 molar equivalent of metal ions (Fig. 4A and B). Interestingly, at both copper concentrations, chemical shift perturbation analysis shows that the recognition of the metal ion is assisted by significant long-range structural rearrangements of the globular domain that involve residues far beyond the binding sites (Fig. 4A and B). In detail, larger chemical shift perturbations (∆ψ\textsubscript{HN}) were mainly observed for the residues located in the three α-helices [Arg\textsuperscript{248}-Arg\textsuperscript{251} (α1); Glu\textsuperscript{172}-Ile\textsuperscript{182} (α2); Glu\textsuperscript{207}-Ile\textsuperscript{215} (α3)] (Fig. 4A and B). These results indicate that in the Cu\textsuperscript{2+}-loaded HuPrP(23–231) the interaction between the N-terminal and the globular domain, driven by the described electrostatic interactions, is altered independently of total copper concentration. At higher copper concentration (6 molar equivalents) we observed in the \textsuperscript{1}H/\textsuperscript{15}N HSQC spectrum a homogeneous drastic reduction of all observable NMR signals indicating that the full-length HuPrP at 25 °C undergoes aggregation in the presence of a large excess of copper (Fig. 4A and B). We therefore investigated whether the modulation in the two-domain coupling by Cu\textsuperscript{2+} binding also affects the unfolding mechanism of Cu\textsuperscript{2+}-loaded HuPrP(23–231). Interestingly, CD thermal unfolding data indicate that the full-length HuPrP upon copper binding (1 or 4 equivalent(s)) shifts the unfolding mechanism from a single sigmoidal cooperative model to a more complex process with two transitions (ESI Fig. 2 and ESI Table 1†). Then, we applied the thermal unfolding NMR experiments scheme used for truncated HuPrP in the range from 5 °C to 80 °C. At 61 °C (ESI Fig. 12A and B†) in the \textsuperscript{1}H/\textsuperscript{13}C HSQC spectra of Cu\textsuperscript{2+}-loaded HuPrP(23–231) there is considerable dispersion of signals in both proton and nitrogen dimensions indicating that the presence of copper stabilizes partially folded intermediate states. We compared the secondary HN and N shifts observed for Cu\textsuperscript{2+}-loaded HuPrP(23–231) with those assigned for the truncated HuPrP intermediate state at the same temperature. As reflected by the QΔα and QΔψ\textsubscript{HN} factor values (eqn (2) in Methods and ESI Fig. 12C and D†), there is a discrete chemical shift correlation suggesting that the copper induced intermediate states may present structural similarities to β-PrPI. To further describe the structural details of the Cu\textsuperscript{2+}-loaded HuPrP(23–231) intermediate state detected in the presence of 1 or 4 equivalent(s), we evaluated the Cα secondary chemical shifts at 61 °C and we estimated the secondary structure populations for both copper concentrations (Fig. 4C). As reported in Fig. 4C and D, in the Cu\textsuperscript{2+} induced intermediate states the three native α-helices are less conserved than β-PrPI and the regions of the globular domain comprising amino acids Gly\textsuperscript{90}–Gly\textsuperscript{142} and Pro\textsuperscript{158}–Ser\textsuperscript{170} are completely unfolded without showing any conformational

for HuPrP(23–231)/Cu\textsuperscript{2+} (1 : 1) and HuPrP(23–231)/Cu\textsuperscript{2+} (1 : 4) at 61 °C onto the representative NMR structure of HuPrP(90–231). The α-helix and β-strand populations are reported in red and blue, respectively. (E and F) Thermal stability of HN protons for HuPrP(23–231)/Cu\textsuperscript{2+} (1 : 1) (E) and (1 : 4) (F) mapped on their corresponding heavy atoms.
preferences to the β-sheet structure. Additionally, both copper induced intermediate states are conformationally restricted by the conservation of the disulphide bridge as revealed by the Cz and Cβ chemical shifts of cysteines (ESI Fig. 6†). Finally, at both 1 : 1 and 4 : 1 copper ratios (Fig. 4E and F) midpoint unfolding temperatures of single HN atoms are mostly included between 37 °C and 57 °C. Overall, our results show that the copper binding in the full-length human prion protein influences the cis inter-domain coupling that in turn modifies the unfolding mechanism with the formation of a stable partially folded intermediate state.

The N-terminal domain regulates the µs–ms dynamics of full-length prion protein

The comparison of the structural details between full-length and truncated HuPrP does not give a full explanation of the reason why the removal of the N-terminal domain induces a dramatic change in the folding process from a single sigmoidal cooperative to a more complex folding/unfolding pathway. Protein dynamics may play a role in the modulation of the unfolding mechanism. Thus, we investigated protein motions of full-length and truncated forms in the nanosecond-to-picosecond and millisecond-to-microsecond timescales. First, [1H]–15N-heteronuclear NOE experiments (ESI Fig. 13A and B†), reporting on dynamics in the ns–ps timescale, show that the presence of the disordered N-terminal tail (residues 23–89) slightly affects the dynamics of the globular domain. In particular, the region from Gly90 to Asn100 shows more pronounced fluctuations, once the N-terminal domain is removed; differently, all secondary structure elements are influenced to a different extent, presenting small variations of backbone motions (ESI Fig. 13C†). Globally, these differences do not seem to result in a clear variation in rigidity between the globular domain of the two proteins in the nanosecond-to-picosecond timescale. We then analysed the dynamics of the globular domain in the millisecond-to-microsecond timescale (ESI Fig. 13D–I†), firstly evaluating 1H–15N cross-peak intensity changes over a range of temperature for both full-length and truncated HuPrP (ESI Fig. 13D and E†). In HuPrP(90–231) a discrete number of residues (Gly131, His155, Tyr149, Tyr166, Tyr218, Glu221, Ser230 and Ser231) localized in different parts of the globular domain show a remarkable signal broadening suggesting the presence of slow conformational rearrangements in these regions (ESI Fig. 13D†). In contrast, in the full-length HuPrP the signal intensities are weakly perturbed at increasing temperatures (ESI Fig. 13E†), indicating that the presence of the N-terminal domain reduces the temperature sensitivity of the residues located inside the globular domain that in turn results in a change in the conformational flexibility of these regions. Dynamic processes on the µs–ms timescale in full-length and truncated HuPrP were further identified by the excess contribution to backbone amide 15N–R2 from chemical exchange line broadening (Rex) (ESI Fig. 14A and B†). In particular, Rex values were determined as the difference between the “total R2” rates (ESI Fig. 13F–I†) and the effective R1 rates derived from R1ρ experiments38 (eqn (5) in Methods). Residues in HuPrP(90–231) showing a significant Rex (Rex ≥ 3 s⁻¹) are mainly localized in the regions surrounding the β-sheet, the z1 and z3 helices, and the amino-acids which surround the β1–z1 and z1–β1 loops and the turn connecting the β2 strand to z2 (ESI Fig. 14A†). Interestingly, in the full-length prion protein the presence of the N-terminal domain significantly alters the chemical exchange line broadening of residues located inside the globular domain. In particular, HuPrP(23–231) shows significant Rex decreases for residues within the two β-strands, z3-helix and especially the two loops, β1–z1 and z1–β2, surrounding the β-sheet (ESI Fig. 14B†). Notably, changes in Rex for HuPrP(23–231) are not only related to the residues directly involved in the inter-domain transient interactions, but they are distributed on internal regions of the protein, suggesting that the µs–ms timescale motions are highly coupled events. Overall, these findings support the idea that the N-terminal domain controls the conformational plasticity of the globular domain on the µs–ms timescale by transient inter-domain interactions.

Conformational equilibrium of human prion protein described by relaxation dispersion experiments

We hypothesized that the µs–ms conformational exchanging states observed for the HuPrP(90–231) might be correlated with β-PrPI. We hence performed 15N R1ρ relaxation dispersion (RD) experiments51–53 and analysed the dispersion curves of selected residues localized in the regions of HuPrP(90–231) showing significant conformational exchange. We fitted the data for 10 residues to the two-site (A and B) exchange Bloch–McConnell formalism34 (eqn (6) in Methods) for both full-length and truncated HuPrP. To understand whether the analysed residues undergo a common motion and share a common exchange rate (kex) with the same population of exchanging states (P(B), P(A)) but with residue specific chemical shift differences ΔδAB, all residues were fitted singularly and simultaneously (ESI Tables 3 and 4†). For HuPrP(90–231) the obtained exchange rates for individual residues are consistently in the 400–3000 (s⁻¹) range, whereas for HuPrP(23–231) the fitted kex are in the range of 200–500 (s⁻¹). Interestingly, for truncated HuPrP the residues Gly131, Tyr150, Glu152, His155, Gln160 and Met166 are characterized by kex values higher than the residues located in the last two helices (z2 and z3), whereas for HuPrP(23–231) the residues display similar exchange rates with the exception of Glu152, His155, and Gln160, which do not show any RD profile (Fig. 5A and B and ESI Table 3†). Notably, the differences in exchange rates between truncated and full-length prion protein forms are mainly detected in the region surrounding the β-sheet and the first α-helix, where the average exchange rate drops from ~2600 to ~350 (s⁻¹) (ESI Table 3†). These results indicate that the removal of the N-terminal domain in the full-length HuPrP alters the two-state conformational transition. After that, in the case of the full-length form, considering the narrow dispersion of kex (ESI Table 3†) obtained from the individual fits, we globally fitted all residues showing dispersion curves (Fig. 5A and B and ESI Fig. 15A†). As reflected by the small values of χglobal/χmin (<2) (eqn (7) in Methods), all analysed residues can be fitted to a common two-state exchange process with a kex of...
Fig. 5  Conformational exchange processes of HuPrP(90–231) and HuPrP(23–231) implicating the N-terminal domain as a dynamic switch. (A) Close-up view of HuPrP(90–231) regions showing a significant increase in $R_{ex}$ upon deletion of the N-terminal domain. The residues investigated by $^{15}$N R$_{1p}$ RD experiments are labelled. (B) Best fit curves to a two-site exchange model assuming a common motion for residues of HuPrP(90–231) (blue) and HuPrP(23–231) (red). (C) Residue-specific $\phi_{ex}$ ($\times 10^3$ (s$^{-1}$)$^{-1}$) parameters obtained from the global fit of the HuPrP(90–231) cluster A residues (blue spheres); the sites reporting different exchange processes are reported in yellow (($^*$) indicates data extracted from the individual fit). (D) Residue-specific $\phi_{ex}$ parameters extracted for HuPrP(23–231) from the global fit (yellow spheres). The residues that do not show any RD profile are reported (red spheres).
313 ± 23 (s⁻¹) indicating that these residues are governed by a single dynamic process (Fig. 5A and B and ESI Table 4†). In contrast, the truncated HuPrP(90–231) shows a wide dispersion of $k_{ex}$ (ESI Table 2†) and large values of $\chi_2$ (ESI Table 4†) revealing that not all sites report on the same exchange process ($k_{ex} = 2197 ± 138$ (s⁻¹)) (Fig. 5C and D). Therefore, we globally fitted all residues of cluster A ($k_{ex} = 2502 ± 106$ (s⁻¹)) (Fig. 5C and ESI Table 5†) obtained by excluding the sites experiencing conformational fluctuations distinct from the global process (see the ESI†). Interestingly, the similarity between the per-site residuals estimated from the global fit ($\chi_{2\text{global}}$) and the values obtained from individual fits ($\chi_{2\text{ind}}$ ($\chi_{2\text{global}}/\chi_{2\text{ind}} < 2$) (Fig. 5C and ESI Table 5†) indicates that the residues included in cluster A undergo a common motion that is uncoupled from the rest of the C-terminal domain. This observation is corroborated by the lowest BIC and AICc (eqn (8) and (9) in Methods) values obtained for the global cluster fit (ESI Table 6†) revealing that the fitted parameters estimated for cluster A provide a more adequate description of the experimental data with respect to those obtained by fitting all residues simultaneously. Overall, RD data indicate that the full-length human prion protein is characterized by long-range coupled μ–ms motions between the region connecting the first β-strand with the second α-helix (Gly131-Ser170) and the rest of the protein (Asn171-Ser231) (Fig. 5D) and strongly suggest that the perturbation of these correlated dynamics plays a crucial role in the regulation of the unfolding process. We therefore analysed the residue-specific exchange parameter $\phi_{ex}$ that is correlated with the chemical shift difference ($\phi_{ex} = P_A P_B A_u N_2$). For cluster A of HuPrP(90–231) the $\phi_{ex}$ values were in the 11 000–23 000 (s⁻²) (ESI Table 4†) range, whereas for HuPrP(23–231) $\phi_{ex}$ values obtained for the fitted residues were within 5000 (s⁻²) (ESI Table 4†). These results identify, in truncated HuPrP, groups of residues (Gly131, Tyr150, Glu152, His155, Gln160, Met166, and Gln223) experiencing larger structural changes in the conformational transition. Of

(A and B) $\phi_{ex}$ parameters (ppm²) derived from the global fit of cluster A ($k_{ex} = 2502 ± 106$ s⁻¹) of HuPrP(90–231) plotted as a function of the squared differences in chemical shift between the native and the intermediate state ($\Delta \delta_{\text{F-U}}$)² (ppm²) (A) and between the native and the denaturated state ($\Delta \delta_{\text{F-U}}$)² (ppm²) (B). (C) Conformational landscape of HuPrP(90–231) revealed by NMR relaxation dispersion and thermal melt data. (D) Best fit curves to a two-site exchange model assuming a common motion for residues of HuPrP(90–231) E219K. (E) Mapping of the residue-specific $\phi_{ex}$ parameters extracted for HuPrP(90–231) E219K from the global fit. The residues that do not show any RD profile are reported as dark grey spheres.
note, residues most affected by the transition are clustered around β1, the β1-α1 loop, α1, the α1-β2 loop, and β2, which are the regions that in the first native–intermediate transition of the thermal unfolding present the greatest structural changes. Therefore, to explore whether the millisecond to microsecond local fluctuations are correlated with the unfolding transitions in HuPrP(90–231) we evaluated the correlation between the Φex values of HuPrP(90–231) [cluster A], obtained from RD measurements, versus the chemical shift difference observed between the native and β-PrPrI states (Fig. 6A and B). If the line broadening in NMR spectra of truncated HuPrP is due to conformational exchange between the native and intermediate states, plots of Φex versus (Δδex, 2)3 should be linear with a slope of pνθβ. As reported in Fig. 6A, residues exhibiting large differences in 15N chemical shift between the native and intermediate states in NMR thermal unfolding also produce large-amplitude relaxation dispersions. Conversely, residues with 15N chemical shifts that are less perturbed during the thermal unfolding show smaller Φex values. Interestingly, the Φex versus Δδex, 2 plot (Fig. 6A) indicates that between the parameters inferred from the RD and the thermal unfolding data exists a good correlation (Pearson correlation coefficient of 0.96) with the excited state population, calculated from the slope, of around 15 ± 2% which is in close agreement with the values obtained for human prion protein by high pressure NMR spectroscopy and kinetic measurements.35,36 We also plotted the Φex values as a function of squared differences in chemical shifts between the native state and those predicted for a random-coil chain (Δδex, 2). As expected (Fig. 6B), there is no correlation between the two parameters confirming that the minor conformation is partially folded. These results provide evidence that truncated HuPrP, in the region connecting the first β-strand with the second α-helix, presents at 25 °C a chemical exchange in which the native (ground) state is in equilibrium with a minor conformational state (excited) that is not completely unstructured (Fig. 6C) but it is structurally similar to β-PrPrI detected during the thermal unfolding. Therefore, considering the structural similarities, it is plausible that the observed low-populated state for HuPrP(90–231) might play crucial role in the formation of the intermediate state (Fig. 6C). Nevertheless, the fact that the HuPrP(90–231) low-populated state and β-PrPrI share characteristic conformational features strongly suggests that β-PrPrI is an intermediate state on protein folding pathways en route to the native state.

To further show that the μs–ms conformational exchanging states play a crucial role in the conformational conversion of the prion protein we investigated the conformational equilibrium of a mutant of the HuPrP(90–231) carrying the dominant-negative E219K polymorphism27 by 15N RD experiments (Fig. 6D and ESI Tables 3 and 4†). Interestingly, for HuPrP(90–231) E219K the exchange rates for individual residues are consistently in the 300–500 (s−1) range (ESI Table 3†) indicating that the mutation causes a significant reduction of the conformational dynamics on the μs–ms timescale (please note that for HuPrP(90–231) the exchange rates are in the 400–3000 (s−1) range) (ESI Table 3†). Notably, the residues Gln152 (α1) and Gln161 (β2) do not show any RD trajectory demonstrating that for these residues the μs–ms timescale dynamics associated with conformational exchange broadening are completely quenched. In order to assess if the analysed residues undergo a common motion sharing a common exchange rate (kex), we globally fitted all residues showing dispersion curves (Fig. 6E). As reported in ESI Table 4†, the χglobal/χind values are below 2 indicating that for the HuPrP(90–231) E219K mutant, different from what was observed for HuPrP(90–231), all residues can be fitted to a single two-state conformational exchange process with kex of 373 ± 15 (s−1) (Fig. 6D). Moreover, the residue-specific Φex exchange parameters predicted for HuPrP(90–231) E219K (~8000 (s−2)) (Fig. 6E) are significantly smaller than those estimated for cluster A of the wild-type HuPrP(90–231) (~23 000 (s−2)).

β-PrPrI activates the amyloid assembly pathway by oligomer formation having seeding activity for templated aggregation

To assess the effect of different pH values and temperatures on the amyloidogenic propensity of human PrPC we performed in vitro fibrillation experiments using ThT fluorescent dye. Both truncated and full-length HuPrP were incubated at 61 °C or 25 °C in two different buffers at pH 6.8 or pH 5.5 and aggregations were performed by subjecting the samples to several cycles of incubation and shaking. Fibril growth was monitored with the use of ThT in real time. Our results show that the aggregation of HuPrP(90–231) is significantly faster at 61 °C compared to that at 25 °C at both pH values (Fig. 7A). In particular, reactions performed at 61 °C show a lag-phase of amyloid formation of about 10 hours (Fig. 7A, light blue line for pH 6.8 and dark blue line for pH 5.5) while the truncated HuPrP at 25 °C barely aggregated after 60 hours at pH 6.8 (ESI Fig. 15B†). Regarding the full length HuPrP, all reactions performed at 61 °C and 25 °C at both pHs did not result in protein aggregation, even after 80 hours (Fig. 7A and ESI Fig. 15B†). Therefore, to gain a better understanding of the aggregation mechanism by which the β-PrPrI intermediate state induces amyloid fibril formation, we investigated by NMR the molecular events occurring at the earliest stages along the aggregation pathway of β-PrPrI. In particular, we compared the 1H–15N HSQC spectrum acquired at 25 °C on the β-PrPrI sample, obtained by incubating HuPrP(90–231) at 61 °C for 15 hours, with that measured for the freshly prepared HuPrP(90–231) monomers (ESI Fig. 16A†). Interestingly, as reported in ESI Fig. 16A† the 1H–15N HSQC spectrum of the β-PrPrI sample exhibits, for a large number of residues, signal loss and broadening without significant chemical shift variations when compared to the spectrum of HuPrP(90–231) suggesting that the monomer is in dynamic equilibrium with β-PrPrI-oligomeric (β-PrPrI(o)) species. Therefore, we analysed residue-specific ratios of signal intensities after and before incubation at 61 °C (I/I0) (ESI Fig. 16B†) reporting on signal loss due to the conformational exchange and increase in rotational correlation time as a consequence of oligomerisation. The highest intensity ratio values were observed at the N-terminal part of the globular domain encompassing the portion from Gly90 to Ala113 indicating the conformational stability of this region. In contrast, intensity
Fig. 7 Role of the β-PrP intermediate state in amyloid fibril formation and in prion conversion. (A) HuPrP(90–231) and HuPrP(23–231) were induced to aggregate by alternating cycles of incubation and shaking at 55 °C. Average ThT fluorescence intensity was plotted against time. (B) Serial dilutions of the artificial β-PrP(o) seeds, previously produced by incubating HuPrP(90–231) at 61 °C, were used to promote the aggregation of HuPrP(23–231). Average ThT fluorescence intensity was plotted against time. (C and D) RT-QuIC experiments monitoring the seeding activity of the β-PrP oligomers. The experiments were conducted collecting from patients the following biological samples: brain homogenates (dilution 10^{-5} v/v) sCJD-129MM1 (→), sCJD-129MM2 (→), sCJD-129MV1 (→), sCJD-129MV2 (→), sCJD-129VV1 (→), sCJD-129VV2 (→), Alzheimer’s disease and non-neurodegenerative disorder (→), amyloid fibrillar assemblies (ng mL^{-1}) β-PrP amyloid fibrils pH 6.8 (→) and 5.5 (→), monomer
ratios below average ± SD and signal loss (*) were mainly observed for the residues of β1 and β2 (Met129*, Leu130*, Val167*, Tyr162*, Tyr169*), for the regions surrounding the two native β-strands (Gly131*, Ser132, Ala133, Met134, Ser135, Asn159*, Gln160*) and for the regions located within the z1 and z3 helices (Asp144, Tyr145, Gln152, His155*, Arg156*, Tyr157*, Thr201, Lys204, Met205, Ile215*, Thr216*, Gln217*, Arg220*, Gln221*) indicating that these regions are most affected by conformational exchange in the intermediate regime and therefore are most likely involved in the process of oligomerisation (ESI Fig. 16B and C).

Notably, the β-PrPI oligomerisation interface (ESI Fig. 16C†) perfectly corresponds to the regions showing a significant increase of β-sheet population. Overall, NMR and ThT data demonstrate that amyloid formation of β-PrPI occurs via a remarkably specific assembly mechanism involving the transient formation of oligomeric species (β-PrPIO).

Next, the β-PrPIO species were used as seeds to promote the conversion of full-length HuPrP. By comparison with HuPrP(23–231) (Fig. 7B, dashed line), we found that the addition of increasing concentrations of β-PrPIO seeds significantly enhanced the full-length HuPrP aggregation reaction, resulting in ThT positive kinetics with lag-phases shorter than the control (Fig. 7B). In addition, to test whether the oligomeric species from the β-PrPI intermediate state, obtained by incubating HuPrP(90–231) at 61 °C at pH 5.5 or 6.8, forms seeds that template aggregation we performed RT-QuIC experiments using the experimental setting employed for the analysis of biological samples collected from patients with a clinical diagnosis of sporadic Creutzfeldt-Jakob disease (sCJD) (Fig. 7C and D).

Besides the aggregates, we have included in the analysis brain homogenates of patients with the six forms of sCJD as well as a few cerebrospinal fluid (CSF) samples collected from sCJD patients with MM, MV or VV polymorphisms at PRNP codon 129. The results clearly show that regardless of the pH at which they were generated, all β-PrPI induced amyloid aggregates were able to efficiently seed the RT-QuIC reaction with a kinetics very similar to that of the sCJD brain homogenates (Fig. 7C and D). All CSF samples collected from sCJD patients induced an efficient seeding activity. As expected, neither the monomeric HuPrP(90–231) nor the brain homogenates and CSF collected from patients with non-CJD patients induced seeding activity by RT-QuIC. Overall, RT-QuIC shows that the β-PrPIO forms active seeds which template the formation of amyloid aggregates with a seeding activity comparable to that of the infectious and pathogenic PrPSc.

Finally, we investigated the effect of Cu(u) binding on the amyloidogenic propensity of human PrPSc using real-time ThT fluorescence experiments. At 25 °C, HuPrP(23–231) in the presence of either 1 or 4 equivalent(s) did not form any aggregates (Fig. 7E). In contrast, at 61 °C with 1 and 4 equivalent(s) of copper, the Cu(u) binding to HuPrP(23–231) induces the formation of ThT-positive intermediates by a double-sigmoidal aggregation kinetics (Fig. 7F). This phenomenon is more likely caused by the existence of amorphous aggregates or oligomeric intermediate species able to bind ThT. In particular, at both copper concentrations, the aggregation of HuPrP(23–231) in the presence of metal ions is significantly slower (lag-phase of about 55 hours) compared to that of HuPrP(90–231). Importantly, the double-sigmoidal curves obtained with 1 and 4 equivalent(s) of Cu(u) exhibit, at the end of the reaction, a different ThT fluorescence intensity that, in both cases, is lower than the value obtained for HuPrP(90–231). Overall, our results suggest that the presence of copper enhances the aggregation of HuPrP(23–231) through the formation of amorphous aggregates having amyloidogenic proprieties.

**Discussion**

The NMR structure of mouse prion protein was originally solved in 1996 and, since then, a number of PrPSc structures from different mammalian species have been determined, mostly in solution and in one case in the solid state. PrPSc solution dynamics have shown the co-existence of two different domains, the N-terminal which is mostly flexible and the globular C-terminal which is mostly rigid. The latter has been shown to adopt a very similar structure within all the mammalian species and to show only local structural perturbations when pathogenic mutations are present. Nonetheless, the “protein only hypothesis” predicted pathogenic conformational transitions of PrPSc to PrPSc, which should be facilitated by accidental cellular conditions or by point mutations. Thus, exploring the conformational equilibria and unfolding/folding mechanism of PrPSc, under different conditions of pH and temperature, represents a crucial way to investigate the molecular basis of the PrPSc to PrPSc transition. Here, using an integrated approach that combines NMR and CD spectroscopies together with ThT fluorescence and RT-QuIC data, we investigated the fundamental forces driving the prion protein folding process and characterized, under physiological conditions, the prion protein conformational equilibrium by exploring the non-native states weakly populated on the folding energy landscape. Using CD and NMR techniques, we show that the N-terminal tail influences the thermal unfolding mechanism of HuPrP via monitoring temperature-induced denaturation of HuPrP(23–231) and HuPrP(90–231). CD thermal unfolding curves, independent of concentration, show that HuPrP(23–231) thermally unfolds following a single sigmoidal cooperative unfolding mechanism, both at pH 6.8 and 5.5. Conversely, the truncated HuPrP(90–231) thermal unfolding has a more complex behaviour, characterized by two successive transitions at both pH values. High-resolution NMR data, confirming the CD results, indicate for truncated HuPrP at 61 °C and pH 5.5 the presence of an intermediate conformation, named β-PrPI.
RD experiments (Fig. 5A and B and ESI Fig. 15A†) show that HuPrP(90–231) interconverts between a populated ground state and a thermally accessible conformation “excited state”. More precisely, this analysis shows that in the excited states z2 and z3 are well preserved whereas the regions surrounding β1, β2 and the first z1 helix, including the loop connecting z1 and z2, present significant structural variations with respect to the native state (Fig. 5C and D). Furthermore, these two regions experience uncoupled motions, characterized by distinct exchange processes. Importantly, RD data also indicate that the full-length human prion protein is characterized by long-range coupled μ-s-ms motions between the region connecting the first β-strand with the second α-helix (Gly131-Ser170) and the rest of the protein (Asn171-Ser231) (Fig. 5C and D), strongly suggesting that the perturbation of these correlated dynamics plays a crucial role in the regulation of the unfolding process. Interestingly, RD analysis of the HuPrP(90–231) E219K polymorph has shown that the change causes a significant reduction of the conformational dynamics on the μ-s-ms timescale (Fig. 6D), providing further evidence that the coupling of μ-s-ms dynamics between the β1-z1 loop, z1, z1-β2 loop, β2, β2-z2 loop and the two last α-helices represents a key mechanism to prevent prion conversion. The good correlation between $\Phi_{\text{ex}}$ values and squared differences in chemical shifts between the native and the intermediate state Δ$\delta_{\text{ex}}^2$ indicates that, at 25°C (Fig. 6A), the truncated HuPrP is in equilibrium, in the μ-s-ms range, with a conformational state significantly similar to β-PrPr. Interestingly, both conformations are characterized by considerable perturbations in the β-sheet and in the z1 helix, with a substantial increase, clearly defined in the thermally induced structure, of the β-character. Our data indicate that the detected excited state may play a crucial role in facilitating the formation of the on-pathway β-PrPr intermediate state that serves as a precursor of prion protein aggregation and amyloid fibril assembly (Fig. 6).

Differently, the full-length HuPrP is characterized by a conformational equilibrium in which the low populated state exhibits a globular domain structural organization very similar to the native conformation (Fig. 5D and ESI Tables 3 and 4†). In this scenario, NMR structural data collected for both proteins identify the coupling of the two domains as a key molecular mechanism in tuning the long-range μ-s-ms conformational dynamics that in turn modulate the folding process. Because the removal of the N-terminal domain alters the unfolding mechanism of HuPrP(90–231), we investigated the structural mechanisms underlying such different folding behaviour. By comparing NMR structural data we show that in the human full-length prion protein the positively charged N-terminal region transiently interacts with two different patches of negatively charged C-terminus defining a more widespread interaction interface compared to that identified in previous studies.18,20,21,66,67 (Fig. 3), without altering the secondary and tertiary organization of the globular domain. Of note, HuPrP patch2 interaction sites are close to the disease-linked mutations (ESI Fig. 11†) whose occurrence increases the kinetics of the misfolding process relative to HuPrP wild-type in vivo.68

Thus, our findings suggest that the electrostatic interaction
network between the two domains regulates the prion folding process and a possible destabilization induced, for example, by mutations or metal-binding might increase the stability of partially folded intermediate species, which are likely to be PrPSc precursors. In this scenario, it has been reported that Cu2+ binding reduces the prion protein folding stability, making a conformation transition more thermodynamically favourable.49 Recently, Sivasankar and co-workers showed the role of Cu2+ in the misfolding, oligomerization and neurotoxicity of prion protein.77 Therefore, we explored the copper binding effects on the single sigmoidal cooperative unfolding mechanism observed for HuPrP(23–231). NMR thermal denaturation experiments show that the full-length HuPrP upon Cu2+ addition is characterized by a two-transitions unfolding mechanism with the formation of partially folded intermediate states that have secondary structural organization substantially different from β-PrPI. Accordingly, ThT measurements indicate that the copper binding induces the formation of HuPrP(23–231) amorphous aggregates by a different aggregation mechanism with respect to β-PrPI.

Very likely, this behaviour is due to a different interaction, previously described,61 between the N- and C-termini, induced by Cu2+ coordination to the octa-repeat region which, once positively charged, becomes able to transiently bind particular the negatively charged spot of α1, α2 and α3 helices (Fig. 3A–D and ESI Fig. 9A†). Therefore, the partially unfolded states, here described to be in equilibrium with the truncated protein at pH 5.5 and to prevalently constitute its structure at 61 °C, appear to be inhibited by the proper transient interaction between the N- and C-termini, since they are experimentally invisible in the full-length HuPrP, even at mildly acidic pH 7.5 and likely substituted by diverse intermediate states formed when HuPrP binds to Cu2+. In most experimental studies, non-native conditions, induced by lowering pH or by adding chemical denaturants, have been exploited to investigate partially unfolded forms of native or pathogenically mutated PrPC, involved in fibril formation.35,36,71

Among them, recently, the Udgaonkar group has shown that the initial stages of misfolded PrPSc are characterized by a loss of the α1 structure which induces a destabilization of the α2–α3 double helix, leading to an α to β structural transition.72 Here, in substantial agreement, we show that under mildly acidic conditions HuPrP(90–231) at 61 °C converts into a β-PrPI, an intermediate state characterized by a significant reduction of the α1 structure, which is accompanied by a concomitant α2–α3 structural perturbation and by a significant enlargement of β1 and β2 strands (Fig. 2A and B). This gain of β-sheet character induces a loss of α2 and α3 helical content, whose structure is stabilized by a large number of hydrophobic interactions forming a core, which has been shown to play a key role in the PrPSc to PrPSc transition.73 Interestingly, β-PrPI, which appears to be induced by the structural reorganization of the HD (residues 95–110), is involved in faster fibril formation and populates a small part of the conformational preferences of HuPrP(90–231) even at 25 °C (Fig. 7A–C). Accordingly, the absence of this unstructured N-terminal makes the thermodynamic features of mouse PrP (MoPrP)(121–231) very similar to those of the full-length MoPrP(23–231) at least at pH 4.0.74 Importantly, in MoPrP(23–231) the formation of this structural intermediate appears inhibited, while another thermally induced intermediate, whose structure is not determined here, reappears in the presence of copper ions. Recently, we have shown how the folding mechanism may influence fibril formation in metal binding proteins.75 In particular, metal ion binding can stabilize an intermediate state that is energetically close to the native structure and being easily accessible represents a structural gate to the initial phases of fibril formation. Similarly, the presence of the disulphide bridge in the prion protein plays the key role of stabilizing the α2–α3 double helix system and therein the whole HuPrP globular domain. Once a mutation or any structural perturbation arising from, e.g., pH lowering, metal binding or truncation of the N-terminal domain induces a loss of the interaction stabilizing the core formed by α1 and α2–α3, the disulphide bridge may paradoxically represent a structural gate to the α to β conversion of the α2–α3 system. Overall, the data suggest that the N- to C-terminal interaction prevents HuPrP(23–231) from undergoing this structural conversion, at least at neutral or mildly acidic pH, unless binding to copper perturbs such interaction leading the full-length to populate a similar PUF. Interestingly, the role of inter-domain long-range transient interactions in controlling protein conformational equilibria here shown could represent a common evolutionary strategy for the stabilization of multidomain proteins.

Conclusion

Prion diseases are a class of neurodegenerative diseases that occur due to misfolding and aggregation into amyloid fibrils of the mainly α-helical cellular prion protein (PrPC). To date, the molecular basis of prion misfolding and aggregation inducing PrP diseases is still poorly understood. Here, we identified the structural and dynamical determinants controlling the prion misfolding process by which PrPSc converts into an amyloid fibril through the formation of a β-enriched intermediate state (β-PrPI) involved in the initial stages of PrPSc fibrillation having a seeding activity comparable to that of human infectious prions. In this scenario, we showed that the coupling of the two N- and C-terminal domains is the key molecular mechanism in tuning long-range ms–ms conformational dynamics that in turn regulate the folding process avoiding β-PrPI formation. This study provides novel structural and dynamical insights into prion misfolding that can be used to develop molecular strategies able to inhibit aggregation of PrP amyloid fibrils.

Methods

Plasmid construction, protein expression and purification

The HuPrP(23–231) and HuPrP(90–231) sequences were inserted in pET-11a vectors (Novagen) as previously described.30–37 The constructs were expressed in Escherichia coli BL21 (DE3) cells (Stratagene). Freshly transformed overnight culture was added at 37 °C to 2 L of minimal medium (MM) plus ampicillin (100 μg mL−1). For isotope labeling 4 g L−1 [13C6] glucose and 1 g L−1 [15N] ammonium chloride were added. At 0.8 OD600 expression was induced with isopropyl
β-D-galactopyranoside to a final concentration of 0.75 mM. The cells were harvested 12 h after induction. The cells were lysed using a homogenizer (PandainPLUS 2000) and the inclusion bodies were suspended in buffer containing 25 mM Tris–HCl, 5 mM EDTA, and 0.8% Triton X-100 (pH 8.0), and then in bi-distilled water several times. Inclusion bodies were dissolved in 5 volumes of 8 M guanidine hydrochloride (GdnHCl), loaded onto a pre-equilibrated HiLoad 26/60 Superdex 200 pg column, and eluted in 25 mM Tris–HCl (pH 8), 5 mM ethylene-diaminetetraacetic acid (EDTA), and 6 M GdnHCl at a flow rate of 2 mL min⁻¹. Protein refolding was performed by dialysis against refolding buffers (20 mM sodium acetate and 0.005% NaN₃, pH 5.5) using a SpectraPor membrane. Purified protein was analysed by SDS-polyacrylamide gel electrophoresis under reducing conditions and the western blot.

**CD spectroscopy**

HuPrP(23–231) and HuPrP(90–231) were prepared in 300 µL of 20 mM sodium acetate at pH 5.5 and phosphate at pH 6.8 with the same ionic strength. Copper binding experiments of HuPrP(23–231) were performed at pH 5.5 in MES buffer having the same ionic strength as that of the previously reported sodium acetate buffer.

The thermal denaturation of prion protein samples was evaluated using a JASCO J-815 CD spectropolarimeter equipped with Peltier temperature control. CD spectra were measured at 5 °C intervals in the 5–55 °C range and from 55–90 °C at regular intervals of 3 °C. After the final spectrum at 90 °C, all samples were cooled to 25 °C, and a final set of spectra were collected. For the investigation of the copper effects on the folding mechanism of HuPrP(23–231) the samples were prepared in the same way with the addition of CuCl₂ to give the appropriate final Cu²⁺ concentrations (1 and 4 molar equivalent(s)). The experiments were conducted at different protein concentrations ranging from 10 µM to 80 µM (only for measurements at pH 5.5) of HuPrP(23–231) and HuPrP(90–231) proteins, and data were collected using a quartz cuvette with a 1 cm path length in the 200–260 nm wavelength range with a pitch of 1 nm. All data were measured with a bandwidth of 1 nm with a scanning speed of 50 min⁻¹ and normalized against reference spectra to remove the background contribution of buffer. The data obtained were analysed using a two-state folding model. The reversibility of the thermal unfolding processes was investigated by comparing the CD spectrum acquired after cooling the heat-denatured sample; moreover, the experimental ellipticity θ₂₃₂/θ₂₁₅ ratios were compared to the reference value obtained from the representative NMR structure using the web-based application PDB2CD.⁷⁸

**Aggregation index (A.I.) determination**

Aggregation of the prion protein samples was assessed using an aggregation index (A.I.) calculated from spectrosopic measurements. UV spectroscopy was performed with a SHIMADZU 1800 spectrometer. Samples of 300 µL were measured in micro-quartz cuvettes with a path length of 10 mm. UV absorbance was recorded from 240 to 360 nm using an integration time of 15 s and steps of 1 nm. The spectra were normalized for the absorbance of the particular buffer. The aggregation index (A.I.) was calculated from the UV spectra as \( A_{280}/A_{280} - A_{350} \times 100 \), where \( A_{280} \) and \( A_{350} \) are the absorbances at 280 and 350 nm, respectively. Usually, A.I. values below 10 indicate the presence in solution of insignificant amounts of soluble aggregates.⁷⁹

**NMR resonance assignments**

All NMR experiments were carried out at 25 °C using a Bruker AVIII HD 600 MHz spectrometer equipped with a triple-resonance Prodigy N₂ cryoprobe with a z-axis pulse field gradient. NMR samples for chemical shift assignment of ¹⁵N–¹³C labeled HuPrP(23–231), ¹⁵N–¹³C labeled HuPrP(90–231) and ¹⁵N–¹³C labeled HuPrP(90–231) E219K proteins were prepared in 20 mM sodium acetate, pH 5.5 and 90% H₂O/10% D₂O. The protein final concentration was 80 µM. Backbone resonances \( C\alpha, C\beta, C', N, HN \) and \( Hz \) of HuPrP(23–231) and HuPrP(90–231) were assigned by analyzing the standard triple resonance experiments⁸⁰ as 3D HNCA, 3D CBCANH, 3D CBCA(CO)NH, 3D HNCO and 3D HNHz using the deposited chemical shifts under the MRBM accession codes 4402, 18426 and 17780. Moreover, to further improve the previous backbone assignment⁸¹–⁸³ two- and three-dimensional TROSY-based⁸⁴ and T₂-filter NMR experiments were performed after a rigorous optimization.⁸⁵ At 25 °C, a nearly complete assignment of backbone and Cβ chemical shifts for HuPrP(23–231) (96%), HuPrP(90–231) (96%) and HuPrP(90–231) E219K (93%) was obtained. The chemical shift assignment for all investigated prion proteins, at different temperatures, was performed by following the peaks trajectories over a temperature range. The spectra were processed using NMRpipe⁸⁶ and analyzed using SPARKY⁸⁷ and CARA.⁸⁸ The ¹H–¹³N HSQC spectrum of the HuPrP(90–231) random coil conformation at 61 °C was reconstructed by using a series of in-house written NMRpipe scripts based on the random coil shifts predicted as reported below. ¹H, ¹³C and ¹⁵N chemical shifts were calibrated indirectly to external DSS references.

**NMR chemical shifts analysis**

The structural rearrangements were estimated by applying a weighted combined ¹H [ΔδH], ¹⁵N [ΔδN] and ¹³C (ΔδC) chemical shift perturbation (CSP) based on the following equation:

\[
ΔH,N,C = \left( \frac{W_H Δδ_H W_H}{T_H^2} + Δδ_N W_N + Δδ_C W_C \right)^{1/2}
\]

where \( W_H, W_N, \) and \( W_C \) are weighing factors for the ¹H, ¹⁵N and ¹³C shifts defined as \( W_H = |γ_H/γ_H| = 1; W_N = |γ_N/γ_H| = 0.101; W_C = |γ_C/γ_H| = 0.251. \) \( Δδ_H, Δδ_N \) and \( Δδ_C \) are the chemical shift differences in ppm between the compared protein states for ¹H, ¹⁵N and ¹³C, respectively; \( γ_H, γ_N \) and \( γ_C \) are the gyromagnetic ratios.
The quality factor used to evaluate the correlation between the HuPrP(23–231) and HuPrP(90–231) secondary chemical shifts ($Q\Delta$) in the region 90–231 is defined as:

$$Q\Delta = \left( \frac{\sum_{i=1}^{N} (\Delta\delta_{90–231} - \Delta\delta_{23–231})^2}{N} \right)^{1/2}$$

in which $\Delta\delta_{90–231}$ and $\Delta\delta_{23–231}$ are the secondary chemical shifts calculated for HuPrP(90–231) and HuPrP(23–231), respectively; $\Delta\delta$ is calculated as the difference between the observed chemical shift $\delta_{obs}$ and the predicted random coil shift $\delta_{random coil}$.

The quality factor ($Q$) used to estimate the correlation between the measured chemical shifts ($\delta_{obs}$) and those predicted ($\delta_{pred}$) from the representative structure of the NMR ensemble (PDB ID code: 2LSB) is defined as:

$$Q = \left( \frac{\sum_{i=1}^{N} (\delta_{obs} - \delta_{pred})^2}{\sum_{i=1}^{N} (\delta_{obs})^2} \right)^{1/2}$$

The random coil shifts were calculated at different temperature and pH values by using the approach defined by Poulsen and co-workers.\textsuperscript{66,67} The prediction of the chemical shifts from the representative NMR conformer was performed using Shift2 software.\textsuperscript{47} The secondary structure propensity (SSP) scores were calculated with the random coil chemical shifts and the average secondary shifts for the fully formed secondary structure as described previously.\textsuperscript{48} The model-free order parameters $S^2$ for the backbone amide groups were predicted from backbone and Cβ chemical shifts using the Random Coil Index (RCI) approach.\textsuperscript{49} Data were analyzed and visualized using the software CHIMERA.\textsuperscript{99} The Adaptive Poisson–Boltzmann Solver (APBS)\textsuperscript{99} was used to calculate spatial distributions of electrostatic potentials using the linearized Poisson–Boltzmann equation and parameters from the PQR files obtained using the PDB2PQR server.\textsuperscript{31} The electrostatic map was generated using CHIMERA.\textsuperscript{99} The NaCl titration experiments were done on 80 μM HuPrP(23–231) and HuPrP(90–231) prion protein samples. A series of $^1$H–$^{15}$N HSQC spectra were collected under the following two conditions: 50 mM and 200 mM. To evaluate the chemical shift differences between HuPrP(23–231) and HuPrP(90–231) induced by addition of sodium chloride we defined the following equation:

$$Q_{HN,N}(\Delta\delta_{90–231} – \Delta\delta_{23–231}) = \left( \frac{\sum_{i=1}^{N} (\Delta\delta_{HN,N}^{90–231} - \Delta\delta_{HN,N}^{23–231})^2}{N} \right)^{1/2}$$

where $\Delta\delta_{HN,N}$ is the weighted combined difference between $^1$HN and $^{15}$N chemical shifts observed upon addition of the salt concentration and the shifts obtained in the absence of NaCl for HuPrP(23–231) and HuPrP(90–231), respectively.

NMR thermal analysis

$^1$H–$^{15}$N and $^1$H–$^{13}$C HSQC spectra were collected every 5 °C from 5 to 55 °C and every 3 °C in the 55–90 °C range for both HuPrP(90–231) and HuPrP(23–231). All NMR spectra acquired for the thermal unfolding characterization were referenced indirectly to external DSS references. 2D $^1$H–$^{15}$N HSQC experiments were carried out with 32 scans per t1 increment, a spectral width of 1459.43 along t1 and 7211.54 along t2, 2048 × 256 complex points in t2 and t1, respectively and a 1.0 s relaxation delay for HuPrP(90–231); meanwhile, for HuPrP(23–231) the $^1$H–$^{15}$N HSQC spectra were acquired with 32 scans per t1 increment, a spectral width of 1581.28 along t1 and 7211.54 along t2, 2048 × 256 complex points in t2 and t1, respectively and a 1.0 s relaxation delay. Spectra were apodized with a square cosine window function and a zero filling to a matrix size 4096 × 4096 before Fourier transform and baseline correction. 2D $^1$H–$^{13}$C CT HSQC (constant time version) spectra were acquired with 32 scans per t1 increment, a spectral width of 5131.08 Hz along t1 and 7211.54 Hz along t2, 2048 × 256 complex points in t2 and t1, respectively and a 1.0 s relaxation delay. The $^1$H–$^{13}$C CT HSQC experiments were acquired with a heteronuclear coupling constant JCH = 145 Hz and a constant time period of 26.6 milliseconds. The $^1$H–$^{13}$C CT HSQC were apodized with a square cosine window function and zero filled to a matrix of size 4096 × 4096 before Fourier transform and baseline correction. $^1$H chemical shifts at different temperatures were referenced externally to DSS,\textsuperscript{66} whereas $^{15}$N and $^{13}$C shifts were calibrated indirectly to DSS. The midpoint temperatures ($T_{1/2}$) were estimated by measuring HN and Hz chemical shifts as a function of temperature in the 15–61 °C range. In particular, in the case of the first transition of HuPrP(90–231), for each well-resolved proton we first normalized the observed chemical shifts with respect to the value measured at the lowest temperature (15 °C) and then we fitted for each residue the data with two models. All copper binding experiments of HuPrP(23–231) were performed at pH 5.5 in MES buffer having the same ionic strength as that of the previously reported sodium acetate buffer.

NMR relaxation measurements

$^{15}$N relaxation experiments were carried out on a 600 MHz spectrometer at 25 °C. In all experiments, the concentration of HuPrP(90–231), HuPrP(90–231) E219K and HuPrP(23–231) samples was about 0.2 mM. $^{15}$N longitudinal relaxation rates ($R_1$) were measured using relaxation delays of 11*, 161, 330, 495, 660*, 825 and 1100* ms. $^{15}$N transverse relaxation rates (“total $R_2$”) were acquired using relaxation delays of 15.84*, 31.68, 47.56*, 63.36, 79.20*, 95.04 and 110.88 ms. Steady-state $^1$H–$^{15}$N heteronuclear Nuclear Overhauser Enhancement (NOE) was measured by acquiring paired interleaved spectra collected with and without an initial proton saturation period (3 s) during the 5 s recycle delay. NOE values were calculated from the ratio of the peak intensities between saturated and reference spectra. For HuPrP(23–231), NOE values were mapped on a structural model of the full-length protein obtained using the software I-TASSER,\textsuperscript{99} using as template the NMR structure of the C-terminal domain (PDB ID code: 2LSB). Only for the HuPrP(90–231) were the $^{15}$N relaxation measurements also performed on a 700 MHz spectrometer at 25 °C and pH 5.5. $^{15}$N $R_1$, $^{15}$N $R_2$ and
[1H]-15N NOE data sets acquired for HuPrP(90–231) at 500 and 600 MHz were analysed using ROTDIF and DYNAMICS software using the Lipari–Szabo approach. An axially symmetric rotational diffusion tensor was optimized against the human prion protein structure (PDB ID: 2LSB) using selected residues with [1H]-15N NOE > 0.65 within the main secondary structure elements. 15N longitudinal relaxation rates in the rotating frame (R₁ρ) were measured in a near-resonance mode with relaxation delays of 16s, 32, 48s, 56, 72s, and 100 ms and spin-lock field strength of 3 kHz centered on a 15N chemical shift of 116.2 ppm. The asterisks indicate duplicate measurements. R₁, R₂, and R₁ρ relaxation rates were obtained from the best single exponential to the experimental intensity data. Effective R₂ rates were determined from the following relation:

$$R_{2}^{\text{effective}} = (R_{1}\rho - R_{1} \cos^{2} \theta)/\sin^{2} \theta$$

where \(\theta = \tan(\rho_{SL}/\Omega)\), \(\rho_{SL}\) is the 15N spin-lock field strength in Hz and \(\Omega\) is the resonance offset from the spin-lock carrier (Hz). \(R_{ex}\) contributions were estimated as the difference between the “total \(R_{2}\)” and the effective \(R_{2}\) rates derived from \(R_{1}\rho\) values obtained by applying a 3 kHz spin-lock field strength.

### NMR R₁ρ relaxation dispersion

\(R_{1}\rho\)-based relaxation dispersion experiments were performed at 25 °C and a proton Larmor frequency of 600 MHz on HuPrP(90–231), HuPrP(90–231) E219K and HuPrP(23–231) samples at a final protein concentration of 0.15 mM. \(R_{1}\rho\) rates were obtained at 15N spin lock field strengths of 600, 800, 1000, 1200, 1500, 2000, 2200, 2500, 2800 and 3000 Hz with carrier centred at 116.2 ppm (the asterisks indicate duplicate measurements). The data were first analysed on a per-residue basis; a given resonance was included only when \(\Omega \leq 0.4 \rho_{SL}/2\pi \) Hz. All data were fitted with a two-state (A, B) chemical exchange model.

In the fast exchange limit, the effective \(R_{2}\) as a function of the effective field \(\omega_{e}\) can be described by the equation reported below:

$$R_{2}^{\text{effective}}(\omega_{e}) = R_{2}^{0} + R_{ex}(\omega_{e}) = R_{2}^{0} + \varphi_{ex}k_{ex}/(k_{ex} + \omega_{e}^{2})$$

where \(R_{2}^{0}\) is the transverse relaxation rate in the absence of conformational exchange; \(\varphi_{ex} = p_{A}p_{B}\Delta \omega_{N}^{2}\); \(p_{A}\) and \(p_{B}\) are the fractional site populations with \(p_{A} + p_{B} = 1\); \(\Delta \omega_{N}\) is the difference in 15N spin chemical shifts between the two states; \(k_{ex} = k_{+} + k_{-}\) is the sum of forward and reverse rate constants; \(\omega_{e}^{2} = \omega_{SL}^{2} + \Omega^{2}\). All \(R_{2}^{\text{effective}}(\omega_{e})\) dispersion curves were fitted individually and globally to eqn (5) using Mathematica (v9, Wolfram Research, Inc.) and CPMG_fit software (kindly provided by Dr Dmitry Korzhnev) by minimization of the following \(\chi^{2}\) target function:

$$\chi^{2} = \sum \frac{(X_{\text{calc}} - X_{\text{exp}})^{2}}{\sigma_{\text{exp}}^{2}}$$

where \(X_{i}\) are the data sets and \(\sigma_{i}\) the relative error. For group fits, all residues showing relaxation dispersion curves were grouped together based on the \(\chi^{2}_{\text{group}}/\chi^{2}_{\text{individual}}\) ratio, following the method proposed by Mulder et al. The residues with \(\chi^{2}_{\text{group}}/\chi^{2}_{\text{individual}} > 2\) were excluded from the cluster (A).

The comparison of the different models was performed using the Bayesian Information Criterion (BIC) and the corrected Akaike Information Criterion (AICc) defined as reported below:

$$\text{BIC} = \chi^{2} + k \ln(n)$$
$$\text{AICc} = \chi^{2} + 2k + \frac{2k(k+1)}{n-k-1}$$

where \(k\) is the number of fit parameters and \(n\) the number of data points.

### Aggregation assay

The HuPrP(90–231) and HuPrP(23–231) recombinant protein solutions were allowed to thaw at room temperature and filtered through a 100 kDa Nanosep centrifugal device ( Pall Corporation). The final reaction volume was 100 \(\mu\)L and the reagents (Sigma) were concentrated as follows: NaCl 170 mM, PBS 10 mM, EDTA 1 mM, thioflavin-T (ThT) 10 \(\mu\)M and 0.134 mg mL\(^{-1}\) human recombinant PrP. pH of the final reaction mixture was adjusted to 5.5 or 6.8. Five replicates for each condition were analyzed in a black 96-well optical flat bottom plate (Thermo Scientific). The plate was sealed with a sealing film (Thermo Scientific) and inserted into a FLUOstar OPTIMA microplate reader (BMG Labtech). The plate was cyclically shaken for 1 minute at 600 rpm (double orbital) and incubated for 1 minute at 61 °C or 25 °C. Fluorescence readings (480 nm excitation) were taken every 15 minutes (30 flashes per well at 450 nm emission). The mean values of the five replicates of fluorescence intensity (arbitrary units, AU) were recorded and plotted in a graph against time. Real-time ThT fluorescence experiments of HuPrP(23–231) in the presence of 1 or 4 equivalents of copper were performed at 25 and 61 °C by adding CuCl\(_2\).

### RT-QuICP experiments

ReCaPrP(90–231) was thawed and filtered through a 100 kDa Nanosep centrifugal device (Pall Corporation). The RT-QuIC reaction mixture was composed of 10 mM PBS (pH 7.4), 150 mM NaCl, 0.13 mg mL\(^{-1}\) recHaPrP(90–231), 1 mM ethylenediaminetetraacetic acid tetrasodium salt (EDTA), 0.002% SDS and 10 \(\mu\)M ThT. Ninety-eight \(\mu\)L of the reaction mixture was placed in a black 96-well optical flat bottom plate (Thermo Scientific) and supplemented with 2 \(\mu\)L of 10% brain homogenates (weight/volume) collected from patients with six forms of sporadic Creutzfeldt–Jakob disease (sCJD: MM1, MV1, VV1, MM2, MV2 and VV2), Alzheimer’s disease (AD) and non- neurodegenerative control. All samples were diluted to 10\(^{-5}\) (volume/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a \(\mu\)L of 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a 10% brain homogenates (weight/volume) before testing. In parallel 98 \(\mu\)L of the reaction mixture was supplemented with 2 \(\mu\)L of HuPrP(90–231) aggregates prepared either at pH 5.5 or 6.8. Before testing all aggregates were diluted to a
sCJD (MM1, MV1 and VV1), Alzheimer's disease and hydrocephalus. Each sample has been analyzed in quadruplicate. The plate was sealed with a sealing film (Thermo Scientific) and underwent intermittent cycles of shaking (1 min at 600 rpm, double orbital) and incubation (1 min) at 55 °C using the OPTIMA fluorescence microplate reader (BMG Labtech). ThT fluorescence was measured every 30 minutes (wavelengths: excitation 450 ± 10 nm; emission 480 ± 10 nm). A sample was considered positive if the fluorescence value of at least 2 out of 4 replicates was higher than 10 000 arbitrary units (AU) before the threshold of time set at 60 hours, as described in a previous publication.29

Data availability

The datasets used and/or analysed during this study are available from the corresponding author on reasonable request.

Author contributions

GL and RF conceived the study. LR and RF designed CD and NMR experiments. LR performed CD and NMR experiments and analyzed the data. GS prepared the prion protein samples. EB and FM conducted ThT-fluorescence fibrillation assays. All authors discussed the experimental results and analyses. LR, GL and RF wrote the manuscript. All authors read and approved the final manuscript.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

The research was supported by “Programma Valere” 2018 of the University of Campania to LR and RF; by MIUR grant no. 20157WZM8A to GM and 2017WBZFHL to CI; by the Italian Ministry of Health (GR-2013-02355724 and Ricerca Corrente) to FM; by the European Community and the Italian Ministry of Health within the EuroNanoMed3 ERANET co-fund SPEEDY project to FM.
