ABSTRACT

Background: The incidence of twin pregnancy has markedly increased recently due to ART and advanced maternal age. The mother may also experience higher obstetrical morbidity and mortality rates. Aim of the work was to investigate factors affecting the time of spontaneous delivery in dichorionic diamniotic twin pregnancy to improve perinatal outcomes.

Methods: The study was a cross-sectional study had been conducted at Elshatby university maternity hospital between October 2019 to May 2020 on 150 cases of dichorionic diamniotic twins pregnancy admitted for spontaneous delivery. History was taken from all women including general, abdominal and vaginal examination to assess pelvic capacity, first twin presentation, amniotic membrane state and cervical os measurements including cervical dilatation, effacement, station and orientation.

Results: In our study ART twin pregnancies are higher than spontaneous pregnancy regarding the complications. In group A, we found that the uterine contractions are more frequent (6.5 times/30 min) and in B was (6.3 times/30 min) while in group C (2.8 times/30 min) (P<0.001). The cervical dilatation in group A on admission was statistically significant compared with the group B and C (p<0.001). PROMs (p=0.042) and incompetent internal os of cervix (IIOC, p<0.001) found to be the most important factor affecting the time of twin delivery specially before 36 weeks.

Conclusions: The frequency and potency of uterine contractions, the cervical internal os dilatation and the state of amniotic membrane are the most important factors affecting the time of delivery in twin pregnancy.

Keywords: Twin pregnancy, DCDA twin pregnancy, Onset of labour

INTRODUCTION

The incidence of twin pregnancy became recently higher than before due to increased rate of ART and advanced maternal age.1 Twin fetuses usually result from two separate ova fertilized by two different sperms called dizygotic twins. Less frequently, twins arise from a single fertilized ovum called monozygotic or identical twins.2,3

Factors that influence twinning

Maternal age

The age of the mother at the time of pregnancy is an important risk factor for multiple births. Dizygotic twinning frequency is four times increased between 15-37 years.4
Pituitary gonadotropin

Increased rate of stimulating multiple follicles occur at this age group 15-37 years old. But now with ART, the incidence of twinning is increased in advanced maternal age.

Parity

Increasing parity shows to independently increase the incidence of twinning in all populations studied.

Heredity

A determinant of twinning, the family history specially of the mother that is more important than that of the father. The age, fertility to multifetal gestation, weight and race are important genetic factors.

Also, the incidence of twin pregnancy is increased in the first month after stopping the COCS due to increased amount of FSH and LH released in the first spontaneous cycle after stopping the COCS.

Infertility therapy

Ovulation induction with FSH plus chorionic gonadotropin or clomiphene citrate remarkably enhances the likelihood of multiple ovulations. The infertility therapy including ovarian stimulation followed by proper timing intercourse or IUI.

Pregnancy complications

Spontaneous abortion

ART twin pregnancy are at increased risk for abortion compared with spontaneous pregnancy.

Low birth weight

Birth weights in twin infants closely paralleled those of singletons until 28 to 30 weeks gestation. Thereafter, twin birth weights progressively lagged. At 35 to 36 weeks and thereafter, twin birth weights clearly differ from singleton one.

In discordant dizygotic pregnancies, difference in placental perfusion between both fetuses is responsible for the discordancy which also may associated with fetal congenital anomalies, genetic syndromes and infection.

Hypertension

Data suggest that fetal number and placental mass are involved in preeclampsia pathogenesis. Women with twin pregnancies have double levels of antiangiogenic soluble fms-like tyrosine kinase-1 (sFlt-1) than singletons due to larger placental mass not placental pathology.

Preterm birth

Delivery before term is a major reason for high neonatal mortality and morbidity in multifetal pregnancy. Prematurity is increased sixfold and tenfold in twins and triplets, respectively in their review.

Similar to singleton pregnancies, approximately 60 percent of preterm births in twins are indicated, about a third result from spontaneous labor and 10 percent follow prematurely ruptured membranes.

Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet and 90 percent of quadruplet pregnancies.

Although the causes of preterm delivery in twins and singletons may be different, neonatal outcome is generally the same at similar gestational ages except for the discordant twin as the cause of discordancy may has long lasting effect.

Prolonged pregnancy

Twin neonates delivered at 40 weeks or beyond had the same features of post term singletons.

Fetal demise

Single fetal death during late second and early third trimester presents the greatest risk to the surviving twin. Although the risks of subsequent death or neurological damage to the survivor are comparatively increased for monochorionic twins at this gestational age, the risk of preterm delivery is equally increased in mono and dichorionic twins.

Regardless, unless there is a hostile intrauterine environment, the goal should be to prolong pregnancy. Time of delivery electively after conservative management of a late second or early third trimester single fetal death is an issue of debate. Dichorionic twins can probably be safely delivered at term. Monochorionic twin gestations are more difficult to manage and are often delivered between 34 and 37 weeks gestation.

Investigators found that cervical canal length (affacement) and fetal fibronectin concentration in the cervix were predictive of preterm birth. At 24 weeks, a cervical canal length of ≤25 mm is a major factor for prediction of preterm delivery before 32 weeks. At 28 weeks, an elevated fetal fibronectin level was the best factor indicating preterm labour.
Prevention of preterm birth

Intramuscular progesterone therapy

Although somewhat effective in reducing recurrent preterm delivery in pregnant with a singleton pregnancy, weekly injections of 17α-hydroxyprogesterone caproate (17-OHPC) are not effective for multifetal gestations.23

Vaginal progesterone therapy

Micronized progesterone administered vaginally to women with twins is of uncertain benefit but some studies show that 100 mg of micronized progesterone intravaginally daily between 24 to 34 weeks reduces rates of delivery before 37 weeks.

Cervical cerclage

Prophylactic cerclage has no or little effect in improvement of perinatal outcome in women with multifetal pregnancies. Studies have included women who were not specially selected and those who were selected because of a shortened cervix that was identified sonographically.24-26

Pessary

A vaginal pessary that encircles and theoretically compresses the cervix, alters the inclination of the cervical canal, and relieves direct pressure on the cervical internal os has been proposed as an alternative to cerclage.

Aim

Aim of the study was to investigate factors affecting the time of spontaneous delivery in dichorionic diamniotic twin pregnancy in order to improve perinatal outcomes according to main determinant factor.

METHODS

Cross-sectional study of 150 pregnant eligible twin pregnancies attending at Elshatby university maternity hospital between October 2019 till May 2020 and all those babies delivered. Maternal and perinatal data had been obtained from mothers and medical files to find the correlation between time of dichorionic diamniotic twin delivery and neonatal complications. Total cases had been divided into three groups according to the gestational age they delivered in. Group (A) less than 32 weeks gestation, group (B) between 32 and 35+6 weeks gestation, group (C) and over 36 weeks gestation.

Exclusion criteria

Monochorionic twins pregnancy, fetal conditions that might need caesarean section, maternal conditions that might need caesarean section, presence of false labor pain, cases of severe discordant growth and both twin IUFD were excluded from the study.

Detailed and careful history was taken from all women

Personal history included name, age, occupation, residence and special habits of medical importance.

Obstetric history including last menstrual period, gestational age and regular antenatal care were taken.

Past history including any medical disorder like diabetes mellitus, hypertension or any surgical procedure were taken.

History of present pregnancy such as duration of pregnancy from last menstrual period, spontaneous or induction of pregnancy, any complications occurred or any medication used during pregnancy were noted.

Examination of the patient

General examination

General examination as regards to level of consciousness, vital data and complexion were done.

Abdominal examination

Abdominal examination as regards to fundal level, lie of the fetus, true labour uterine contractions diagnosis and monitoring the fetal heart rate were done.

Pelvic examination

Pelvic examination as regards to pelvic capacity, first twin presentation, state of amniotic membrane and cervical assessment as regard cervical dilatation, effacement and orientation were done.

Investigations

CBC, RH, trans-abdominal ultrasound, trans-vaginal ultrasound and CTG. All women will be had vaginal examination for assessment of their pelvis. All women will be had trans-abdominal/trans-vaginal ultrasound for assessment of twins' condition. All women will be tested by intrapartum fetal heart monitoring CTG. TVUS was done to identify any abnormal findings as placenta previa or absence of fetal heart motion and presence of cervical mucus sludge. Also, to assess the cervical canal length and internal os diameter.

Ethical approval

This study was approved ethically by ethics committee for the scientific research. All institutional and national guidelines for the care and use of animals (insects) were followed.
**Statistical analysis**

Data were collected and analyzed using IBM SPSS software package version 20.0 (Armonk, NY: IBM Corp).

**RESULTS**

We reviewed 150 cases of DCDA twin pregnancies delivered at Elshatby university maternity hospital. Among 150 twin deliveries, 23.33% (35/150) were in group A, 36% (54/150) in group B and 40.67% (61/150) in group C. The mean gestational age of admission was 30.8 weeks, 25.4 weeks in group A, 31.8 weeks in group B and 35.9 weeks in group C.

The mean maternal age was 24.83 years. Preterm birth risk was relatively low for women in their late thirties. Risks for adverse outcomes were higher among younger women (Table 1).

In our study ART twin pregnancy are at higher risk than spontaneous twin pregnancy for adverse maternal and fetal outcomes (Table 2).

We evaluated the parity and a history of preterm labour effect on the outcome of twin gestation and found that the incidence of preterm delivery is higher in nulliparous than multiparous women who had no history of preterm delivery (Table 2).

True labour uterine contractions found more in group A (6.5 times/30 min) compared to group B (6.3 times/30 min).
and group C (2.8 times/30 min) (p<0.001). The cervical internal os of cervix and dilation on admission examination in group A was statistically significant compared with the B and C groups (p<0.001). PROMs (p=0.042) and incompetent internal os of cervix (IIOC, p<0.001) represents a strong predictor for preterm labour with gestational age less than 36 weeks of gestation. And all IIOC were found before 32 weeks of gestation on admission. However, pregnancy induced hypertension, gestational diabetes and others did not affect the timing of labour of the twins in this study (Table 3 and 4).

In our study, the incidence of IUGR significantly reduced with increased the gestational age at delivery (Table 5).

In our study, the incidence of NICU admission was significantly higher at group A of gestation. It decreased and disappeared at higher gestational ages. And most common perinatal complication was neonatal respiratory distress syndrome which is highly presented in group A. (Table 6).

Administration of corticosteroids to stimulate fetal lung maturation has been beneficial for twin (Table 6).

Continued.
Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet and 90 percent of quadruplet pregnancies. In an analysis of nearly 350,000 twin births, Kogan and coworkers found that in 16 year period of studying and collecting data ends in 1997, the term birth rate among twins decreased by 22 percent.31

Joseph et al attributed this decline to an increased rate of indicated preterm deliveries. This trend is not necessarily negative as it was associated with decreased adverse perinatal outcomes among twins that reached 34 weeks.32

Results gathered from 300,000 twin births, Kahn et al found that at and above 39 weeks, the rate of stillbirth is very high. At Parkland hospital, twin gestations is considered to be prolonged at 40 weeks of gestation.33

McMahon et al found that women with twin gestations at 24 weeks with negative fibrinectin and closed cervix on digital examination and no cervical internal os changes on ultrasonic examination had low risk of preterm labour before 32 weeks.34

In a systematic review and meta-analysis of trans-vaginal cervical length for anticipating preterm birth, Conde-Agudelo et al concluded that cervical canal length between 20-24 weeks of gestation is a major indicator factor for spontaneous preterm labour in twin asymptomatic pregnant females. These authors found that a cervical length ≤20 mm was most accurate for predicting birth <34 weeks, with a specificity of 97 percent and positive likelihood ratio of 9.0.35

Comparative study revealed that in twin pregnancies there is a high risk of preterm delivery that is about 85%, 70.4% and 9.8% for birth A, B and C group respectively. In about 80% of cases of preterm delivery, this is the consequence of spontaneous labor or PPROM. The results showed that in twin pregnancies cervical canal length is more important than obstetrical history of preterm delivery as a predictor for preterm labour.

Pakrashi et al found in their results of study of almost 300,000 live births that the incidence of preterm labour associated with PROM increased with gestational plurality from 13 percent with singletons to 20 percent with triplets or more.26,28

Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet and 90 percent of quadruplet pregnancies.29

DISCUSSION

Adverse pregnancy outcomes are more common in twin pregnancy than singleton gestation, predominantly due to increased risks for preterm delivery. The perinatal morbidity and mortality are markedly decreased in twin pregnancy due to improvement of neonatal facilities and modalities of management.27 So the ideal time of twin delivery is at 38 weeks or beyond to minimize adverse neonatal outcomes unless there is maternal indication of preterm termination.28

This study revealed that in twin pregnancies there is a high risk of preterm delivery that is about 85%, 70.4% and 9.8% for birth A, B and C group respectively. In about 80% of cases of preterm delivery, this is the consequence of spontaneous labor or PPROM. The results showed that in twin pregnancies cervical canal length is more important than obstetrical history of preterm delivery as a predictor for preterm labour.
Aina-Mumuney et al reviewed 1035 deliveries results showed that the twin pregnancy in primigravida pregnant women delivered one week earlier than multipapous pregnant women of the same condition.36

The present study results that the incidence of preterm labour was found higher in ART twin pregnancy than spontaneous twin conception and these results are in accordance with those reported by Moise et al and Tallo et al who performed studies of 40 and 68 IVF twins pregnancy, respectively.37 These investigators found that the adverse neonatal outcomes regarding prematurity, low birth weight and high morbidity and mortality were higher in ART twin gestation than spontaneous twin pregnancy.38 Similarly, Bernasko et al also found that high incidence of discordancy among the ART twin and adverse pregnancy outcome in comparison to spontaneous twin pregnancy.39 Olivennes et al study showed that after 28 weeks the perinatal outcomes are the same in ART twin pregnancy and spontaneous twin pregnancy.40

Our study findings go along with the findings of Friedman et al who found that in the twins less than 36 weeks, there is no accelerated fetal maturation in comparison to singleton pregnancy.40 The studies of Luke et al and Kiely et al found that the incidence of IUGR is higher in twin pregnancy 38 weeks of gestation. In our study, the incidence of IUGR significantly reduced as the gestational age is more advancing at time of delivery.

In this study, the most important factors affecting the time of labour in twins were the true uterine contractions frequency and potency, condition of amniotic membrane and condition of cervical internal os and cervical canal. Other distributing factors for onset of labour are maternal age, parity, pregnancy (spontaneous or induction) and maternal medical condition.

Study limitations

Cases withdrawal due to non-available places at NICU or incubators was the only obstacle of this study.

CONCLUSION

In conclusion, we found out that the most important clinical factors affecting the timing of delivery in twins are the true uterine contraction frequency and potency, state of amniotic membrane and cervical dilatation and effacement. Other distributing factors for onset of labour are maternal age, parity, pregnancy (spontaneous or induction) and maternal medical history among maternal complications. The statistical results showed that the role of these clinical factors was more significant in the group with early gestational age. An appropriate use of tocolytics could help improving perinatal outcomes in twin pregnancies. Therefore, physicians should regard these factors during examinations and effectively use tocolytic agents to increase the gestational age toward full term to reduce perinatal complications.
