July 5, 2019

Abstract

Expansion testing aims to decide whether an $n$-node graph has expansion at least $\Phi$, or is far from any such graph. We propose a quantum expansion tester with complexity $\tilde{O}(n^{1/3}\Phi^{-1})$. This accelerates the $\tilde{O}(n^{1/2}\Phi^{-2})$ classical tester by Goldreich and Ron [Algorithmica ’02], and combines the $\tilde{O}(n^{1/3}\Phi^{-2})$ and $\tilde{O}(n^{1/2}\Phi^{-1})$ quantum speedups by Ambainis, Childs and Liu [RANDOM ’11] and Apers and Sarlette [QIC ’19], respectively. The latter approach builds on a quantum fast-forwarding scheme, which we improve upon by initially growing a seed set in the graph. To grow this seed set we borrow a so-called evolving set process from the graph clustering literature, which allows to grow an appropriately local seed set.
1 Introduction and Summary

The (vertex) expansion of a graph is a measure for how well connected the graph is. For an undirected graph \( G = (V, E) \), with \(|V| = n\) and \(|E| = m\), it is defined as

\[
\Phi(G) = \min_{S \subseteq V: |S| \leq n/2} \frac{\partial S}{|S|},
\]

where \( \partial S \) is the set of nodes in \( V \setminus S \) that have an edge going to \( S \). See [LR99] for a discussion on the relevance of expansion for a range of graph approximation algorithms, and [HLW06] for a survey on expander graphs and their applications. Since exactly determining \( \Phi(G) \) is an NP-hard problem [LRV13], we consider the relaxed objective of testing the expansion. Goldreich and Ron [GR02, GR11] initially studied this problem in the bounded-degree model, where they proposed the following question: given query access to \( G \), does it have expansion at least some \( \Phi \), or is it far from any graph having expansion \( \tilde{\Omega}(\Phi^2) \)? In this model, given graphs \( G \) and \( G' \) with degree bound \( d \), \( G \) is \( \epsilon \)-far from \( G' \) if at least \( \epsilon nd \) edges have to be added or removed from \( G \) to obtain \( G' \). They proved an \( \Omega(n^{1/2}) \) lower bound on the query complexity of this problem, and proposed an elegant tester based on random walk collision counting with query complexity\(^1\)

\[
\tilde{O}(n^{1/2} \Phi^{-2}).
\]

In rough strokes, the algorithm picks a uniformly random node, and counts collisions between \( \tilde{O}(n^{1/2}) \) independent random walks of length \( \tilde{O}(\Phi^{-2}) \) all starting from this node. If the graph is far from being an expander, then the random walk will get stuck in certain low-expansion subsets, leading to an increased number of collisions. The graph is hence rejected if the number of collisions exceeds some constant.

Figure 1: The GR tester counts collisions between independent random walks starting from some seed node. Low expansion of the graph results in an increased number of collisions.

Goldreich and Ron had to base the correctness of their tester on some unproven combinatorial conjecture. However, in later works by Czemaj and Sohler [CS10], Kale and Seshadri [KS11] and Nachmias and Shapira [NS10] the correctness was unconditionally established. The ideas underlying this tester and its analysis were more recently extended towards testing the \( k \)-clusterability of a graph [CPS15, CKK+18], which is a multipartite generalization of the expansion testing problem.

In this work we consider the expansion testing problem in the quantum setting, where we allow to perform queries in superposition. We refer to the nice survey by Montanaro and de Wolf [MdW16] for a general overview of quantum property testing. Ambainis, Childs and Liu [ACL11] were the first to describe a quantum algorithm for expansion testing. The gist of their algorithm is to combine an appropriate derandomization of the GR tester with Ambainis’ quantum algorithm for element distinctness [Amb07]. The latter allows to count collisions among the set of \( \tilde{O}(n^{1/2}) \) random walk

\(^1\)In this section we hide polynomial dependencies on \( \log n \), the degree bound \( d_M \) of the graph, and the distance parameter \( \epsilon \). In the rest of the paper, \( \tilde{O} \) simply hides any poly-logarithmic dependencies.
endpoints using only $\tilde{O}(n^{1/3})$ quantum queries. The improved query complexity of their quantum expansion tester is

$$\tilde{O}(n^{1/3} \Phi^{-2}).$$

In addition they proved an $\tilde{\Omega}(n^{1/4})$ lower bound on the quantum query complexity.

In later work of the current author together with Sarlette [AS19], as well as in the current work, a very different approach is taken. Quantum walks, which form the quantum counterpart of random walks, are used to explore the graph. Rather than picking random neighbors, a quantum walk explores a graph through quantum queries to its neighborhood. In particular, this allows to create a “quantum sample” that appropriately encodes the random walk distribution. As we detail in Section 1.1 below, we can then use standard tools from quantum algorithms to estimate the random walk collision probability. In [AS19] we introduced a new quantum walk technique called “quantum fast-forwarding” (QFF) that allows to approximately prepare these quantum samples in the square root of the random walk runtime. This yielded a new quantum expansion tester with query complexity

$$\tilde{O}(n^{1/2} \Phi^{-1}),$$

quadratically improving the dependency of the GR tester on $\Phi$, which corresponds to the random walk runtime. Up to this work, this left the problem of quantum expansion testing with two different testers with a complementary speedup. In this work, however, we present a new quantum tester which closes this gap. Essentially we improve the QFF tester from [AS19] by initially doing some classical work in the graph: from the initial node $v$, we first grow a local node subset or “seed set” of size $n^{1/3}$. In earlier work by the author [A19] it was already shown that such seed sets allow to more efficiently create quantum samples, essentially by improving the projection of the initial state on the final quantum sample. Indeed, starting from this seed set, rather than directly from $v$, we can run the QFF tester with an improved query complexity $\tilde{O}(n^{1/3} \Phi^{-1})$. To prove correctness of the tester, we must ensure that if the initial node $v$ is inside some low-expansion set, then the seed set largely remains inside that set. Thereto we borrow a so-called “evolving set process” from the local graph clustering literature [AGPT16], allowing to grow such a set in complexity $\tilde{O}(n^{1/3} \Phi^{-1})$. This allows to prove our main result:

**Theorem 1.** There exists a quantum expansion tester with query complexity $\tilde{O}(n^{1/3} \Phi^{-1})$.

The resulting speedup combines those of [ACL11] and [AS19]. To summarize, we gather the different algorithms and approaches in Table 1.
1.1 QFF Tester

Our tester builds on the QFF tester from [AS19], hence we describe this tester first. Let $P$ denote the random walk (RW) transition matrix, and $P^t|v\rangle$ the $t$-step RW probability distribution\(^2\) starting from a node $v$. The tester builds on the observation that the squared 2-norm $\|P^t|v\rangle\|^2$ exactly equals the collision probability of a pair of random walks:

$$\|P^t|v\rangle\|^2 = \sum_{u \in V} P^t(u, v)^2 = \sum_{u \in V} P(X_t = u \mid X_0 = v)^2,$$

where we let $X_t$ denote the random walk position at time step $t$. Hence, we can estimate the collision probability between the $t$-step RW endpoints simply by estimating $\|P^t|v\rangle\|^2$. This we can do rather straightforwardly using quantum algorithms, in particular making use of quantum walks (QWs). Starting from an initial node $v$ of the graph, a QW allows to generate the quantum sample

$$|\psi_t\rangle = P^t|v\rangle + |\Gamma\rangle,$$

which encodes the RW probability distribution $P^t|v\rangle$ as one of its component, with $|\Gamma\rangle$ some auxiliary garbage component that is orthogonal to the RW component, and which we will not care about. Given the ability to generate such quantum samples, we can then use a standard quantum routine called quantum amplitude estimation to estimate the norm $\|P^t|v\rangle\|^2$ of the RW component. Now, similarly to the GR tester, if we set $t \in O(\Phi^{-2})$ then we can reject the graph if $\|P^t|v\rangle\|^2$, and hence the collision probability, is larger than some threshold.

The amplitude estimation routine requires $\tilde{O}(\|P^t|v\rangle\|^{-1})$ quantum samples, so that the complexity of this quantum expansion tester is $\tilde{O}(\|P^t|v\rangle\|^{-1} QS_t)$, where $QS_t$ denotes the quantum query complexity of creating the quantum sample $|\psi_t\rangle$. If the graph is regular\(^3\) then $P$ has a uniform stationary distribution, i.e., the vector $|\pi\rangle = n^{-1/2} \sum_{u \in V} |u\rangle$ is the unique eigenvalue-1 eigenvector of $P$. This allows to bound

$$\|P^t|v\rangle\| \geq |\langle \pi | v \rangle| = n^{-1/2}, \tag{1}$$

so that $\tilde{O}(\|P^t|v\rangle\|^{-1} QS_t) \in \tilde{O}(n^{1/2} QS_t)$. In order to bound $QS_t$, we can use an existing QW approach by Watrous [Wat01] which gives $QS_t \in O(t)$. Since we choose $t \in \tilde{O}(\Phi^{-2})$, this yields a quantum query complexity $\tilde{O}(n^{1/2} \Phi^{-2})$, thus giving no speedup with respect to the GR tester. In [AS19] however, we introduced a more involved QW technique called quantum fast-forwarding (QFF). Building on a Chebyshev truncation of the $P^t$ operator, this technique allows to quadratically improve the complexity to $QS_t \in O(t^{1/2})$, resulting in a quantum query complexity

$$\tilde{O}(n^{1/2} \Phi^{-1}).$$

Given that the GR tester has complexity $\tilde{O}(n^{1/2} \Phi^{-2})$, this yields a complementary speedup to the $\tilde{O}(n^{1/3} \Phi^{-2})$ expansion tester in [ACL11]. Whereas their speedup follows from a quantum routine for accelerating the collision counting procedure, the speedup in the QFF tester follows from accelerating the random walk runtime.

1.2 QFF Tester with Seed Sets

In this paper we refine the QFF tester, improving its complexity to $\tilde{O}(n^{1/3} \Phi^{-1})$. We improve its suboptimal $n^{1/2}$-dependency by initially constructing or “growing” a seed set around the initial node, from which we then run the QFF tester. This idea is derived from earlier work of the author [A19].

\(^2\)We use the ket-notation $|v\rangle$ to simply denote the indicator vector on node $v$.

\(^3\)Later on we adapt the graph to ensure this.
where seed sets are used to create a superposition over the edges of a graph, leading to a similar speedup. The main insight is derived from the bound in (1), showing that the suboptimal $n^{1/2}$-dependency stems from a small projection of the initial state $|v\rangle$ onto the uniform superposition $|\pi\rangle$. Growing a seed set allows to improve this dependency: if we grow a set $S \subseteq V$ from $v$, and we use the quantum superposition $|S\rangle = |S\rangle^{-1/2} \sum_{u \in S} |u\rangle$ as an initial state, this bound becomes

$$\|P^t|S\rangle\| \geq |\langle \pi |S\rangle| = |S|^{1/2}n^{-1/2}.$$

This suggests the following new tester: (i) pick a uniformly random node $v$, (ii) grow a seed set $S$ from $v$ of appropriate size, and (iii) create $\tilde{O}(n^{1/2}|S|^{-1/2})$ QW samples $|\psi_t\rangle = P^t|S\rangle + |\Gamma\rangle$, allowing to estimate $\|P^t|S\rangle\|$. Assuming that the construction of $S$ requires $|S|$ queries, and momentarily ignoring the $\Phi$-dependency, this tester has a combined complexity of $\tilde{O}(|S| + \|P^t|S\rangle\|^{-1}) = \tilde{O}(|S| + n^{1/2}|S|^{-1/2})$. If we choose $|S| = n^{1/3}$, this becomes $\tilde{O}(n^{1/3})$ as we aimed for.

Using a similar reasoning as before, we again wish to reject the graph if our estimate is larger than some threshold. Indeed, as depicted in Figure 2, if the seed set is localized in some low-expansion set, then the 2-norm $\|P^t|S\rangle\|$ will be larger than when the graph has no low-expansion sets. The difficulty however is to ensure that the seed set $S$, when grown from some initial node $v$ in a low-expansion set, effectively remains inside that set. If this is not the case, then a RW from $S$ will no longer be stuck in the low-expansion set, thus no longer giving rise to an increased 2-norm. As a consequence, we cannot simply use a breadth-first search from $v$, as we did in [A19]: a BFS might exit a low-expansion set more easily than a random walk. Luckily, however, the problem of locally exploring a low-expansion set (or “cluster”) turns out to be well-studied under the name “local graph clustering” [ST13, ACL06, AGPT16, OSV12].

![Figure 2: The new tester classically grows an appropriately local seed set around the initial node. From this set a quantum sample can be generated more efficiently. We use an evolving set process to ensure that the seed set mostly remains inside the initial low-expansion set.](image)

In particular, we can use a so-called “evolving set process” (ESP) as used by Andersen, Oveis-Gharan, Peres and Trevisan in [AGPT16]. An ESP is a Markov chain on subsets of the nodes, which evolves by expanding or contracting its boundary based on the RW behavior on the graph. Given an initial node $v$ inside a low-expansion set, they simulate an ESP to explicitly retrieve this set. Since we are interested in growing a potentially much smaller seed set $S$ inside the cluster, we slightly adapt their algorithm, leading to the following result. The algorithm either returns a low-expansion set, allowing to immediately reject the graph, or it returns an appropriate seed set.

**Proposition 1.** Fix a parameter $M \geq 0$. Given a random node $v$ from a set $S'$ of expansion $\tilde{O}(\Phi^2)$, we can use an ESP to return a set $S$ such that with constant probability either $\Phi(S) < \Phi$ or $|S| \geq M$ and $|S \cap S'|/|S| \in \Omega(1)$. The complexity of generating this set is $\tilde{O}(M\Phi^{-1})$.

Building on this tool, we can now sketch our new quantum tester, summarized in Algorithm 1. Since the ESP process requires $\tilde{O}(n^{1/3}\Phi^{-1})$ steps by the above proposition, and estimating $\|P^t|S\rangle\|$ requires $\tilde{O}(\|P^t|S\rangle\|\Phi^{-1}) \in \tilde{O}(n^{1/3}\Phi^{-1})$ steps, we retrieve the promised tester complexity $\tilde{O}(n^{1/3}\Phi^{-1})$. 

4
Algorithm 1 Quantum Expansion Tester

Do:
1: select a uniformly random starting node $v$
2: grow a seed set $S$ from $v$ using an ESP
3: if $\Phi(S) < \Phi$ then reject
4: use quantum amplitude estimation to estimate $\|P^t|S\rangle\|$ for $t \in \tilde{O}(\Phi^{-1})$
5: if $\|P^t|S\rangle\|$ too large then reject else accept

1.3 Open Questions

We finish this section by discussing some open questions related to this work.

- In [A19] a breadth-first search is used to grow a seed set $S$, requiring a number of steps $\tilde{O}(|S|)$. In the current work we use a more refined ESP algorithm to grow $S$, which in particular ensures that the set remains inside some low-expansion subset (say with expansion at most $\Phi$). This procedure however requires an increased number of steps $\tilde{O}(|S|\Phi^{-1})$. We leave it as an open question whether such an appropriate set can be grown in $\tilde{O}(|S|)$ steps. The query complexity of the tester then becomes $\tilde{O}(|S| + n^{1/2}|S|^{-1/2}\Phi^{-1})$. Setting $|S| = n^{1/3}\Phi^{-2/3}$ this would lead to an improved complexity $\tilde{O}(n^{1/3}\Phi^{-2/3})$.

- The use of an ESP for the expansion testing problem could also be useful for improving the $\Phi$-dependency of the classical GR tester. If we could for instance grow a pair of seed sets, both of size $n^{1/2}$, that behave to some extent as “random subsets” of a local cluster, then we could simply count collisions between these sets, thus avoiding the use of random walks. A higher number of collisions would then again signal a low expansion of the graph. Ideally an ESP-like procedure would allow to grow these sets in $\tilde{O}(n^{1/2}\Phi^{-1})$ steps, improving on the $\tilde{O}(n^{1/2}\Phi^{-2})$ complexity of the GR tester.

- Clusterability testing, as recently studied in [CPS15, CKK+18], uses very similar techniques to the GR expansion tester. It seems feasible that we can use the techniques from this paper to similarly improve on these testers.

- Goldreich and Ron [GR02] proved a classical lower bound $\Omega(n^{1/2})$ for expansion testing, suggesting that their tester has an optimal dependency on $n$. In the quantum setting however, the only known lower bound is $\Omega(n^{1/4})$ as proven by Ambainis, Childs and Liu [ACL11], thus leaving a large gap to all current quantum testers, which have a $\tilde{O}(n^{1/3})$-dependency. While our work does not provide any new insights towards closing this gap, we do feel that this is an interesting question to resolve.

2 Preliminaries

In this section we formalize the query model and the definition of an expansion tester. We also describe some necessary random walk properties, and define the notion of a quantum walk.

2.1 Query and Property Testing Model

We are given query access to some undirected graph $G = (\mathcal{V}, \mathcal{E})$, with node set $\mathcal{V} = [n]$ and edge set $\mathcal{E}$. We denote $|\mathcal{E}| = m$. For any $v \in \mathcal{V}$, we let $d(v)$ denote the degree of $v$, the maximum degree $d_M = \max_{v \in \mathcal{V}} d(v)$, and $d(S) = \sum_{v \in S} d(v)$ denotes the total degree of a set $S \subseteq \mathcal{V}$. We say that $G$ has degree bound $d$ if $d_M \leq d$. In the context of property testing of bounded-degree graphs [GR02], the following queries are allowed:
• **uniform node query**: return uniformly random node \( v \in V \)

• **degree query**: given \( v \in V \), return degree \( d(v) \)

• **neighbor query**: given \( v \in V \), \( k \in [d(v)] \), return \( k \)-th neighbor of \( v \)

Throughout the paper we will assume that \( G \) is regular. If this is not the case, then we can always modify the graph to ensure this: to any node \( i \) with degree \( d(i) < d \) we add \( d - d(i) \) parallel self loops. This effectively renders the graph regular, ensuring that a random walk converges to the uniform distribution, as we will require later. Notably this does not change the expansion of the graph. Goldreich and Ron [GR11] achieve the same effect by modifying the random walk rather than the graph, but modifying the graph will prove more elegant for our purpose.

Since we wish to study quantum algorithms, we will allow to perform degree and neighbor queries in superposition. To illustrate this, assume that a neighbor query, given \( v \in V \) and \( k \in [d(v)] \), returns a node \( u \). Using quantum notation, this is described as a unitary transformation

\[
|v⟩|k⟩|x⟩ \mapsto |v⟩|k⟩|x + u⟩,
\]

where \( x \) is some arbitrary \( [\log n] \)-bit string, and “+” denotes addition modulo \( [\log n] \). We can now imagine the first register being in a superposition \( d(v)^{-1/2} \sum_{k \in [d(v)]} |v⟩|k⟩|x⟩ \), so that the query operation now becomes

\[
\frac{1}{\sqrt{d(v)}} \sum_{i \in [d(v)]} |v⟩|k⟩|x⟩ \mapsto \frac{1}{\sqrt{d(v)}} \sum_{i \in [d(v)]} |v⟩|k⟩|x + u^{(k)}⟩,
\]

where we let \( u^{(k)} \) denote the \( k \)-th neighbor of \( v \). We will call a single such query a “quantum query”. We refer the interested reader to the survey by Montanaro and de Wolf [MdW16] for more details on the quantum query model.

We will follow the property testing model for bounded-degree graphs by Goldreich and Ron [GR02]. Given two \( n \)-node graphs \( G = ([n], \mathcal{E}) \) and \( G' = ([n], \mathcal{E}') \) with degree bound \( d \), they define the relative distance between \( G \) and \( G' \) as the number of edges that needs to be added or removed to turn \( G \) into \( G' \), divided by the maximum number of edges \( nd \). This is equal to \( |\mathcal{E} \triangle \mathcal{E}'|/(nd) \), with \( \triangle \) the symmetric difference between \( \mathcal{E} \) and \( \mathcal{E}' \). \( G \) is then said to be \( \epsilon \)-far from \( G' \) if \( |\mathcal{E} \triangle \mathcal{E}'|/(nd) \geq \epsilon \). When studying a certain property \( P \) of graphs, \( G \) is said to be “\( \epsilon \)-far from having property \( P \)” if \( G \) is \( \epsilon \)-far from any graph \( G' \) having property \( P \).

### 2.2 Expansion Testing

We define the (vertex) expansion of a subset \( S \subset V \) as

\[
\Phi(S) = \frac{|\partial S|}{|S|}.
\]

Here \( \partial S = \{ u \in S^c \mid \exists v \in S \text{ s.t. } (u, v) \in \mathcal{E} \} \) is the set of nodes in \( S^c \) that have an edge going to \( S \). The expansion of a graph \( G \) is then defined as

\[
\Phi(G) = \min_{S \subset V: |S| \leq n/2} \Phi(S).
\]

We consider the following definition of an expansion tester due to Czumaj and Sohler [CS10].

**Definition 1.** An algorithm is a \((\Phi, \epsilon)\)-expansion tester if there exists a constant \( c > 0 \), possibly dependent on \( d \), such that given parameters \( n, d \), and query access to an \( n \)-node graph with degree bound \( d \) it holds that
• if the graph has expansion at least $\Phi$, then the algorithm outputs “accept” with probability at least $2/3$,
• if the graph is $\epsilon$-far from any graph having expansion at least $c\Phi^2 \log^{-1}(dn)$, then the algorithm outputs “reject” with probability at least $2/3$.

We note that this is a slightly more constrained definition than the one in e.g. [KS11, ACL11, AS19]. In these works the log-factor in the reject case is actually left as an additional free parameter $\mu$. We also mention that in the traditional setting of property testing, the expression “$c\Phi^2 \log^{-1}(dn)$” in the second bullet should be replaced by “$\Phi$”. Although unproven, the relaxation in this definition seems necessary to allow for efficient (sublinear) testing.

Apart from the vertex expansion, we also define the conductance. When studying random walks, this is often a slightly more appropriate measure. For a subset $S \subset V$ it is defined as

$$\phi(S) = |\mathcal{E}(S, S^c)|/d(S),$$

where $\mathcal{E}(S, S^c) = \{(u, v) \in \mathcal{E} \mid u \in S, v \in S^c\}$ denotes the set of edges between $S$ to $S^c$. The conductance of a graph $G$ with $m$ edges is then defined as $\phi(G) = \min_{S \subset V : d(S) \leq m/2} \phi(S)$. If $G$ is $d$-regular, as we will assume throughout the paper, this simplifies to $\phi(G) = \min_{S \subset V : |S| \leq n/2} |\mathcal{E}(S, S^c)|/(d|S|)$. Since $|\partial S| \leq |\mathcal{E}(S, S^c)| \leq d|\partial S|$, this allows to relate vertex expansion and conductance as follows:

$$\Phi(S)/d \leq \phi(S) \leq \Phi(S). \quad (3)$$

2.3 Random Walks

We will consider lazy random walks (RWs), described by a Markov chain on the node set. From any node the RW jumps with probability $1/2$ to any of its neighbors uniformly at random, and otherwise stands still. If we let $P(u, v)$ denote the RW transition probability from node $v$ to node $u$, then

$$P(u, v) = \begin{cases} 
1/(2d(v)) & (v, u) \in E \\
1/2 & u = v \\
0 & \text{elsewhere}. 
\end{cases}$$

If the underlying graph is connected, then the RW converges to a unique limit distribution in which every node has a probability proportional to its degree. On a regular graph, this corresponds to a uniform distribution.

2.3.1 Diffusion Core

Central to the study of expansion testers is the so-called “diffusion core” of a set $S \subseteq V$. The diffusion core allows to lower bound the probability that a RW of given length stays entirely inside $S$, as a function of its conductance $\phi(S)$. Let $\tau_v(S^c)$ denote the escape time of $S$ from $v$, i.e., the hitting time of a RW from $v \in S$ to the complement $S^c$. We then define the diffusion core of $S$ as follows:

**Definition 2.** For $\alpha, \beta > 0$, the $(\alpha, \beta)$-diffusion core of $S$ is defined as

$$S_{\alpha,\beta} = \{v \in S \mid P(\tau_v(S^c)) > \alpha \phi(S)^{-1} \geq \beta\}. \quad (4)$$

Throughout we define the “canonical” diffusion core $S_d = S_{1/2,1/2}$. Using a reasoning similar to Spielman and Teng [ST13], we can lower bound the size of the diffusion core.
Lemma 1.\[
\frac{d(S_{\alpha,\beta})}{d(S)} > 1 - \frac{\alpha}{2(1-\beta)}.
\]

Proof. Let $Y_v$ denote the event that $\tau_v(S^c) > \alpha \phi^{-1}$, let $\pi$ denote the stationary distribution of the RW, and let $\pi_S$ denote the distribution $\pi$ conditioned on being in the set $S$: $\pi_S(v) = \mathbb{I}(v \in S)\pi(v)/\pi(S)$. From [ST04, Proposition 2.5] we know that
\[
\mathbb{P}_{v \sim \pi_S}(Y_v) \geq 1 - \alpha/2.
\]

For all $v \notin S_{\alpha,\beta}$, it holds by definition that $\mathbb{P}(Y_v) < \beta$, so that we can bound
\[
\mathbb{P}_{v \sim \pi_S}(Y) = \sum_{v \in S} \mathbb{P}(v \sim \pi_S(v)) < (1 - \pi_S(S_{\alpha,\beta}))\beta + \pi_S(S_{\alpha,\beta}).
\]

Combined with the former inequality, and the fact that $\pi_S(S_{\alpha,\beta}) = d(S_{\alpha,\beta})/d(S)$, this proves the claimed statement. \qed

As we will require this later, we also wish to prove something slightly stronger: there exists a subset $S'$ of the diffusion core $S_d$, from which we can bound the probability that a random walk stays inside the diffusion core, rather than only inside $S$.

Lemma 2. There exists a node subset $S'$ of the diffusion core $S_d$, with $d(S') > d(S)/6$, from which a $(8\Phi(S))^{-1}$-step RW remains inside $S_d$ with probability at least $1/4$:
\[
\forall v \in S': \quad \mathbb{P}(\tau_v(S^c_d) > (8\Phi(S))^{-1}) \geq 1/4.
\]

Proof. In the following we use the shorthand $\phi = \phi(S)$. We can set $S'$ equal to the $(5/8, 5/8)$-diffusion core, $S' = S_{5/8, 5/8}$. From inequality (4) we see that $S' \subseteq S_d \subseteq S$. From Lemma 1 we know that $d(S') > d(S)/6$.

We will show that $S'$ serves as a sort of diffusion core for $S_d$. Thereto fix any $v \in S'$ and let $\kappa$ denote the hitting time $\kappa = \tau_v(S^c_d)$. Then we define $t$ such that
\[
\mathbb{P}(\kappa \leq t) > \frac{3}{4}.
\]

(5)

Now let $Y$ be the event that $\kappa \leq t$ and $\tau_u(S^c) \leq (2\phi)^{-1}$, with $u = X_\kappa$ a random variable corresponding to the node at which the RW hits $S^c_d$. Then we have that $Y \Rightarrow (\tau_v(S^c) \leq t + (2\phi)^{-1})$. Since $u \notin S_d$, it holds that $\mathbb{P}(\tau_u(S^c) \leq (2\phi)^{-1}) > 1/2$. Combined with (5) this allows to bound $\mathbb{P}(Y) > (3/4)(1/2) = 3/8$, and therefore $\mathbb{P}(\tau_v(S^c) \leq t + (2\phi)^{-1}) > 3/8$. However, since $v \in S'$ we also have that $\mathbb{P}(\tau_v(S^c) > 5/(8\phi)) \geq 5/8$, or equivalently $\mathbb{P}(\tau_v(S^c) \leq 5/(8\phi)) \leq 3/8$. This gives a contradiction if $t + (2\phi)^{-1} \leq 5/(8\phi)$, such that necessarily $t > 1/(8\phi)$. On its turn, this implies that $\mathbb{P}(\kappa \leq (8\phi)^{-1}) \leq 3/4$ for all $v \in S'$, which proves the claimed statement. \qed

We will also use the following lemma, which in essence was already present in [CS10, NS10, KS11]. It argues that a graph which is $\epsilon$-far from having a certain expansion must have a large subset with low expansion.

Lemma 3. Let $G$ be an undirected $n$-node graph with degree bound $d$ that is $\epsilon$-far from having expansion $\geq \beta$, with $\beta \leq 1/10$. Then the following holds:

- There exists a subset $A \subseteq V$, with $cn/4 \leq |A| \leq (1+\epsilon)n/2$, such that $\Phi(A) < r_d \beta$, with $r_d$ a constant dependent on $d$. 

8
• For any $t \leq 1/(2r_d\beta)$ and distribution $v$ having a $\gamma$-overlap with the diffusion core of $A$, it holds that

$$\|P^tv\| \geq n^{-1/2}\left(1 + \frac{\gamma}{2}\left(\sqrt{\frac{2}{1+\epsilon}} - 1\right)\right).$$

**Proof.** The first bullet is proven in [CS10, Corollary 4.6]. The second follows by rewriting $P^tv$ as $\mu w_A + (1 - \mu)w_{A^c}$, with $\mu \geq 0$, where $w_A$ and $w_{A^c}$ correspond to $P^tv$ conditioned on being in $A$ resp. $A^c$. We can then bound

$$\|P^tv\| = \mu\|w_A\| + (1 - \mu)\|w_{A^c}\| \geq \mu|A|^{-1/2} + (1 - \mu)n^{-1/2} \geq n^{-1/2}\left(1 + \mu\left(\sqrt{\frac{2}{1+\epsilon}} - 1\right)\right),$$

where we first used the standard bound $\|w\| \geq \sup(w)^{-1/2}\|w\|_1$ which follows from the Cauchy-Schwarz inequality, and then the first bullet stating that $|A| \leq (1 + \epsilon)n/2$.

To bound the parameter $\mu$, note that $\mu = (P^tv)(A)$, so that this represents the probability that $t$ steps of the RW from $v$ end in $A$. By definition of the diffusion core, we know that a $(t \leq 1/(2\Phi(A)))$-step RW, starting anywhere in $A_d$, remains inside $A$ with probability at least $1/2$. Since $v$ has a $\gamma$-overlap with $A_d$, this proves that the $(t \leq 1/(2r_d\beta))$-step RW from $v$ remains inside $A$ with probability at least $\gamma/2$, and hence $\mu \geq \gamma/2$. \qed

### 2.4 Quantum Walks

Quantum walks (QWs) form an elegant quantum counterpart to random walks on graphs. They similarly explore a graph in a local manner, by performing queries in superposition to the neighbors of certain nodes, as illustrated in (2) in Section 2.1. In particular, starting from some node state $|v\rangle$, QWs allow to create a quantum state or “quantum sample” of the form

$$|\psi_t\rangle = P^t|v\rangle + |\Gamma\rangle,$$

where we recall that $P$ is the lazy RW transition matrix. Here the first component forms a quantum encoding of the RW probability distribution, whereas the second component denotes some auxiliary garbage state in which we will not be interested. In our earlier work on quantum expansion testing, we introduced a QW technique called “quantum fast-forwarding” (QFF) that allows to create the above quantum sample in the square root of the classical runtime. We extract the following lemmas from [AS19], recalling that $d_M$ denotes the maximum degree of the graph.

**Lemma 4 (QFF).** There exists a QW algorithm to create the quantum sample $|\psi_t\rangle$ using $\tilde{O}(t^{1/2}d_M^{1/2})$ queries.

Given access to such quantum samples, we can use a standard quantum routine called “quantum amplitude estimation” to estimate $\|P^t|v\rangle\|$. This leads to the following lemma, which is an immediate corollary from [AS19, Theorem 5].

**Lemma 5 (2-norm estimator).** There exists a QW algorithm that, with probability at least $1 - \delta$, outputs an estimate $a$ such that $\|P^t|v\rangle\| - a \leq \epsilon$. The algorithm uses $\tilde{O}(\epsilon^{-1}\log\delta^{-1})$ quantum samples, or $\tilde{O}(t^{1/2}d_M^{1/2}\epsilon^{-1}\log\delta^{-1})$ queries by Lemma 4.

Differently from [AS19], we will start from an initial seed set $S \subseteq V$ rather than from a single node $v$. If we let $|S| = |S|^{-1/2}\sum_{u \in S}|u\rangle$, then we will be interested in estimating $\|P^t|S\rangle\|$. Using standard quantum tools, the above results directly carry over to this more general setting, provided that we can efficiently perform a “quantum reflection” around the state $|S\rangle$. Making use of the data structure discussed in [A19, Section 3.2], we can indeed do so in $\tilde{O}(1)$ steps.
3 Evolving Sets Processes

Evolving Set Processes (ESPs) have been used for analyzing the mixing time of Markov chains [MP05], and as an algorithmic tool for performing local graph clustering [AP09, AGPT16]. Derived from some original Markov chain over a node set $\mathcal{V}$, an ESP is a Markov chain over subsets of the node set. For our particular case we will assume that the original Markov chain corresponds to the (lazy) RW. Given that the current state of the ESP is $S \subseteq \mathcal{V}$, its next state is then determined by the following rule: draw a variable $U$ uniformly at random from the interval $[0,1]$, and set the next state $S' = \{ v \in \mathcal{V} : P(S,v) \geq U \}$.

Here $P(S,v)$ denotes the probability that a single RW step from $v$ ends up in $S$, and is given by $P(v,S) = |\mathcal{E}(v,S)|/(2d(v)) + \mathbb{I}(v \in S)/2$. This gives rise to an ESP transition matrix $K : 2^\mathcal{V} \times 2^\mathcal{V} \rightarrow [0,1]$. Notice that only states in the inner or outer boundary of $S$ can be added or removed: $|\mathcal{E}(v,S)| = d(v)$ and $\mathbb{I}(v \in S) = 1$ if $y$ and all of its neighbors lie in $S$, whereas $|\mathcal{E}(v,S)| = \mathbb{I}(v \in S) = 0$ if $v$ nor any of its neighbors lie in $S$. This process has absorbing states $S = \emptyset$ and $S = \mathcal{V}$, both of which have no boundary. For algorithmic purposes, it is desirable to prevent the ESP from being absorbed in the empty set. To this end, the transition probabilities can be slightly altered:

$$\hat{K}(S,S') = \frac{d(S')}{d(S)} K(S,S').$$

Clearly the transition probability to the empty set is now equal to zero. $\hat{K}$ is again a stochastic transition matrix, and the resulting process is called the volume-biased ESP (yet for brevity we will simply refer to it as the ESP). We refer the reader to [AGPT16, LPW17] for more details on the ESP and its volume-biased variant.

Starting from some low-expansion set $S$, ESPs are used as a means of locally constructing or exploring $S$. In our case, we only wish to retrieve a smaller subset, typically of size $|S|^{1/3}$. This subset however should be sufficiently localized “inside” $S$, i.e., have a sufficient overlap with the smaller diffusion core of $S$. To this end we refine the ESP analysis: we use our Lemma 2 to show that also the ESP will remain in the diffusion core with large probability. The following Section 3.1 introduces some useful properties of the ESP, and in Section 3.2 we prove the main tool.

3.1 ESP Complexity and Properties

As we wish to use an ESP as an algorithmic means, it is desirable to quantify the resources needed to simulate it. Thereto we define the cost of a sample path

$$\text{cost}(S_0, \ldots, S_t) = d(S_0) + \sum_{i=1}^t \left( d(S_i \Delta S_{i-1}) + |\partial(S_{i-1})| \right),$$

with $d(S)$ the total degree of a subset $S$ and $S \Delta S'$ the symmetric difference between $S$ and $S'$. We also define a stopping time $\tau(T,B,\theta)$ for the ESP:

**Definition 3.** The stopping time $\tau(T,B,\theta)$ is a random variable that equals the first time $\tau$ at which any of the following holds:

(i) $\phi(S_\tau) \leq \theta$,  
(ii) $\tau = T$,  
(iii) $\text{cost}_\tau > B$.

The following theorem from [AGPT16] bounds the complexity of sampling from the ESP with stopping rule $\tau(T,B,\theta)$.
Theorem 2 ([AGPT16]). There exists an algorithm that takes as input a node \( v \), two integers \( T, B \geq 0 \) and \( \theta \in [0,1] \). Let \( S_0 = \{v\} \) and define the stopping time \( \tau = \tau(T, B, \theta) \). The algorithm generates a sample path \((S_0, \ldots, S_{\tau})\) of the ESP and outputs the last set \( S_{\tau} \). The runtime and query complexity of the algorithm is \( O(B \log m) \).

We will use several properties that can be attributed to the output set:

- **Size**: The cost of simulating the process is related to the size of the output set.
  
  **Lemma 6 ([AGPT16, Theorem 5.4]).** For any starting set \( S_0 \) and any stopping time \( \tau \) that is upper bounded by \( T \), it holds that
  
  \[ \mathbb{E}[\text{cost}_\tau/d(S_\tau)] \leq 1 + 4 \sqrt{T \log m}. \]

- **Overlap**: If a random walk has a high probability of staying inside a certain set, then with high probability the ESP will also largely remain inside that set.
  
  **Lemma 7 ([AGPT16, Lemma 4.3]).** Consider any set \( S \subseteq V \), a starting set \( S_0 = \{v\} \) for some \( v \in S \), and an integer \( T \geq 0 \). Then the following holds for all \( \beta > 0 \):
  
  \[ \mathbb{P}(\min_{t < T} d(S_t \cap S)/d(S_t) \geq 1 - \beta^{\tau_v(S^c) \leq T}) \geq 1 - 1/\beta. \]

- **Conductance**: After \( T \) steps, the ESP encounters with high probability a set of conductance \( \tilde{O}(T^{-1/2}) \).
  
  **Lemma 8 ([AP09, Corollary 1]).** Fix any integer \( T \), and let \( \theta_T = \sqrt{4T^{-1} \log m} \). For any starting set \( S_0 \) and constant \( c \geq 0 \), it holds that
  
  \[ \mathbb{P}(\min_{t < T} \phi(S_t) \leq \sqrt{c} \theta_T) \geq 1 - 1/c. \]

### 3.2 ESP for Growing Seed Set

Using the above lemmas, combined with our Lemma 2, we can prove the following theorem. This constitutes the main tool that we will use to grow seed sets.

**Theorem 3.** Fix constants \( \alpha, \beta > 0 \) and a parameter \( M \geq 0 \). Let \( S \subseteq V \) be such that

\[ \phi(S) \leq \frac{1}{32\alpha \log m}. \]

Let \( S' \subseteq S \) be as defined in Lemma 2, and assume that \( S_0 = \{v\} \) for some \( v \in S' \). Let \( S_\tau \) be the set returned by the ESP with stopping rule \( \tau(T, B, \theta) \) and parameters \( T = 4\alpha \theta^{-2} \log m \), \( B = 5\alpha M \sqrt{T \log m} \), and \( \theta = \gamma \). Then with probability at least \( 1 - 2\alpha^{-1} - \beta^{-1} \) we have that

\[ \frac{d(S_\tau \cap S_d)}{d(S_\tau)} \geq 1 - 3\beta/4, \]

and either

\[ \phi(S_\tau) \leq \gamma \quad \text{or} \quad d(S_\tau) \geq M. \]

The runtime and query complexity of generating this set is \( O(M\gamma^{-1} \log^2 m) \).
Proof. Let $X$ denote the event that $d(S_r \cup S_d)/d(S_r) \geq 1 - 3\beta/4$, and $Y$ the event that $\phi(S_r) \leq \gamma$ or $d(S_r) \geq M$. We will show that $\mathbb{P}(X) \geq 1 - \beta^{-1}$ and $\mathbb{P}(Y) \geq 1 - 2\alpha^{-1}$, so that by the union bound we find that $\mathbb{P}(X \cap Y) \geq \mathbb{P}(X) + \mathbb{P}(Y) - 1 \geq 1 - 2\alpha^{-1} - \beta^{-1}$. This proves the statements on the output set. The complexity statement follows from Theorem 2.

Towards bounding $\mathbb{P}(X)$ we combine Lemma 7 with Lemma 2. Since $v \in S'$, we know that

$$\mathbb{P}(\tau_\delta(S'_\delta) \leq (8\phi(S))^{-1}) \leq 3/4.$$ 

Our assumption on $\phi(S)$ implies that $T \leq (8\phi(S))^{-1}$, and so by Lemma 7 we get that

$$\mathbb{P}(\min_{t \leq T} d(S_r \cap S_d)/d(S_r) \geq 1 - 3\beta/4) \geq 1 - \beta^{-1}.$$ 

Since $\tau \leq T$, the left-hand side lower bounds $\mathbb{P}(X)$, so that $\mathbb{P}(X) \geq 1 - \beta^{-1}$.

Towards bounding $\mathbb{P}(Y)$, we condition it on the possible stopping rule outcomes:

$$\mathbb{P}(Y) = \mathbb{P}(Y \mid \phi(S_r) \leq \theta) \mathbb{P}(\phi(S_r) \leq \theta) + \mathbb{P}(Y \mid \text{cost}_S > B) \mathbb{P}(\text{cost}_S > B) + \mathbb{P}(Y \mid \tau = T) \mathbb{P}(\tau = T).$$

Since $\theta = \gamma$ we know that $\mathbb{P}(Y \mid \phi(S_r) \leq \theta) = 1$. Next we wish to bound the second term by using Lemma 6. In combination with Markov’s inequality this states that $\mathbb{P}(Z_\alpha) \leq 1/\alpha$, where we let $Z_\alpha$ denote the event that

$$\text{cost}_S / d(S_r) \geq \alpha(1 + 4\sqrt{T\log m}) = \alpha + 4B/(5M).$$

If we lower bound $\mathbb{P}(Z_\alpha) \geq \mathbb{P}(Z_\alpha \mid \text{cost}_S > B) \mathbb{P}(\text{cost}_S > B)$, then we find $\mathbb{P}(Z_\alpha \mid \text{cost}_S > B) \mathbb{P}(\text{cost}_S > B) \leq \alpha^{-1}$. With $\bar{Z}_\alpha$ the negation of $Z_\alpha$, this leads to the bound

$$\mathbb{P}(\bar{Z}_\alpha \mid \text{cost}_S > B) \mathbb{P}(\text{cost}_S > B) \geq \mathbb{P}(\text{cost}_S > B) - \alpha^{-1}.$$ 

Now if both cost$_S > B$ and $\bar{Z}_\alpha$ hold, then

$$d(S_r) > \frac{\text{cost}_S}{\alpha + 4B/(5M)} > \frac{B}{\alpha + 4B/(5M)} > M,$$

using the bound $B > 5\alpha M$. As a consequence, if both cost$_S > B$ and $Z_\alpha$ hold, then also $Y$ holds, and so $\mathbb{P}(Y \mid \text{cost}_S > B) \geq \mathbb{P}(Z_\alpha \mid \text{cost}_S > B)$. This gives the desired bound

$$\mathbb{P}(\text{cost}_S > B) \mathbb{P}(Y \mid \text{cost}_S > B) \geq \mathbb{P}(\text{cost}_S > B) - \alpha^{-1}.$$ 

Finally we will upper bound $\mathbb{P}(\tau = T)$ using Lemma 8. For $c = \alpha$ this states that

$$\mathbb{P}(\min_{t \leq T} \phi(S_t) \leq \gamma) \geq 1 - \alpha^{-1}.$$ 

Since $\min_{t \leq T} \phi(S_t) \leq \gamma$ implies that $\tau < T$, this shows that

$$\mathbb{P}(\tau = T) \leq 1 - \mathbb{P}(\min_{t \leq T} \phi(S_t) \leq \gamma) \leq \alpha^{-1}.$$ 

If now we combine the bounds (6) and (7) we get the final bound on $\mathbb{P}(Y)$:

$$\mathbb{P}(Y) \geq \mathbb{P}(\phi(S_r) \leq \theta) + \mathbb{P}(\text{cost}_S > B) - \alpha^{-1} \geq 1 - \mathbb{P}(\tau = T) - \alpha^{-1} \geq 1 - 2\alpha^{-1}.$$
4 Quantum Expansion Tester

We are now ready to construct our new quantum expansion tester, yielding the main contribution of this paper.

Algorithm 2 Quantum Expansion Tester

Input: parameters $n$ and $d$; query access to an $n$-node graph $G$ with degree bound $d$; expansion parameter $\Phi$; promise parameter $\epsilon$; running time parameter $\mu < 1/4$

Do:

1. set $(t, \epsilon', \delta, T, B) \in \tilde{O}(d^2 \Phi^{-2}, n^{-1/3} d^{-1}, \epsilon, \Phi d^{-1}, d^2 \Phi^{-2}, dn^{1/3} \Phi^{-1})$
2. for $K \in O(\epsilon^{-1})$ times do
3. select a uniformly random starting node $v$
4. run ESP from $S_0 = \{v\}$ with stopping rule $\tau(T, B, \theta)$, outputting $S$
5. if $|S| \leq n/2$ and $\Phi(S) \leq \Phi/2$ then abort and output “reject”
6. use 2-norm estimator to create estimate $a$ of $\|P^t|S\|$ to precision $\epsilon'$, with probability $1 - \delta$
7. if $a > \sqrt{|S| n^{-1} (1 + n^{-1})} + \epsilon'$ then abort and output “reject”

Output: if no “reject”, output “accept”

Theorem 4 (Quantum Expansion Tester). If $d \geq 3$ then Algorithm 2 is a $(\Phi, \epsilon)$ expansion tester for $c = 1/(1000 d^2 r_d)$, with $r_d$ as in Lemma 3. The runtime and number of queries of the algorithm are bounded by $\tilde{O}(n^{1/3} \Phi^{-1} d^2 \epsilon^{-1})$.

Proof. We will prove the theorem for parameters

$$t = 16d^2 \Phi^{-2} \log n, \epsilon' = n^{-1/3} \nu/4, \nu = (\sqrt{2/(1+\epsilon)} - 1)/(32d), \delta = \epsilon/3000,$$
$$K = 960/(\epsilon(1 - \delta)), \theta = \Phi/(2d), T = 1280 \Phi^{-2} d^2 \log m, B = 20^{5/2} n^{1/3} d |(2d)\Phi^{-1} \log m.$$

First we prove that if $\Phi(G) \geq \Phi$, then the algorithm accepts with probability at least $2/3$. Thereto note that by definition of the vertex expansion, necessarily $\Phi(S) \geq \Phi$ if $|S| \leq n/2$, and therefore $\Phi(S) \geq \Phi$. Hence the algorithm cannot falsely reject in step 4. To exclude rejection in step 6, we use the result in [NS10, Proof of Theorem 2.1] showing that if $\Phi(G) \geq \Phi$ then for all nodes $v \in V$ and time $t \geq 16d^2 \Phi^{-2} \log n$ it holds that

$$\|P^t|s\| \leq \sqrt{n^{-1} (1 + n^{-1})}.$$

This allows to bound

$$\|P^t|S\| \leq |S|^{-1/2} \sum_{s \in S} \|P^t|s\| \leq \sqrt{|S| n^{-1} (1 + n^{-1})}.$$

Using the 2-norm estimator from Lemma 5, the estimate $a$ will with probability $1 - \delta$ be such that

$$a \leq \sqrt{|S| n^{-1} (1 + n^{-1})} + \epsilon'.$$

Step 6 will therefore reject falsely only with probability at most $\delta$. The total probability of a faulty rejection can then be bounded by $K \delta < 1/3$. Since the algorithm accepts if it never rejects, it will correctly accept the graph with probability at least $2/3$. 

13
Next we prove that if $G$ is $\epsilon$-far from having expansion $\geq c\Phi^2 \log^{-1}(dn)$, then the algorithm rejects with probability at least $2/3$. Thereto we use Lemma 3 from Section 2.3.1, which states that in this case there exist a "bad" subset $A$, with $(1 + \epsilon)n/2 \geq |A| \geq \epsilon n/4$, such that

$$\Phi(A) < r_d c \Phi^2 \log^{-1}(dn) = \frac{1}{1000} \left(\frac{\Phi}{2d}\right)^2 \frac{1}{\log(dn)}. \quad (8)$$

From $A$, we can define the diffusion core $A_d$ and the subset $A' \subseteq A_d$ as in Lemma 2, which states that $d(A') \geq d(A)/6$. By the degree bound $d$, this implies that $|A'| \geq |A|/6(6d)$ and hence the initial node $v$ will be in $A'$ with probability at least $|A|/(6dn) \geq \epsilon/(24d)$.

Conditioning on $v \in A'$, we can analyze the ESP output set $S$ using Theorem 3. Our choice of parameters corresponds to $\alpha = 20$, $\beta = 5/4$ and $M = \lceil n^{1/3}d \rceil$. Using the bound (8), which by (3) implies the same upper bound for $\phi(A)$, $S$ will with probability at least $1/60$ be such that (i) $d(S \cap A_d) \geq d(S)/16$, and therefore $|S \cap A_d| \geq |S|/(16d)$, and (ii) either $\phi(S) \leq \Phi/(2d)$ or $d(S) \geq M$. If $\phi(S) \leq \Phi/(2d)$ and $|S| \leq \nu/2$, then we have a proof that $G$ has vertex expansion $\Phi(G) \leq \Phi/2$, and hence we reject the graph in step 5. To see this, simply note that $\phi(S) \leq \Phi/(2d)$ implies that $\Phi(S) \leq \Phi/2$ (again by (3)). In any other case, we know that $d(S) \geq M$ and hence $|S| \geq M/d$. Given such a set $S$, consider the uniform distribution $\pi_S$ over $S$. Since $|S \cap A_d| \geq |S|/(16d)$, we know that $\pi_S$ has a $(16d)^{-1}$-overlap with $A_d$. By the second bullet of Lemma 3 this implies that for all $t \leq 500d^2 \log(dn) \Phi^{-2}$,

$$\|P_t \pi_S\| \geq n^{-1/2} \left(1 + \frac{1}{32d} \left(\sqrt{\frac{2}{1 + \epsilon}} - 1\right)\right).$$

Setting $\nu = (\sqrt{2/(1 + \epsilon)} - 1)/(32d)$, and using the fact that $|S| = |S|^{1/2} \pi_S$, this shows that $\|P_t |S|\| \geq |S|^{1/2} n^{-1/2}(1 + \nu)$. By Lemma 5, the estimate $a$ will then with probability $1 - \delta$ be such that

$$a \geq \sqrt{|S|n^{-1}(1 + \nu)} - \epsilon'.$$

If we strictly lower bound this by $\sqrt{|S|n^{-1}(1 + n^{-1})} + \epsilon'$, then we will correctly reject the graph with probability at least $1 - \delta$. We can easily prove the lower bound:

$$\sqrt{|S|n^{-1}(1 + n^{-1})} + \epsilon' \leq \sqrt{|S|n^{-1}(1 + n^{-1}/2)} + \epsilon' < \sqrt{|S|n^{-1}(1 + \nu)} - \epsilon'$$

if $\epsilon' < |S|^{1/2} n^{-1/2}(\nu/2 - n^{-1/4})$. Since $|S| \geq M/d$, this inequality holds by our choice $\epsilon' = n^{-1/3} \nu/4$ if $n$ is sufficiently large.

Now we can bound the total probability of correctly rejecting the graph in a single iteration. Thereto we multiply the probability that $v \in A$ ($\geq \epsilon/(24d)$), the ESP process succeeds ($\geq 1/60$) and the 2-norm estimator succeeds ($\geq 1 - \delta$), yielding a total rejection probability of at least $\epsilon(1 - \delta)/1440$. The total probability of correctly rejecting at least once in $K$ iterations is therefore at least $K \epsilon(1 - \delta)/1440 \geq 2/3$ by our choice of $K$. This concludes the proof that Algorithm 2 is a $(\Phi, \epsilon)$-expansion tester.

Towards proving the runtime of the algorithm, we consider a single iteration of the for-loop. By Theorem 3, the complexity of simulating the ESP in step 4 is

$$O(M \theta^{-1} \log^2(dn)) \in O(n^{1/3} d^2 \Phi^{-1} \log^2(dn)).$$

By Lemma 5, the $(\epsilon', \delta)$ 2-norm estimator in step 6 requires a number of queries

$$\tilde{O}(t^{1/2} d^{1/2} \epsilon'^{-1} \log \delta^{-1}) \in \tilde{O}(n^{1/3} d^{3/2} \Phi^{-1} \log \epsilon^{-1}).$$

Since we iterate the for-loop $K \in O(\epsilon^{-1})$ times, this gives the claimed complexity.
This work greatly benefited from discussions and comments by Alain Sarlette, Anthony Leverrier, Ronald de Wolf and André Chailloux. Part of this work was supported by the CWI-Inria International Lab.
