(Dated: February 18, 2022)

We study the effects of spin accumulation (inside reservoirs) on electronic transport with tunneling and reflections at the gates of a quantum dot. Within the stub model, the calculation focuses on the current-current correlation function for the flux of electrons injected into the quantum dot. The linear response theory used allows to obtain the noise power in the regime of thermal crossover as a function of parameters that reveal the spin polarization at the reservoirs. The calculation is performed employing diagrammatic integration within the universal groups (ensembles of Dyson) for a non-ideal, non-equilibrium chaotic quantum dot. We show that changes in the spin distribution determines significant alteration in noise behavior at values of the tunneling rates close to zero, in the regime of strong reflection at the gates.

I. INTRODUCTION

The experimental control of electron transport in nanostructures may lay the grounds for the development of devices for processing quantum information \cite{1, 2, 3}. These devices may rely on the spin degrees of freedom, and are thus called spintronics \cite{4}. The control of the spin is a subtle process which requires the fabrication of special samples and manipulating them so as to detect low intensity currents in semiconductors \cite{5, 6, 7}. The accumulation of spin, when detected, allows the extraction of information of great value to the phenomenon of electron transport \cite{1, 8}.

To induce a spin polarization in a material sample which can be a reservoir of electrons, one creates a population of non-equilibrium spins with a finite interval of relaxation time. This population can be achieved through optical or electronic mechanisms. Routinely, the optical techniques require the injection of circularly polarized photons in order to transfer their angular momentum to electrons through a complex sample \cite{8}. The electronic injection involves the presence of magnetic electrodes connected to a sample, creating spin polarization in a non-equilibrium regime \cite{3, 4}.

Fluctuation properties of a non-equilibrium current indicates that just the average electronic currents are not enough for a complete description of the full quantum transport \cite{9}. The accumulation of spin in electronic reservoirs modifies the fluctuation properties of the non-equilibrium electronic current. Such a modification follow through a mechanism proposed in \cite{10} which reveals that noise power presents a asymmetry under reversal of the current/voltage in the presence of spin accumulation inside at least one reservoir. On the other hand, performing direct measurements of the fluctuations in semiconductor quantum dots can be a very hard task, precisely because the typical currents are of the order of nA and temperatures on the order of mK, very small indeed. A experimental procedure found in Ref. \cite{11}, and justified theoretically in \cite{12, 13}, is to perform the Full Counting Statistics (FCS) which consists of counting the numbers of electrons and their degrees of freedom within a certain window of time. Real-time measurements can also be applied to study the spin transport properties on generic interfaces of heterostructures, according to the results in \cite{14, 15}. Tunneling rates not only allow to find the conductance, but the shot-noise (width of the conductance distribution) \cite{11}.

![FIG. 1: A schematic picture showing a quantum dots coupled to polarizable reservoirs via several leads with open channels in the presence of temperature and voltage.](image)
In the limit of high temperatures, noise provides information on the thermal fluctuations characteristics of dissipative systems. On the other hand, experimental measurements of noise at low temperatures, also known as shot-noise, use tunneling rate in the non-ideal quantum transport \cite{11}, yielding important information about the discrete process of charge transmission \cite{10}. In mesoscopic systems both noise sources are present. A relevant parameter to measure the noise in quantum dots is the asymmetry factor \( a = (G_i - G_j)/(G_i + G_j) \), with \( G_i \equiv N_i \Gamma_i \), and \( N_i, \Gamma_i \) denoting, respectively, the number of open channels and the tunneling rate in the lead \( i \). Therefore, the tunneling rates play a crucial role in mesoscopic systems and in measures of the noise.

Motivated by these recent advances in the noise measurements \cite{11} and by the asymmetry in current/tension seen in \cite{10}, we propose and study a myriad of possibilities to measure the spin accumulation in reservoirs through solely non-equilibrium electronic transport. This study is an alternative to that of active spin polarization in transport which usually requires the presence of ferromagnetic leads \cite{17} and measurements in spin polarization through spin current is, in principle, much more difficult than measure tunneling in charge transport. For this, we consider the role of tunneling rates in the electronic transport for quantum dots coupled to reservoirs through normal guides. Considering independent electron spin distributions of these reservoirs, we show that the average noise displays new and surprising effects due to the asymmetry parameter \( a \). There are many theories for the calculation of electron counting statistics. To name a few: Non-linear \( \sigma \) models (replica \cite{18}, supersymmetric \cite{19}, and Keldysh \cite{20}, quantum circuit theory \cite{21}, cascade approach \cite{22}, stochastic path integral technique \cite{23}, semi-classical methods based on solving Boltzmann-Langevin equations \cite{24}, etc. In this paper, we use one more, and proven powerful, method based on the Random Matrix Theory (RMT). More specifically, using RMT \cite{3, 25} we study the generalization of the interesting experimental setup recently proposed in Ref. \cite{10}.

We consider an open QD connected to \( m \) reservoirs labeled by \( \alpha = 1, \ldots, m \) through leads with open electronic channels. The system, schematically represented in Fig. 1, contains reservoirs with electro-chemical potentials \( \mu_\alpha = \mu_{\alpha \uparrow} + \mu_{\alpha \downarrow} \), where \( \uparrow \) and \( \downarrow \) denoting, respectively, the contributions of spins up and down. The reservoirs are kept at a fixed temperature \( T \) in a way that the system can reach the thermal crossover. The tunneling rates, \( \Gamma_i \), can be controlled through changes in the gate voltage. We consider non-equilibrium corrections at the electro-chemical potentials owing to the accumulation of spin. This is denoted by \( \delta \mu_\alpha = (\mu_{\alpha \uparrow} - \mu_{\alpha \downarrow})/2 \). Because of the difference \( n_{\alpha \uparrow} - n_{\alpha \downarrow} \) at the reservoirs, where \( n_\alpha \) is the total number of electrons, there is a well defined direction of the spin polarization at, say, reservoir \( \alpha \), which we describe by the unit vector \( \mathbf{m}_\alpha \). We show that tunneling rates drastically affects the measurements in spin distribution at reservoirs of QD. We further show that a great change in the average noise power occurs in a region of spin accumulation close to where most experiments have performed.

II. SCATTERING THEORY OF QUANTUM TRANSPORT

In Section A, we will make a brief presentation of the linear response theory using Landauer-Büttiker scattering formalism. We follow \cite{10} that verify the asymmetry current/voltage and present their main results, making our work self-contained. The theory presented includes an arbitrary topology and the separation of spin degrees of freedom. In section B, we present original results for average noise including the spin accumulation in the presence of tunneling rates.

A. General Formulation

In the limit of low bias voltages, we construct a theory of multi-terminal and multi-channel scattering, generating the Landauer-Büttiker framework for quantum transport \cite{10}. We start by considering the time-dependent current \( I_\gamma(t) \) at lead \( \gamma \), for \( \gamma = 1, 2, \ldots, m \), with \( m \) being the number of leads connected to the chaotic quantum dots. Within the framework of the scattering theory for quantum transport, the current-current correlation function can be written in the form \cite{10}

\[
\langle \delta I_\alpha(t) \delta I_\beta(0) \rangle = \int \frac{dw}{2\pi} e^{-iwt} S_{\alpha\beta}(w),
\]

where \( \delta I_\alpha(t) \equiv I_\alpha(t) - \langle I_\alpha(t) \rangle \) is the current fluctuation around the mean value \( \langle I_\alpha(t) \rangle \). The Fourier transform of the current-current correlation function, Eq. (1), namely \( S_{\alpha\beta}(w) \), is the noise, which, in the absence of interaction, can be written as \cite{10}

\[
S_{\alpha\beta}(w) = \sum_{\gamma \nu} \sum_{(c_1, p) \in \gamma} \sum_{(c_2, q) \in \nu} \frac{e^2}{h} \int d\epsilon A_{\gamma\nu}^{c_1, p; c_2, q}(\epsilon; \epsilon', \epsilon) \times A_{\gamma\nu}^{c_2, q; c_1, p}(\beta; \epsilon', \epsilon) \left\{ f^p_\gamma(\epsilon) \left[ 1 - f^q_\nu(\epsilon') \right] \right\} + f^q_\nu(\epsilon') \left[ 1 - f^p_\gamma(\epsilon') \right] \right\}; \quad \epsilon' = \epsilon + ehw.
\]

The matrix \( A_{\gamma\nu}^{c_1, p; c_2, q}(\alpha; \epsilon, \epsilon') \equiv \delta_{c_1, c_2} \delta_{p, q} \delta_{\alpha \alpha} \delta_{\gamma \nu} - [S_{\alpha\nu}(\epsilon) S_{\alpha\nu}(\epsilon'))]_{c_1, p; c_2, q} \) is the current matrix, where \( S(\epsilon) \) is the scattering matrix; \( S \) which can depend on the energy \( \epsilon \) and describes the charge transport through the circuit. Also, \( f^p_\gamma(\epsilon) = (1 + \exp[(\epsilon - \mu_p)/k_BT])^{-1} \) is the Fermi distribution function, related to the thermal reservoir connected to the lead \( \alpha \). The sum in Eq. (2) extends over spin indices \( p, q = \pm \) polarizable along the unit vector \( \mathbf{m}_\alpha \), open channels indices \( c_1, c_2 \in \gamma \) and over all leads, including \( \alpha \) and \( \beta \).
The scattering matrix $S(\varepsilon)$ used to describe the mesoscopic system is uniformly distributed over the orthogonal ensemble, if the system has both time-reversal and spin rotation symmetry, over the unitary ensemble, if only time-reversal symmetry is broken by an intense external magnetic field, or over the symplectic ensemble, if the spin rotation symmetry is broken by an intense spin-orbit interaction [26].

A particularly interesting limit of the resulting linear response theory is that at zero frequency, for which there is a successful model established to treat noise of a phase-coherent conductor [27]. In this limit, we define $S_{\alpha\beta} = S_{\alpha\beta}(0)$ and the transport is described in terms of external fields contained in the symmetries of the scattering matrices, the energies present in the corresponding Fermi distributions in the reservoirs, and on the open channels in the leads. In the limit of both low temperatures and voltages, the scattering matrix is uniform within an energy windows in the vicinity of Fermi level, in a form that the scattering matrix is given by $S = S(\varepsilon) = S(E_F), \forall \varepsilon$, with $E_F$ denoting the Fermi energy. From Ref. [27], along with the limits discussed above, spectral noise of the current-current correlation function function can be written as [10, 28]:

\[
S_{\alpha\beta} = 2k_B T \left[ \delta_{\alpha\beta} 2N_\alpha - \text{Tr} \left( 1_\beta S^\dagger 1_\alpha S + 1_\alpha S^\dagger 1_\beta S \right) \right] \\
+ \frac{1}{4} \sum_{\gamma,\rho=\pm} \sum_{p,q=\pm} f_{\gamma\rho}^{pq} \left[ \mathcal{T}_{\gamma\alpha\rho\beta}^{00} + 2p \text{Re} \mathcal{T}_{\gamma\alpha\rho\beta}^{20} + pq \mathcal{T}_{\gamma\alpha\rho\beta}^{zz} \right].
\] (3)

The matrix $S$ has dimension $2M \times 2M$, with $M = \sum_\gamma N_\gamma$ denoting the total number of open channels in the leads. The matrix $1_\alpha$ projects states on the transport guide $\alpha$. We also define

\[
\mathcal{T}_{\alpha\beta}^{ab} = \text{Tr} \left[ \left( 1_\gamma \otimes \sigma^a \right) S^\dagger 1_\alpha S \left( 1_\rho \otimes \sigma^b \right) S S^\dagger 1_\beta \right]
\] (4)

where $a, b \in \{0, z\}$, $\sigma^z = \sigma \cdot \mathbf{m}_p$ with $\sigma$ is the Pauli vector/matrix and $\sigma^0$ a identity matrix $2 \times 2$.

**B. Non-ideal Mesoscopic Billiards**

Now, we present our new results, extending [10] to include tunneling and reflections. The scattering matrix incorporates the non-ideal coupling between the ideal-channels of the leads and the internal modes of the QD. This coupling describes the tunneling rate $\Gamma_\alpha \in [0, 1]$ of the entrance and exit of the electronic modes of lead $\alpha$ in the QD. In RMT, the tunnel rate is generically referred to as tunneling barrier. The presence of barriers imposes a distribution of the scattering matrices within the Poisson kernel [4, 26, 29, 30] of RMT and integration in the Haar measure corresponding to extracting non-analytical results for the averages. Therefore we will use the diagrammatic method proposed in Ref. [29], to find the leading term in the semi-classical expansion of the average noise. Following Refs. [25, 31], the matrix $S$ can be parameterized by the stub model, being composed by an average part, $R$, and a fluctuating part, $\delta S$:

\[
S = R + \delta S \\
\delta S = T[1 - RU]^{-1}UT^\dagger.
\]

The matrix $U$ is random orthogonal, unitary or symplectic, depending on the Dyson ensemble, with dimensions $2M \times 2M$. The matrices $T$ and $R$ are diagonal, $2M \times 2M$, matrices, given by $T = \text{diag}(i\sqrt{\Gamma_{11}}, \ldots, i\sqrt{\Gamma_{m12N_m}})$ and $R = \text{diag}(i\sqrt{1 - \Gamma_{11}}, \ldots, i\sqrt{1 - \Gamma_{m12N_m}})$.

In the limit of many open channels $M \gg 1$, we can expand $S$ in powers of $U$ and perform a diagrammatic integration, obtaining average moments of the scattering matrices in the Poisson kernel. According to Eq. (3), the average noise requires the calculation of the semiclassical expansion of the trace of products of two and four scattering matrices. We performed the calculation and verified explicitly that the only ladder diagrams (diagrams with traversing Fermi distributions in the reservoirs, and on the open channels in the leads. In the limit of both low temperatures and voltages, the scattering matrix is uniform within an energy windows in the vicinity of Fermi level, in a form that the scattering matrix is given by $S = S(\varepsilon) = S(E_F), \forall \varepsilon$, with $E_F$ denoting the Fermi energy. From Ref. [27], along with the limits discussed above, spectral noise of the current-current correlation function function can be written as [10, 28]:

\[
S_{\alpha\beta} = 2k_B T \left[ \delta_{\alpha\beta} 2N_\alpha - \text{Tr} \left( 1_\beta S^\dagger 1_\alpha S + 1_\alpha S^\dagger 1_\beta S \right) \right] \\
+ \frac{1}{4} \sum_{\gamma,\rho=\pm} \sum_{p,q=\pm} f_{\gamma\rho}^{pq} \left[ \mathcal{T}_{\gamma\alpha\rho\beta}^{00} + 2p \text{Re} \mathcal{T}_{\gamma\alpha\rho\beta}^{20} + pq \mathcal{T}_{\gamma\alpha\rho\beta}^{zz} \right].
\] (3)

The matrix $S$ has dimension $2M \times 2M$, with $M = \sum_\gamma N_\gamma$ denoting the total number of open channels in the leads. The matrix $1_\alpha$ projects states on the transport guide $\alpha$. We also define

\[
\mathcal{T}_{\alpha\beta}^{ab} = \text{Tr} \left[ \left( 1_\gamma \otimes \sigma^a \right) S^\dagger 1_\alpha S \left( 1_\rho \otimes \sigma^b \right) S S^\dagger 1_\beta \right]
\] (4)

where $a, b \in \{0, z\}$, $\sigma^z = \sigma \cdot \mathbf{m}_p$ with $\sigma$ is the Pauli vector/matrix and $\sigma^0$ a identity matrix $2 \times 2$.

\[
\langle \text{Tr} \left( 1_\beta S^\dagger 1_\alpha S \right) \rangle = 2\delta_{\beta\alpha} \left[ N_\beta - G_\beta \right] + 2G_\beta G_\alpha \frac{G_T}{G_T} \left[ 2 - \Gamma_\gamma - \Gamma_\alpha - \Gamma_\rho - \Gamma_\beta + \sum_{\gamma} \frac{G_\gamma}{G_T} \right]
\] (5)

The average of Eq. (4) is calculated in a generic form for any ensemble, arbitrary number of leads and different tunneling rates in each lead. We obtain the following, new, result valid for the universal ensembles:
We also show that this equation satisfies the conservation law \( S_{ij} = -S_{ji} \), with \( i = 1, 2 \), indicating that the behavior of any \( S_{ij} \) is identical.

\[
\frac{\langle S_{11} \rangle}{k_B T \langle g \rangle} = \frac{6G_1G_2}{G_T^2} + \frac{G_1G_2 \Gamma_1(2G_2 + G_1)}{G_T^2} + \frac{4G_1^2\Gamma_1 + 3G_1^3\Gamma_2}{G_T^2} + |\Delta|\coth(|\Delta|) \left[ \frac{G_1^2G_2(2 - \Gamma_1)}{G_T^3} + \frac{2G_1G_2^2(1 - \Gamma_1)}{G_T^3} + \frac{G_1^2\Gamma_2}{G_T^2} \right] + |\Phi + \Delta|\coth \left( \frac{|\Phi + \Delta|}{2} \right) + |\Phi - \Delta|\coth \left( \frac{|\Phi - \Delta|}{2} \right) \left[ \frac{G_1G_2^2}{G_T^2} + \frac{G_1^2(1 - \Gamma_2) + G_2^2(1 - \Gamma_1)}{G_T^3} \right]
\]

(7)

Before we analyze equation (7), we should first verify several of its basic limits. We start by considering the limit \( k_B T \gg eV, \delta \mu \) and obtain the universal thermal noise \( \langle S_{11} \rangle = 4k_B T \langle g \rangle \). Another important case which leads to the shot-noise power is the limit \( eV \gg \delta \mu, k_B T \),
through which we find that \( F = (S_{11})/2eI \) where \( F \) is the Fano factor and \( 2eI \) is the Poisson noise:

\[
F = \frac{G_1 G_2}{G_T^2} + \frac{G_1^2 (1 - \Gamma_2) + G_2^2 (1 - \Gamma_1)}{G_T^2}.
\]  

(8)

From Eq. (8), we can see that the case of symmetric contacts, \( G = G_1 = G_2 \) and \( \Gamma_1 = \Gamma_2 = \Gamma \), the Fano factor simplifies to \( F = 1/4 \times (2 - \Gamma) \), under typical ballistic QD for which \( F = 1/4 \) in the case of ideal contacts. It is also possible to see in Eq. (7) that the noise is non-zero even when \( eV \to 0 \) for an arbitrary value of temperature crossover. The spin accumulation maintains the noise for arbitrary electrochemical potentials for both shot-noise power and thermal noise power. The general Eq. (7), in the case of symmetric contacts simplifies to the following expression:

\[
\frac{(S_{11})}{k_B T(g)} = \frac{6 + 5\Gamma}{4} + \frac{2 - \Gamma}{4} \left[ |\Delta| \coth (|\Delta|) + |\Phi + \Delta| \coth \left( \frac{\Phi + \Delta}{2} \right) + |\Phi - \Delta| \coth \left( \frac{\Phi - \Delta}{2} \right) \right].
\]  

(9)

The behavior of equation (9) is displayed in Figure 2. In the left figure, we fix \( \Phi \) at a fixed generic value and also fix several values of the barriers. We observe in this figure that the barrier greatly amplifies the signal of \( (S_{11})/k_B T(g) \). We observe two anomalous characteristics of the first derivative: The first centered at the inversion point of the spin polarization of the reservoir, and the second in the region of saturation at which \( \Phi = \Delta \). In these zones drastic changes of the rate of increase in the noise, encoded in the value of its first derivative which stabilizes between two plateaus as the bias voltage decreases. In the right figure, we investigate the finite value of \( \Gamma = 0.5 \) of the tunneling rate and the disappearance of one of the plateaus. The elimination of one of the plateaus of the first derivative indicates that the tunneling rate has an important role in the study of the saturation zone as the bias voltage is decreased. It is one of the important effects of the tunneling rate on the spin accumulation in the system. Taking the limit \( \delta \mu \gg eV, k_B T \), we obtain

\[
\frac{(S_{11})}{g} = \frac{3}{4} (2 - \Gamma) |\delta \mu|,
\]  

(10)

which can be rewritten in terms of the Fano factor as \( (S_{11})/(g) = 3 \times F \times |\delta \mu| \).

IV. OPAQUE LIMIT

A particularly interesting regime in experiments involving tunneling rates is called “Opaque Limit”. The experimental data in real-time traces of Refs. 11-14 are basically in this category. The opaque limit is well-defined in Ref. 33, where analytical calculation using semiclassical method were performed allowing the obtention of time scales typical of transport phenomena in ballistic cavities. This regime is defined by taking limits of \( N_o \to \infty \) and \( \Gamma_o \to 0 \) such that \( G_o \) be finite. Taking this limit, the general expression (7) simplifies to the following equation

\[
\frac{(S_{11})}{k_B T(g)} = \frac{(1 - a^2)}{2} \left[ 3 + |\Delta| \coth (|\Delta|) \right]
\]  

+ \( \frac{(1 + a^2)}{2} \left[ |\Phi + \Delta| \coth \left( \frac{\Phi + \Delta}{2} \right) \right]
\]  

+ \( |\Phi - \Delta| \coth \left( \frac{|\Phi - \Delta|}{2} \right) \right],
\]  

(11)

where we have defined \( a \equiv (G_1 - G_2)/G_T \), thus totally encoding the open channels. The entrance and exit

FIG. 3: We depict the behavior of the noise in the regime of spin accumulation as a function of the tunneling rate \( \Gamma \) in a QD with non-ideal contacts, through the parameter \( a = (G_1 - G_2)/G_T \). Note that for ideal contacts, \( \Gamma_1 = \Gamma_2 = 1 \), the noise is highly asymmetrical with respect to this parameter. In the other curves we vary the values of \( \Gamma_1, \Gamma_2 \) till we reach the opaque limit, \( \Gamma_1, \Gamma_2 \to 0 \). In this case the noise becomes symmetrical with respect to \( a \).
events of the QD are uncorrelated and the asymmetric parameter \( a \) of the tunneling rate was used in Ref. [11] to designate the normalized moments of a single level in the QD.

In Figure 3, we analyze how the tunneling rates affect the noise, equation (7), through the QD.

In Figure 4, we show the concavity and the sign of the noise power for all values of the tunneling rate and of the asymmetry parameter.

FIG. 4: In this figure we show the concavity and the sign of the noise power for all values of the tunneling rate and of the asymmetry parameter.

In Figure 5, we show the behavior of the shot noise in the case of spin accumulation as a function of \( a = (G_1 - G_2) / G_T \), in a QD with non-ideal contacts, equation (13). For any value such that \( \delta \mu \geq eV \), the result will always be the same for the shot noise which is a direct consequence of the spin accumulation in the reservoirs.

where \( f(a, \Gamma_1, \Gamma_2) = 4 + 3\Gamma_1(a - 1) - 3\Gamma_2(a + 1) \) and \( g(\Phi, \Delta) \) is a function of \( \Phi \) and of \( \Delta \). We observe that the sign of the second derivative is fixed by the sign of \( f \). We separate the diagram generated by \( \Gamma_1 \times \Gamma_2 \) into three distinct regions according to the sign (+) and (−) as is exhibited in figure 4. The (+) and (−) regions determine, respectively, upward or downward concavity, whereas (+/−) determines a change of concavity in the sign of the noise power in \( a \in [-1,1] \). Note that these regions are separated by the straight lines \( \Gamma_1 = 2/3 \) and \( \Gamma_2 = 2/3 \) in the diagram. The particular case of ideal, maximum tunneling rate, case is a vertex of the diagram situated in the (−) region, whereas the opaque, zero tunneling, limit is close to the vertex in the neighborhood of the (+) region in the diagram.

Finally, we consider the limit \( eV, \delta \mu \gg k_B T \) in (11). This limit allows us to get the shot-noise given by the following expression

\[
\langle S_{11} \rangle \langle g \rangle = \frac{(1 + a^2)}{2} (|eV + \delta \mu| + |eV - \delta \mu|) + \frac{(1 - a^2)}{2} |\delta \mu|; \quad (13)
\]

where

\[
\langle S_{11} \rangle \langle g \rangle = 2 \frac{(1 + a^2)}{2} |eV|, \quad eV \gg \delta \mu
\]

\[
\langle S_{11} \rangle \langle g \rangle = 2 \frac{(3 + a^2)}{4} |\delta \mu|, \quad \delta \mu \gg eV
\]

One of the principal result of this paper is the following:

In systems with accumulation of the spin, the Fano factor, \( F = (1 + a^2) / 2 \), measured experimentally in
Ref. [11] without taking into account the spin accumulation, presents a correction given by \((1 - a^2)/4\). Thus the Fano factor changes to \(F = (3 + a^2)/4\) in the limit \(\delta \mu \gg eV\) with \(F = \langle S_{11} \rangle / 2eI\). Figure 4 shows the shot-noise, equation (13), as a function of the parameter \(a\). For any value where \(\delta \mu \geq eV\) the result for the shot-noise will always be the same, once again indicating a saturation of the spin accumulation in the noise power. When \(eV \geq \delta \mu\) the shot-noise power approaches the result without spin accumulation.

V. SUMMARY AND CONCLUSIONS

In this paper we have analyzed the effect of tunneling and reflection at the gates of open quantum dots on the spin accumulation in electronic reservoirs. We analyzed separately the spin-up and spin-down Fermi distributions, and studied the average current-current correlation function using the Landauer-Büttiker formalism. More specifically, we investigated noise power in the presence of reflection at the voltage gates of the QD using the Poisson kernel as the scattering matrix distribution. We have obtained general equation for the study of the multi-terminal case with spin accumulation at the thermal crossover, and gave details for the two-terminal case. The dominant term in the semi-classical expansion of the noise power which is valid for all Universal Classes of Random Matrix Ensembles, and in all limits, was shown to be greatly affected by spin accumulation in the reservoirs.

We found that important modification in the behavior of the average noise ensues when tunneling rates are taken into account, especially close to the opaque limit.

In particular, by introducing the asymmetry parameter, we have shown the symmetrization of the noise power in the opaque limit of the thermal crossover. We performed a complete analysis of the rather surprising change of the concavity of the trace of the noise as a function of the asymmetry parameter, and have shown that only the opaque limit is totally symmetrical with well defined concavity. We have also exhibited results showing the effect of the tunneling rate on the saturation of the spin accumulation, potentially of experimental value as it shows the effects of the induced potentials due to the spin accumulation.

In Ref. [14], it was shown that fine adjustment of the voltage gates can alter the orbital configuration of the QD, restoring the tunneling between resonant levels of excited spin states in the presence of a magnetic field. An asymmetry parameter was used in Ref. [11] to obtain the noise in the presence of finite tunneling rates. Typical values used in that reference were in the range 1000 Hz - 10000 Hz, generating clear noise signal as a function of the asymmetry parameter. We performed an analysis of the correction to the shot-noise power and the Fano factor, resulting from the spin accumulation, in terms of reflections at the gates and the asymmetry parameter. Our findings may facilitate the experimental study of spin accumulation in reservoirs of mesoscopic systems in general. Other recent studies including electron-electron interaction or capacitance can be investigated considering barriers and spin accumulations [33, 36].
