\textbf{A B S T R A C T}

In this article, we explore an event detection framework to improve multi-document summarization. Our approach is based on a two-stage single-document method that extracts a collection of key phrases, which are then used in a centrality-as-relevance passage retrieval model. We explore how to adapt this single-document method for multi-document summarization methods that are able to use event information. The event detection method is based on Fuzzy Fingerprint, which is a supervised method trained on documents with annotated event tags. To cope with the possible usage of different terms to describe the same event, we explore distributed representations of text in the form of word embeddings, which contributed to improve the summarization results. The proposed summarization methods are based on the hierarchical combination of single-document summaries. The automatic evaluation and human study performed show that these methods improve upon current state-of-the-art multi-document summarization systems on two mainstream evaluation datasets, DUC 2007 and TAC 2009. We show a relative improvement in ROUGE-1 scores of 16% for TAC 2009 and of 17% for DUC 2007.

\section{1. Introduction}

Many automatic summarization systems have been proposed in order to cope with the growing number of news stories published online. The main goal of these systems is to convey the important ideas in these stories, by eliminating less crucial and redundant pieces of information. In particular, most of the work in summarization has been focused on the news domain, which is strongly tied to events, as each news article generally describes an event or a series of events. However, few attempts have focused on the use of automatic techniques for event classification for summarization systems for the news domain [1]. In fact, most of the work on multi-document summarization are either based on centrality-based [2–5], Maximal Marginal Relevance (MMR) [6–9], and coverage-base methods [10–15]. Generally, centrality-based models are used to generate generic summaries, the MMR family generates query-oriented ones, and coverage-based models produce summaries driven by topics or events.

The use of event information in multi-document summarization can be arranged in the following categories: initial hand-based experiments [16]; pattern-based approaches based on enriched representations of sentences, such as the cases of the work presented by Zhang et al. [15] and by Li et al. [13], which define events using an event key term and a set of related entities, or centrality-based approaches working over an event-driven representation of the input [1], where events are also pattern-based defined; and, clustering-based event definition [17].

The major problem of these approaches is that it is difficult to relate different descriptions of the same event due to different lexical realizations. In our work, we address this problem by using an event classification-based approach and including event information supported by two different distributed representations of text—the skip-ngram and continuous bag-of-words models [18]. Our event detection and classification framework is based on vector-valued fuzzy sets [19,20]. We evaluate our work using the standard summarization evaluation metric, ROUGE [21]. Moreover, to better understand the impact of using event information, we also perform a human evaluation using the Amazon Mechanical Turk\footnote{http://www.mturk.com/}.

Our main goal in this work was to produce event-based multi-document summaries that are informative and could be useful for humans. The human evaluation shows that our summaries are on average more useful for humans than the reference summaries. While we conducted our experiments in the news domain, our methods are also applicable to other domains, such as opinion and meta-review summarization in consumer reviews [22].

In this document, the next section describes the related work to contextualize the findings obtained in the experimental results. Section 3.2 introduces the Event Detection framework; which is enhanced by the Continuous Skip-gram Model presented in Section 3.3; both are included in a Event-based Multi-Document Summarization framework (Section 3). The experimental results are included and discussed in Section 4. Section 5 details the conclusions and discusses future research directions.

2. Related work

An early attempt at event-based multi-document summarization, proposed by [16], manually annotated events and showed that events are an useful cue for summarization systems. However, manually extracting events is undesirable as it hampers the automation of summarization systems.

Most of the work in automatic summarization concentrates on extracting summarization. In fact, extracting the important content is the first step of a generic summarization system. The extracted information can subsequently be further processed if the goal is to generate abstracts. For this case, the important content is generally devised as a set of concepts that are synthesized to form a smaller set and then used to generate a new, concise, and informative text. The alternative goal can also be to generate extracts where the identified content consists of sentences that are concatenated to form a summary.

The most popular multi-document summarization baselines follow into one of the following general models: centrality-based [2–4], Maximal Marginal Relevance (MMR) [6–9], and coverage-base methods [10–15, 23, 24].

Traditionally, centrality-based models are used to produce generic summaries, the MMR family generates query-oriented ones, and coverage-base models produce summaries driven by topics or events.

The most popular centrality-based method is the centroid [2] for multi-document summarization distributed in the MEAD framework. Expected n-call@k [7–9] adapted and extended MMR with new simplicity and ranking methods.

Concerning the idea of using event information to improve summarization, previous work [1, 21–15] defines events as triplets composed by a named entity, a verb or action noun, and another named entity, where the verb/action noun defines a relation between the two named entities. This information is then included in a generic unit selection model, often trying to minimize redundancy while maximizing the score of the important content. Others have tried to use term information and word overload to summarize the same events [25, 26].

In our work, we use, not only event information, but also their classification according to ACE [27]; we additionally explore the possibility of using events to filter out unimportant content; and, to our best of our knowledge, we present the first analysis of the impact of using this type of information on multi-document summarization.

Over the past years, the research community has been exploring event detection. The bulk of the event detection work started in the end of 1990s with the Topic Detection and Tracking (TDT) effort [28–31]. The TDT project had two primary tasks: First Story Detection or New Event Detection (NED), and Event Tracking. The objective of the NED task was to discover documents that discuss breaking news articles from a news stream. In the other task, Event Tracking, the focus was on the tracking of articles describing the same event or topic over a period of time. More recent work using the TDT datasets [32–34] on Event Threading tried to organize news articles about armed clashes into a sequence of events, but still assumed that each article described a single event. Passage Threading [33] extends the event threading work by relaxing the one-event-per-news-article assumption. For this purpose, it uses a binary classifier to identify “violent” events in paragraphs.

Even though the TDT project ended in 2004, new event detection research continued. The most well-known example is Automatic Content Extraction (ACE). The goal of ACE research is to detect and recognize events in text. Beyond the identification of events, the ACE 2005 [27] task identifies participants, relations, and attributes of each event. This extraction is an important step towards the overarching goal of building a knowledge base of events [35]. More recent research [36] explores bootstrapping techniques and cross-document techniques augmenting the ACE 2005 with other corpora, including MUC-6 (Message Understanding Conference).

The idea of augmenting the ACE 2005 corpus stems from the low occurrence of some event types in the sentences of the dataset. Most sentences do not contain any event or describe an event that does not exist in the list of event types, which makes the identification of events a complex task. Additional features combined with supervised classifier [37], such as SVM, improved the identification of events. But a more simple and efficient approach based on Fuzzy Logic outperformed the best results. For this reason, we are using it in this work.

As discussed above, events are hard to detect. However, the identification of anomalous events makes the task simpler [38]. Still, determining if two events are the same or are related is, as noted by Hovy et al. [39], an unsolved problem. Even event co-reference evaluation is not a trivial problem [40].

While word embeddings have been used in many NLP tasks [41, 42], they have not been used in event detection or summarization to the best of our knowledge. The closest work found is a summarization work that trains a neural network to learn the weights for a small set of features.

Even considering that clustering-based event definition approaches could handle this type of problem, the work of Li et al. [17] models events in a similar way of topics.

3. Event-based multi-document summarization

Our multi-document summarization approach is based on a single-document centrality summarization method, KP-Centrality [43] (Fig. 1). This method is easily adaptable [44] and has been shown to be robust in the presence of noisy input. This is an important feature, since the multiple documents given as input in multi-document summarization are more likely to contain unimportant information compared to single-document summarization.

3.1. From single-document to multi-document summarization

Our goal is to extend the KP-Centrality method for multi-document summarization. The simplest method would be to concatenate all documents and use the single-document method to produce the summary. We shall use this approach as a baseline. This baseline works quite well for a small number of documents, but the performance decreases as the number of documents increases. This means that KP-Centrality has limitations identifying redundant content, such as events, when it is written with different words. Another limitation of the baseline method is to ignore temporal information as more recent news documents tend to contain more relevant information and sometimes include brief references to the past events to provide some context.

To overcome the first limitation, we consider two simple but effective alternative approaches for improving the baseline method. The
first approach is a two-step method where we summarize each document individually in such a way that each of the summaries have the size of the final multi-document summary. This is followed by the concatenation of all the resulting summaries, which is then summarized again into the final summary. In both steps, we use the KP-Centrality method to generate the summaries. The advantage of this approach is to reduce the redundancy of information at document level (intra-document). This means that we also need to reduce the redundancy of information between document (inter-documents). The second method we propose is similar reduces the redundancy inter-documents. Rather than considering all summaries simultaneously, we take one summary $s_1$, concatenate with another summary $s_2$, summarize the result to obtain a summary of documents $s_1$ and $s_2$, which we denote as $s_{1\ldots2}$. Next, we take $s_{1\ldots2}$ and perform the same operation with $s_3$, obtaining $s_{1\ldots3}$. This is done recursively for all the $N$ documents in the from the input, and the final summary is the one obtained in $s_{1\ldotsN}$.

We will denote these methods as hierarchical single-layer and waterfall. These are illustrated in Figs. 2 and 3, respectively.

The waterfall method is sensitive to the order of the input documents. Since at each iteration the summaries of the documents are merged with the summary of the previous documents, the content of the initial documents is more likely to be removed than the content in the last documents. Thus, it is likely to consider the order of the documents. We chose to organize the documents chronologically where the older documents are summarized and merged in the first iteration of the waterfall method. The waterfall method has two drawbacks. One limitation is the size of the intermediate summaries. Once we decided the size of the final summary, the size of the intermediate summaries is not enough to contain all necessary information for the summarization process. From this limitation also emerges the second, which is the identification of redundant content between documents when written with different words.

Our solution to the first limitation of the waterfall method is as we merge more documents recursively, the intermediate summaries that contains the information of the documents so far, will grow in size to avoid losing important information. For that reason, we increased the number of sentences in the intermediate summary as a function of the number of documents that have been covered. More formally, the size of the summary at a given time or document $t$ is defined as:

$$L = \delta \times K \times \log(t + \phi)$$  

where $K$ is the maximum number of words in the final summary, $\phi$ is a constant to avoid zeros ($\phi = 2$). $\delta$ is a scale factor that is 1 for the generation of the initial documents summaries and 200 for the remaining cases. Since the more recent documents contain more important content, we also increased the size of initial documents summaries created by the hierarchical single-layer based on Eq. (1) to not give an unfair advantage to the waterfall method.

The identification of redundant sentences written in different ways is not an easy task. For instance, the sentence “The Starbucks coffee co. plan to acquire Pasqua coffee is leaving a bitter aftertaste in the mouths of some patrons of the San Francisco-based coffeehouse.” and “Starbucks, the nation ’s largest coffee retailer, announced Tuesday that it would buy Pasqua for an undisclosed amount.” have essentially the same meaning: a company plans to buy another. Nevertheless, the only common content between the two sentences are the company names. For this purpose, we propose two alternatives that complement each other. On the one hand, news documents describe events (e.g., Company acquisitions), thus sentences that cover the same event are good candidates to contain redundant information. On the other hand, different lexical realizations with the same meaning can be addressed using distributed word representations.

From this point, we present the two extensions to our multi-document summarization framework.
3.2. Supervised event classification

Our event detection method is based on the Fuzzy Fingerprints classification method [20], which is based on the work by Homem and Carvalho’s [19]. This work approaches the problem of authorship identification by using the crime scene fingerprint analogy that leverages the fact that different authors have different writing styles. The algorithm is computed as follows: (1) Gather the top-k word frequencies in all known texts of each known author; (2) Build the fingerprint by applying a fuzzifying function to the top-k list. The fuzzified fingerprint is based on the word order and not on the frequency value; (3) For each document, perform the same computations to obtain a fingerprint and assign the author with the most similar fingerprint.

Our motivation for the use of event information is the existence of secondary events that are not relevant to the main event of the documents, which need to be excluded from the summary. To do this, we use the event fingerprint method to identify sentences that describe events. Since we needed training data to build the event fingerprint of each event type, we used the ACE 2005 Multilingual Corpus [27]. These event fingerprints are used to generate each sentence fingerprint. For example, the fingerprint of the sentence “ETA, whose name stands for Basque Homeland Freedom, has killed nearly 800 people since 1968 in its campaign for Basque independence” considering, for example, only four event types would be the following vector: [Die = 0.01907, Attack = 0.0078, Divorce = 0.1061, Null or No-event = 0.01907]. All sentences that the event fingerprint method classified as not containing any event are removed (E.E. - filtering events). The exception to this simple rule occurs when the method is not confident in the classification result (confidence less than 0.0001, obtained when we compute the fingerprint of the sentence). This event filtering is an optional pre-processing step of the multi-document summarization.

After filtering out the sentences that do not describe events, we also need to identify similar events. This is accomplished by using the sentences event fingerprints as features in the summarization process. This means that each sentence has 27 new features, each corresponding to one of the 27 different event types: Appeal, Arrest-Jail, Attack, Be-Born, Charge-Indict, Convict, Declare-Bankruptcy, Demonstrate, Die, Divorce, Elect, End-Org, End-Position, Fine, Injure, Marry, Meet, N (Null/No Event), Phone-Write, Release-Parole, Sentence, Start-Org, Start-Position, Sue, Transfer-Money, Transfer-Ownership, Transport, Trial-Hearing.

Our approach to the extraction of event information does not fall in any of the previously known categories (exploratory hand-based experiments; pattern-based approaches; and, clustering-based), since it is a supervised classification method.

3.3. Unsupervised word vectors

Although the event detection method described above is supervised, where features are extracted from annotated data, we also need to leverage the large amount of raw text (without annotation) in an unsupervised setup. The small size of the annotated data is insufficient to cover also possible ways of describing events. Large amounts of raw text without event annotations are easy to obtain and contain different descriptions about the same event. Thus, we need a method to relate the event descriptions. For this purpose, we use the method recently introduced by Mikolov et al. [18], which uses raw text to build a representation for each word, consisting of a d-dimensional vector. Two models were proposed in this work, the skip-ngram model and the continuous bag-of-words model, which we shall denote as SKIP and CBOW, respectively. While both models optimize their parameters by predicting contextual words, the models differ in terms of architecture and objective function. SKIP iterates through each word \( w_t \) at index \( i \), and predicts each of the neighboring words up to a distance \( c \). More formally, given a document of \( T \) words, the model optimizes its parameters by maximizing the log likelihood function:

\[
\mathcal{L} = \frac{1}{T} \sum_{t=1}^{T} \sum_{j \in \text{context}(i)} \log p(w_{t+j} \mid w_i)
\]

where the probability \( p(w_{t+j} \mid w_i) \) is the output probability given by the network. The log likelihood function is optimized using gradient descend.

CBOW is similar to SKIP, in the sense that it uses word vectors to predict surrounding words, but predicts each word \( w_t \) conditioned on all surrounding words up to a distance of \( c \). That is, we estimate the parameters that maximize the probability \( p(w_t \mid w_{t-c}, \ldots, w_{t+c}) \).

To use this information as features in our summarization model, we added to the representation of each sentence a vector consisting in the average of the vectors representing each word in that sentence. Each word is described by 50-features vector.

We have also experimented using a distributed representation of sentences [45], but the results were worse than averaging word vectors due to overfitting.

4. Experiments

We evaluate our work in two distinct ways: through the automatic estimation of the informativeness, using ROUGE; and through a human study, designed according to two previous reference studies [46,47], using the Amazon Mechanical Turk.

4.1. Datasets

To empirically analyse the performance of our event-based multi-document summarization methods, we use two standard evaluation datasets: DUC 2007\(^2\) and TAC 2009\(^3\). However, the set of events types occurring in evaluation datasets only partially overlaps with the events types detected by our event detector. Hence, we created a subset for each of the evaluation datasets. Tables 1 and 2 identify the selected topics.

4.1.1. DUC 2007

The main summarization task in DUC 2007 is the generation of 250-word summaries of 45 clusters of 25 newswire documents and 4 human reference summaries. Each document set has 25 news documents obtained from the AQUAINT corpus [48].

4.1.2. TAC 2009

The TAC 2009 Summarization task has 44 topic clusters. Each topic has 2 sets of 10 news documents obtained from the AQUAINT 2 corpus [49]. There are 4 human 100-word reference summaries for each set, where the reference summaries for the first set are query-oriented multi-document summaries, and for the second set are update summaries. In this work, we used the first set of reference summaries.

\(^2\) http://www-nlpir.nist.gov/projects/duc/duc2007/tasks.html
\(^3\) http://www.nist.gov/tac/2009/Summarization/
Regarding the event-based features, they are obtained from the Event Fuzzy Fingerprint method and consist of scores associated with event fingerprints as described in Sections 3.2 and 3.

To create the CBOW and SKIP models we used New York Times articles covering a 16-year period from January of 1994 to December of 2010, included in the English Gigaword Fifth Edition [52]. Since the results obtained with both models were very similar, we opted to present only the results with the SKIP model.

Internally, the KP-Centrality method uses a distance metric to compute semantic similarity between the sentences. In these experiments, we explored the several metrics presented by Ribeiro and de Matos [5], but only present the results using the Euclidean distance, as it was best-performing one in this context.

In the next sections, we analyze the results of the automatic informativeness evaluation and of the human study. Although we have experimented both the single-layer and waterfall architectures in both datasets, we only present the best performing model for each dataset.

### 4.3. Results

#### 4.3.1. Informativeness evaluation

Table 3 provides the results on the DUC 2007 dataset using the waterfall summarization model. Our first observation is that our proposed approach, even without using any event information, filtering or the temporal dilation of the size of the initial and intermediate summaries, achieves better results than the baseline. Note that, although the presented results are for the waterfall architecture, the single-layer approach using all features (event information and filtering in addition to average word embeddings of sentences and temporal dilation) also achieved better results than the baseline (0.3522 ROUGE-1 score). The same does not happen for other summarization models: MEAD and Portfolio achieved better results than the baseline, but Filatova’s event-based summarizer, MMR ($\lambda = 0.3$ was the best performing configuration), Expected n-call@k, TopicSum, and LexRank did not.

Another important aspect is that, in the DUC 2007 except the use of event information without event filtering, word embeddings, and temporal dilation, all our variants improve over not using event information or temporal dilation. After we observed the summaries, we find out that the intermediate summaries were not large enough to keep all important events till the generation of the final summary. At the same time, the sentences describing the same event types were not exactly the same events, but follow up events (which are semantic similar), such as a new strike, or another company acquisition.

The best performing baseline was MEAD and only achieved a performance similar to the default model without event information or the temporal dilation. The best results in the DUC 2007 were obtained when using the average word embeddings of the sentences (SKIP model) combined with the event distribution scores and using event filtering and temporal dilation.

Fig. 4 shows an example of a summary produced by our best method on the DUC 2007 dataset and the corresponding reference summary.

Table 3 also presents the obtained results on the TAC 2009 dataset. Note that, in this dataset, our best results were achieved using the single-layer architecture instead of the waterfall architecture. Nonetheless, the best result achieved by the waterfall approach (using all features) was better than our baseline (0.5163 ROUGE-1 score). On the other hand, all other approaches, achieved worse results than the baseline. The results in the TAC 2009 results exhibit the same behavior in term of features and temporal dilation observed in the DUC 2007 dataset: the best results use all features and temporal dilation of the size of the initial and intermediate summaries.

The event filtering consistently lower the results in the TAC 2009. The smaller number of documents to summarize 10 vs. 25 suggest that there is less redundant content in the TAC 2009 than in the DUC 2007. Some of the topics in the TAC 2009 are more complex, in the sense, that there are more relevant events, but with distributed lower
relevance of those events making the distinction between primary and secondary events hard even for humans as topic D0910B exemplifies. Under this conditions, an event classification error have more impact in the final outcome and should be avoided. Our event filtering results were also inline with Filatova’s event-based summarizer, which had worse performance than Expected n-call@k and MMR on the TAC 2009.

We have also observed that when the connection between news documents covering a topic is weak, the cascade method performs worse than the single-layer. This fact also helps to explain the performance differences between the hierarchical methods and datasets.

In order to give a better perspective over the results shown in Table 3, we need to know the ROUGE-1 of the perfect summary. This results corresponds to the optimal selection of important sentences achievable in the evaluation datasets (oracle) and it is shown in Table 4. We also included the results obtained using our best summarizer configuration. These values are obtained by testing all summaries from each topic of the subsets of the TAC 2009 and DUC 2007 datasets.

We obtained 8 summaries for each topic: one using our event-based summarizer, another using the reference summary, and 7 using the baseline systems. Then, we created 5 HITs, one per judge, for each of the 17 topics. An individual judge could only do one HIT per topic and it paid $0.05 if accepted. We selected the reference summaries from our event-based summarizer with the corresponding summaries are for humans. To evaluate usefulness, we needed a set of summaries from our event-based summarizer with the corresponding evaluation scores. We also needed a similar set for the baseline system to establish a proper comparison. Obtaining such sets presents both conceptual and practical difficulties. Defining usefulness or relevance of summaries are subjective decisions of each reader that can be influenced by their background.

Our solution was to use multiple judges for the same news story and provide a Likert scale to assign a score to each question. We used a five-level Likert scale, ranging from strongly disagree (1) to strongly agree (5).

We used the Amazon’s Mechanical Turk service to recruit and manage our judges. To the best of our knowledge, this has not been done before for this purpose. Each assignment (called HIT) consisted of answering 9 evaluation questions. Evaluating one summary was a HIT and it paid $0.05 if accepted. We selected the reference summaries from each topic of the subsets of the TAC 2009 and DUC 2007 datasets.

We obtained 8 summaries for each topic: one using our event-based summarizer, another using the reference summary, and 7 using the baseline systems. Then, we created 5 HITs, one per judge, for each of the 17 topics. An individual judge could only do one HIT per summary of a topic and summarizer.

The use of the Mechanical Turk created the practical problem of the uneven quality of the judges: some of the judges used bad shortcuts to accomplish a HIT, producing meaningless results. We used several heuristics to weed out bad HITs. For example, very fast work

Event-based Summary

Iranian Foreign Minister Kamal Kharrazi, who made the announcement in New York, and his British counterpart, Robin Cook, had portrayed the move as a way to improve ties that have remained strained over the issue and agreed to exchange ambassadors. LONDON _ The British government said Wednesday that it would continue to press Iran to lift the death sentence against the author Salman Rushdie when its foreign secretary, Robin Cook, meets the Iranian foreign minister in New York on Thursday. VIENNA, Austria (AP) – The European Union on Monday welcomed a move by the Iranian government to distance itself from an Islamic edict calling for British author Salman Rushdie’s death even as two senior Iranian clerics said the ruling was irrevocable. The move follows the Iranian government’s distancing itself last month from bounties offered for the death of Rushdie and a strong reaction by hard-liners who support the killing of the Booker Prize-winning author. He said that Iran will ask the United Nations to effectively put a ban on insulting religious sanctities in a bid to prevent disputes such as the Rushdie affair. On February 14, 1989, late Iranian leader Ayatollah Khomeini issued a religious edict, pronouncing a death sentence on the Indian-born British author Salman Rushdie and his publishers in protest against the publication of Rushdie’s novel “The Satanic Verses”, which was believed by Moslems as defaming Islam, and exhorting all Moslems to carry out the sentence.

Reference

In 1989, Ayatollah Khomeini of Iran issued a death sentence on British author Salman Rushdie because his book “Satanic Verses” insulted Islamic sanctities. Rushdie was born in India, but his book was banned and his application for a visit was denied. British Airways would not permit Rushdie to fly on its airplanes. Reacting to diplomatic pressures by Britain and other European Nations, Iran announced in 1996 that the death sentence was dropped. President Rafsanjani said there was a difference between a fatwa (ruling) and a hokm (command) and that Khomeini did not mean the sentence to be a command. Despite official retraction of the death sentence, Iranian Islamic fundamentalists continue to demand Rushdie’s death. The Khordad Foundation raised the reward for Rushdie’s death to 2.5 million dollars and announced, “There is nothing more important to the foundation than seeing Imam Khomeini’s decree executed.” In 1998, Grand Ayatollah Lankarani and Grand Ayatolla Hamedani said the fatwa must be enforced and no one can reverse it. More than half of Iran’s parliament signed a letter saying the death sentence against Rushdie still stands. A hard-line student group offered $333K to anyone who kills Salman Rushdie; residents of a village in northern Iran offered land and carpets to anyone who kills him and thousands of Iranian clerics and students pledged a month’s salary toward a bounty. In February 2000, the Islamic Revolutionary Guard said in a radio report that the death sentence was still in force and nothing will change it.

Fig. 4. Example of summary produced by our summarizer and the reference summary from the Topic D0712C DUC 2007 - “Death sentence” on Salman Rushdie.
Tables 5 and 6 show the average scores obtained in the user study. As we can observe in both tables, the judges rated our event-based multi-document summaries as more useful than reference summaries and the baseline systems. They also reported that they preferred our event-based summaries to be nearly the same. We empirically observed that the waterfall method produces more coherent summaries than the single-layer method, which is explained in part by the fact that the most of the extracted sentences belong to few documents (in general, the single-layer method, which is explained in part by the fact that the waterfall method produces more coherent summaries than the single-layer method). Among the event-based and topic-based baselines, the human evaluation clearly shows that the Filatova and Hatzivassiloglou event-based method performed better than the topic based summarizer (TopicSum). More interesting is the fact that the overall human score of the Filatova and Hatzivassiloglou event-based were either the best or second best baseline. Among the event-based and topic-based baselines, the human evaluation clearly shows that the Filatova and Hatzivassiloglou event-based method performed better than the topic based summarizer (TopicSum). More interesting is the fact that the overall human score of the Filatova and Hatzivassiloglou event-based were either the best or second best baseline.

In summary, the automatic evaluation of the informativeness results show that the proposed framework achieves better results than previous models. To this contributed, not only the single-document summarization method on which our multi-document approach is based, but also the use of event information and the better representation of text. Note that a simple baseline that combines all input documents and summarizes the resulting meta-document achieves better results than all other approaches in the TAC 2009 dataset and also achieves better results than five of the reference methods in the DUC 2007. One implication is that our event-based multi-document summaries does not discard the sub-topics, which penalizes the Focus score in the TAC 2009 dataset when compared to the centroid-based method (MEAD) that selected the sentences for the summary using a single topic (centroid). Another implication is that increasing the focus in a single sub-topic can reduce the Context Coverage. However the results are not conclusive.

Even though the overall results are higher for our event-based multi-document summaries in TAC 2009, we cannot conclude that our method is better than the reference. The reason lies in the smaller size of reference summaries when compared to the remaining summaries (100 vs. 250 words).

The evaluation scores for the Focus category highlight an important difference in the topics of the datasets. While in TAC 2009 most topics describe several equal-importance sub-topics/events spread in time, there is a single main topic center on a date in several topics of DUC 2007. One implication is that our event-based multi-document summaries do not identify the sub-topics, which penalizes the Focus score in the TAC 2009 dataset when compared to the centroid-based method (MEAD) that selected the sentences for the summary using a single topic (centroid). Another implication is that increasing the focus in a single sub-topic can reduce the Context Coverage. However the results are not conclusive.

(c) **Referential clarity** - It should be easy to identify in the summary to whom or what the pronouns and noun phrases are referring to. If a person or other entity is mentioned, it should be clear what their role in the story is. So, a reference would be unclear if an entity is referenced but its identity or relation to the story remains unclear.

(d) **Non-redundancy** - There should be no unnecessary repetition in the summary. Unnecessary repetition might take the form of whole sentences that are repeated, or repeated facts, or the repeated use of a noun or noun phrase (e.g., “Barack Obama”) when a pronoun (“he”) would suffice.

(e) **Focus** - The summary should not have extraneous information.

(f) **Context Coverage** - The summary should cover all main events of a story and give a brief context about them.

(g) **Grammaticality** - The summary should have no datelines, system-internal formatting, capitalization errors or obviously ungrammatical sentences (e.g., fragments and missing components) that make the text difficult to read.

(h) **Overall** - What is the overall quality of the summary?

5. Conclusions

In this work, we explore a multi-document summarization framework based on event information and word embeddings that achieves performance above the state-of-the-art.

The multi-document summarization framework was developed by extending a single-document summarization method, KP-CENTRALITY, in two hierarchical ways: single-layer and waterfall. The single-layer approach combines the summaries of each input document to produce the final summary. The waterfall approach combines the summaries of the input documents in a cascade fashion, in accordance with the temporal sequence of the documents. Event information is used in two different ways: in a filtering stage and to improve sentence representation as features of the summarization model. Related to event information, we also explored the temporal sequence of the input documents by increasing the size of the initial and intermediate summaries, used by our framework. To better capture content/event information expressed using different terms, we use two distributed representations of text: the skip-gram model, the continuous bag-of-words model, and the distributed representation of sentences. Event detection is based on the Fuzzy Fingerprint method and trained on the ACE 2005 Corpus.

To evaluate this multi-document summarization framework, we used two different setups: an automatic evaluation of the effectiveness of the summaries using ROUGE-1, and a user study. Our experiments showed that the use of event information combined with a distributed text representation (th SKIP model) further improved a generic multi-document summarization approach above state-of-the-art. Although we propose two different strategies for developing our multi-document methods, single-layer and waterfall, the best results were not achieved by the same architecture in the evaluation datasets because waterfall approach seems to be preferable to summarize large number of documents (e.g., 25 documents) and the single-layer seems more suitable for small number of documents (e.g., 10 documents). We confirmed this tendency by reducing the documents per topic to 10 in DUC 2007 and experimenting with waterfall and single-layer architectures. Both architectures achieved better results than the baseline and the reference systems. Analysis of the results also suggests that the waterfall model offers the best trade-off between performance and redundancy.

A possible future research direction is the compression of the sentences selected by our extractive summarizer. The process of compressing sentences should use event information to delete irrelevant words and to shorten long phrases. A solution to adequately compress sentences using event information entails solving multiple sub-problems. For example, the identification of the relation between named entities (relationship extraction), identification of sentences mentioning the same event (event co-reference), and extract when the events take place (temporal information extraction), among other problems.
