Telomeres, telomerase and colorectal cancer

Roberta Bertorelle, Enrica Rampazzo, Salvatore Pucciarelli, Donato Nitti, Anita De Rossi

Abstract

Colorectal cancer (CRC) is the third most common cancer worldwide and, despite improved treatments, is still an important cause of cancer-related deaths. CRC encompasses a complex of diseases arising from a multi-step process of genetic and epigenetic events. Besides heterogeneity in the molecular and biological features of CRC, chromosomal instability is a hallmark of cancer and cancer cells may also circumvent replicative senescence and acquire the ability to sustain unlimited proliferation. Telomere/telomerase interplay is an important mechanism involved in both genomic stability and cellular replicative potential, and its dysfunction plays a key role in the early steps of carcinogenesis. The erosion of telomeres, mainly because of cell proliferation, may be accelerated by specific alterations in the genes involved in CRC, such as APC and MSH2. Although there is general agreement that the shortening of telomeres plays a role in the early steps of CRC carcinogenesis by promoting chromosomal instability, the prognostic role of telomere length in CRC is still under debate. The activation of telomerase reverse transcriptase (TERT), the catalytic component of the telomerase complex, allows cancer cells to grow indefinitely by maintaining the length of the telomeres, thus favouring tumour formation/progression. Several studies indicate that TERT increases with disease progression, and most studies suggest that telomerase is a useful prognostic factor. Plasma TERT mRNA may also be a promising marker for the minimally invasive monitoring of disease progression and response to therapy.
INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer worldwide; over 1.2 million new cancer cases and nearly 600,000 deaths are estimated to have occurred in 2008[1]. Despite improved treatments, increased awareness and early detection, which have all contributed to prolonged survival, CRC is still an important cause of cancer-related deaths[2]. CRCs encompass a complex of diseases with different molecular pathways and biological characteristics arising from a multi-step process that involves several genetic and epigenetic events[2,3]. The stepwise change in morphology from normal epithelium to carcinoma occurs through a multi-step genetic model with the loss of the functions of tumour suppressor genes, such as adenomatous polyposis coli (APC) and TP53, and the gain of the function of oncogenes, such as KR-43. Recent genome-wide sequencing analyses have estimated as many as 80 mutated genes in CRC. Although a smaller number of mutations are considered drivers of tumourigenesis, multiple genetic hits are required for tumour onset and progression[4]. Many efforts have been made to identify molecular markers that predict the outcome of CRC patients, and several genetic and epigenetic alterations that are involved in the development of CRC have been proposed as prognostic markers of disease progression; however, no agreement has been reached[5].

Besides great heterogeneity of the molecular and biological features, chromosomal instability may play a key role in the early steps of carcinogenesis[6]. Cancer cells may also circumvent replicative senescence and acquire the ability to sustain unlimited proliferation[7]. Telomere/telomerase interplay is an important mechanism involved in the genomic stability and cellular replicative potential, and telomere/telomerase dysfunction has emerged as playing a key role in carcinogenesis. Here, we review the role of telomeres and telomerase in the genesis and progression of CRC.

TELOMERES AND TELOMERASE

Telomeres are specialised DNA structures located at the end of chromosomes; they are essential for stabilising chromosomes by protecting them from end-to-end fusion and DNA degradation[8]. In human cells, telomeres are composed of (TTAGGG)n tandem repeats that are associated with the capping proteins Telomeric Repeat binding Factor (TRF)1, TRF2, Repressor/Activator Protein1 (RAP1), TRF1-interacting Nuclear protein 2 (TIN2), TTC1 (also known as TINT1, PTOP, PIPI), and Protection Of Telomers 1 (POT1), which constitute the shelterin complex[9]. Telomeres are progressively shortened during each cell division by replication-dependent loss of sequences at the DNA termini, caused by the failure of DNA polymerase to completely replicate the 3’ end of chromosomes[10]. When telomeres become critically short (i.e., the Hayflick limit), they are no longer protected by the shelterin complex; at that point they are recognised as DNA double-strand breaks that trigger a DNA damage response (DDR), and the cells undergo replicative senescence and apoptosis[11]. If protective mechanisms, such as that of the TP53 protein, are inactive, cells continue to proliferate; the further erosion of telomeres impairs their role in protecting chromosome ends and ultimately causes chromosomal instability[12]. Thus, telomere erosion may play two conflicting roles: tumour suppression by inducing cell death, and tumour promotion by causing genetic instability, a key event in the initiation of carcinogenesis. It has been recently advanced that short telomeres may also affect genome-wide DNA methylation, which may modulate oncogene and oncosuppressor gene expression[13]. However, cell division-associated telomere shortening prevents unlimited cell proliferation and thus tumour development/progression. To escape this proliferation barrier, cells must stabilise their telomeres. Most tumours maintain their ability to grow indefinitely through the inappropriate expression of telomerase, a ribonucleoprotein complex containing an internal RNA component [telomerase RNA (TR), or telomerase RNA component] and a catalytic protein with telomere-specific reverse transcriptase activity [telomerase reverse transcriptase (TERT)][14]. TERT which synthesises de novo telomere sequences by using TR as a template, is the rate-limiting component of the telomerase complex, and its expression is correlated with telomerase activity[15]. While TR has broad tissue distribution and is constitutively present in normal and tumour cells, expression of TERT, which is usually repressed in normal somatic cells, occurs in germ-line cells and most cancer cells. TERT is essential for unlimited cell growth and thus plays a critical role in tumour formation and progression[16].

Regulation of telomerase operates at several biological levels: transcription, mRNA splicing, subcellular localisation of each component and the assembly of TR and TERT in an active ribonucleoprotein. Transcription of the TERT gene is most likely the key determinant in the regulation of telomerase activity; notably, TERT transcriptional activity is specifically up-regulated in cancer cells, but is silent in most normal cells. The TERT gene consists of approximately 35 kb DNA and comprises 16 exons and 15 introns. At the transcriptional level, more than 20 transcription factor-binding sites that act as activators or repressors have been identified within the TERT promoter. The cooperation of MYC and SP1 is required for the full activation of the TERT promoter, while TP53, through its interaction with SP1, down-regulates TERT. TERT is also directly activated by nuclear factor-κB, hypoxia-inducible factor (HIF)-1, and the ETS/MYC complex. The histone methyltransferase SMYD3 also directly contributes to inducible and constitutive TERT expression in normal and malignant human cells. TERT expression is suppressed by the oncosuppressor genes WT127 and MEN1, and through the MAD/MYC and TGF-β/SMA pathways. The cell cycle inhibitors p16INK4a and p27KIP1 have also been shown to down-regulate TERT expression in cancer cells[17].

Regulation of TERT transcription may also involve DNA methylation, because the TERT promoter contains

a cluster of CpG sites. At the post-transcriptional level, modulation of telomerase may occur by alternative splicings that may be tissue-specific; at least 10 different variants of TERT mRNA have been described, and some of these splicing products may exert a dominant negative function by competitive interaction with components of the telomerase complex[18,19]. Telomerase activity is also controlled through post-translational modifications of the TERT protein. Phosphorylation of the protein at critical sites by the PI3K/AKT kinase pathway seems to be crucial for telomerase activity[20]. Telomere-associated shelterin plays a role in the activity of telomerase; TPP1 is heterodimerised with POT1 and the POT1-TPP1 complex can recruit and stimulate telomerase activity, thereby regulating telomere length through the TPP1-telomerase interaction[21]. Notably, recent studies have suggested that, in addition to maintaining telomere length, TERT is involved in several other cell functions. The expression of TERT increases replicative kinetics[22,23], promotes cell growth under adverse conditions and may also act as an anti-apoptotic agent[24-26]. High levels of telomerase confer resistance to several antineoplastic drugs[27,28].

We direct our attention here to the questions listed in Table 1. The answers to these questions are important in defining the role of telomere/telomerase interplay in the CRC carcinogenesis.

TELOMEROSES AND GENETIC INSTABILITY IN THE GENESIS OF COLORECTAL CANCERS

There are at least two major pathways by which molecular events can lead to CRC; most CRCs (approximately 85% of cases) are characterised by chromosomal instability (CIN), while the other CRCs have a microsatellite instability (MSI) phenotype. CIN is a dynamic process of allelic imbalance at several chromosomal loci, with chromosome amplification and translocation, and it is an efficient mechanism for causing the loss of oncosuppressor genes, such as APC, TP53, and SMAD family member 2 and 4 involved in the TGF-β signaling pathway, and the activation of oncogenes, such as KRAS and BRAF, which activate the mitogen-activated protein kinase signalling pathway[29]. The MSI phenotype is generated by a defective DNA mismatch repair (MMR) system. Alterations to one of the seven known MMR genes (MSH2, MLH1, MSH6, PMS1, PMS2, MSH3, and MLH3) cause unrepaired errors in the nucleotide repeat sequences, known as microsatellites. Methylation of promoters of MMR genes, particularly MLH1, is the most frequent mechanism for silencing MMR genes in sporadic CRCs, which in fact is frequently associated with the CpG island methylator phenotype[30,31]. While the significance of telomere alterations in MSI is unclear, telomere dysfunction may be considered a major driving force in the generation of CIN.

Several studies have demonstrated that telomeres are shorter in CRCs than in the adjacent mucosa (Table 2). While telomere length in somatic cells primarily reflects cellular proliferation, in tumour cells it reflects the balance between cellular proliferation with telomere loss and telomerase activity with de novo synthesis of telomeric sequences. Evidence that telomeres are shorter in CRCs than in adjacent mucosa, even in well-differentiated tumours, strongly supports the concept that telomere erosion is a critical initial event in colorectal carcinogenesis. TRF1 is a main negative regulator of telomere length; over-expression of TRF1 in colorectal cells is correlated with shorter telomeres[32]. Telomere shortening in colorectal polypos was recently correlated with large-scale genomic rearrangements[33]. Notably, telomere shortening in adenomas is not correlated with polyp size. In addition, the great differences in telomere length (differences of up to 4.6 kb between normal mucosa and polyps) are too large to be explained by replicative telomere erosion alone. Thus, the telomere length in CRC may reflect the short telomere length in the cells that originated the tumours, and telomere erosion may even precede the colorectal adenomagenesis[34]. Because this pattern has been observed in colorectal adenomas from patients with familial adenomatous polyposis, it remains to be established whether it also occurs in sporadic CRCs.

Approximately 15% of CRCs present MSI, whereas the TP53 gene is the known major genetic alteration in CRCs with chromosomal instability and stable microsatellites (MSS)[35,36]. A study performed on a large number of CRCs demonstrated that both MSI and MSS tumours have shorter telomeres compared with adjacent mucosa, but MSI cancers have shorter telomeres than MSS cancers[37]. This result matches another study[38]. The MSI pathway involves the failure of the MMR system, which maintains genetic stability by repairing DNA replication errors and preventing chromosomal recombinations; a deficiency in MMR helps cells overcome cellular crises caused by the critical shortening of telomeres[39]. Thus, cells from MSI cancers may undergo more replicative cycles and more pronounced shortening of telomeres before stabilising compared with cells from MSS cancers. The difference is particularly great and significant when MSI tumours are compared with cells from MSS cancers. The difference is particularly great and significant when MSI tumours are compared with cells from MSS cancers.
with mutated TP53, telomeres may protract their shortening with cell proliferation. However, TP53 is a well-known negative regulator of the TERT promoter, and mutated TP53 protein may also result in TERT activation, so telomere stabilisation may occur earlier than it does in MSI tumours.[41]

The down-regulation of MSH2 is associated with greater telomere shortening than in control cells; thus

### Table 2: Telomere lengths and colorectal cancer

| Ref.          | Cases                                                                 | Main findings                                                                 |
|---------------|----------------------------------------------------------------------|------------------------------------------------------------------------------|
| Hastie et al[39], 1990 | 23 (20 CRCs, 3 adenomas) and patient-matched non-cancerous mucosa (frozen samples) | TL Decrease with age in non-cancerous cells (33 bp per year) Shorter in CRCs and adenomas than in normal mucosa |
| Engelhardt et al[36], 1997 | 80 (50 CRCs, 20 polyps, 10 colitis) and CRC patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in CRCs than in normal mucosa Shorter in CRCs than in polyps and colitis Longer in late-stage cancer with higher telomerase activity Do not differ between colon and rectum cancer |
| Takagi et al[33], 1999 | 61 CRC (including 12 non-ulcerating and 39 ulcerating tumours, according to Borrmann’s classification) and patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in non-ulcerating CRCs than in normal mucosa Shorter in non-ulcerating than in ulcerating tumours Not correlated with tumour stage or grade Not correlated with telomerase activity |
| Katayama et al[34], 1999 | 35 (26 CRCs, 9 polyps) (frozen samples) | TL Do not differ between CRCs and polyps |
| Nakamura et al[35], 2000 | 124 CRC and patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in CRCs than in normal mucosa Decrease with age in both cancer and non-cancerous cells (44 and 50 bp/yr) |
| Plentz et al[37], 2003 | 10 (adenoma-carcinoma transition) (paraffin-embedded samples) | TL Shorter in high-grade dysplastic areas than in the surrounding adenoma |
| Gertler et al[38], 2004 | 57 CRC and patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in CRCs than in adjacent mucosa Decrease with age only in non-cancer cells (19 bp per year) Correlate with tumour stage, being longer in advanced tumours Correlate with TERT mRNA levels Lead to a poor prognosis if TL cancer/TL non-cancer > 0.9 Do not differ between colon and rectum cancer |
| Garcia-Aranda et al[39], 2006 | 91 CRC (23 right-colon, 13 left-colon, 55 rectum) and patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in CRC than in adjacent mucosa Shorter in right-colon cancers than in tumours located in other sites Shorter in poorly differentiated tumours Tend to be longer in telomerase-positive CRCs Have prognostic value (longer telomeres: poor clinical outcome) Correlated with the expression of TRF1 protein |
| O’Sullivan et al[40], 2006 | 38 (26 adenomas, 12 CRCs) (paraffin-embedded samples) | TL Shorter in adenomas than in adjacent and distant mucosa Similar in CRCs and adjacent and distant mucosa |
| Raynaud et al[41], 2008 | 15, each case with normal mucosa, low-grade dysplasia, high-grade dysplasia and carcinoma (paraffin-embedded samples) | TL Shorter in low-grade and high-grade dysplasia than in carcinoma Inversely correlated with activation of the DDR pathway |
| Rampazzo et al[42], 2010 | 118 CRC (53 right-colon, 30 left-colon, 35 rectum) and patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in CRCs than in adjacent mucosa Shorter in right-colon cancers than in tumours located in other sites Shorter in MSI than in MSS tumours Decrease with age only in non-cancer cells Not correlated with tumour stage or grade Not correlated with TERT mRNA levels |
| Valls et al[43], 2011 | 147 CRC and patient-matched non-cancerous mucosa (frozen samples) | TL Shorter in CRCs than in adjacent mucosa In cancer correlate with TL in normal mucosa Do not differ between colon and rectum cancer Not correlated with tumour stage |
| Roger et al[44], 2013 | 135 (85 polyps from 10 patients with FAP, 50 CRCs) (frozen samples) | TL Shorter in polyps than in normal mucosa Correlated with genomic rearrangement in polyps Independent of adenoma size In polyps may reflect the TL of the originating cells |

TL: Telomere lengths; CRC: Colorectal cancer; DDR: DNA damage response; OS: Overall survival; FAP: Familial adenomatous polyposis.
MSH2 deficiency may accelerate telomere shortening. It is worth noting that the leukocyte telomeres of patients with Lynch syndrome, a hereditary CRC syndrome caused by germline mutations in MMR genes are shorter than those of age-matched controls. Whether a shorter telomere length in leukocytes is a risk factor for CRC or a consequence of either disease treatment or disease burden is a controversial question, but there is general agreement that telomere shortening is an early event in colorectal carcinogenesis, even in sporadic CRC (Figure 1). Activation of the DDR is almost universal during the earliest stages of carcinogenesis. A recent study suggested that telomere length is inversely correlated with activation of the DDR pathway, and telomere fusion may lead to general genomic instability.

While there is general agreement that telomere shortening, which is mainly caused by high proliferation of preneoplastic lesions and most likely accelerated by alterations in genes such as APC and MSH2, is an early event in the CRC carcinogenesis, there is no agreement concerning the role of telomere length as a marker of disease progression. Only a few studies report that telomeres are longer in late stage cancer than in preneoplastic lesions and/or early neoplastic stages; the activation of telomerase and/or high levels of telomerase expression may explain the increase in telomere length with disease progression. However, other studies have not indicated any correlation between telomere length and tumour stage or grade. Telomere lengths may stabilise with tumour progression because of increased telomerase activity that compensates for replicative telomere loss.

**TELOMERASE AS A MARKER OF DISEASE PROGRESSION IN COLORECTAL CANCER**

Two main strategies are used to estimate telomerase levels: quantification of TERT mRNA and quantification of telomerase activity. The telomerase level, even in telomerase-positive tumour cells, is estimated to be relatively low (approximately 100 molecules per cell), so its detection, either as mRNA or activity, requires methods based on polymerase chain reaction (PCR) amplification. In general, all quantitative data acquired with real-time PCR must be normalised by a housekeeping gene. The ideal housekeeping gene should not vary with disease progression. The glyceraldehyde 3-phosphate dehydrogenase gene, which is often employed as housekeeping gene, is activated by HIF and is thus expressed at higher levels in advanced disease than in tumours at early stages. Other genes, such as the hypoxanthine-guanine phosphoribosyltransferase 1 (HPRT1) gene, which does not vary with tumour stage, allow a more reliable estimation of TERT levels. In CRC, a study by real-time PCR with HPRT1 as a housekeeping gene demonstrated that there is a good relationship between the levels of all TERT transcripts and the full-length TERT transcript; in addition, levels of TERT mRNA correlated with telomerase activity, as estimated with a telomere repeat amplification.
protocol (TRAP) assay[54]. Although there are no clinically approved telomerase assays, several promising approaches have recently been published[57].

There is general agreement that TERT levels and telomerase activity increase with the adenoma-carcinoma sequence[60,64,70], and are higher in CRCs than in adjacent non-cancerous mucosa (Table 3). Normal adjacent mucosa may have some detectable TERT mRNA and telomerase activity, mainly because of intestinal crypt basal cells[62,63]. These findings strongly support the hypothesis that telomerase activation is subsequent to telomere erosion (Figure 1).

Most studies have demonstrated that TERT expression and/or telomerase activity increase with tumour progression (Figure 2A and Table 3). Well-differentiated and moderately differentiated tumours have significantly lower TERT levels than poorly differentiated tumours do, and late-stage tumours (Dukes C and D) show higher telomerase activity than early-stage tumours[65,67]. Only a few studies have found no correlation between levels of telomerase activity, as assessed by the semi-quantitative TRAP assay, and tumor progression[58,59,64]. Unlike telomere length, levels of telomerase expression/activity do not correlate with MSI status and increase with disease progression in both MSI and MSS tumours[68,73]. The finding that TERT mRNA is higher in tumours bearing TP53 mutations[66] may support the hypothesis that high TERT expression is a marker of poor outcome and poor response to therapy[27,73].

**TELOMERASE, BUT NOT TELOMERES, MAY ACT AS A PROGNOSTIC FACTOR IN COLORECTAL CANCERS**

Pathologic tumour staging remains a key determinant of CRC prognosis and treatment. Invasive cancers are confined within the wall of the colon (stages I and II), but if untreated they spread to regional lymph nodes (stage III) and then metastasise to distant sites (stage IV). Although radical resection and adjuvant therapy are effective curative treatments, the risk of disease recurrence cannot be foreseen, even among patients at the same tumour stage. Although 5-fluorouracil-based adjuvant chemotherapy is the standard care for stage III patients, the role of adjuvant therapy for stage II is still debated. The controversial results obtained in various studies[74-78] may reflect the molecular and biological heterogeneity of CRC and highlight the need for definitive prognostic markers able to stratify patients.

While most studies do not confirm the prognostic role of telomere length (Table 2), there is general agreement that high levels of TERT and/or telomerase activity are associated with poor prognosis (Table 3). Only two studies do not confirm the prognostic value of TERT[72] or telomerase activity[62]. High levels of TERT mRNA and/or telomerase activity have been associated with worse overall survival (OS) and this negative prognostic effect is independent of pathologic stage. In particular, over a median follow-up of 70 mo, patients with high levels of TERT mRNA (above the median) had approximately double the risk of death compared with patients with low levels of TERT (below the median) did[63]. Only two studies analysed stage II patients in detail. In one study, in which telomerase activity was determined with TRAP assay, patients with telomerase-positive CRCs had longer disease-free survival (DFS) than did patients with telomerase-negative tumours[62]. In the second study, TERT levels estimated using real-time PCR significantly stratified stage II patients; stage II patients with high TERT levels showed significantly worse median OS and DFS than patients with low TERT levels did[73].

In recent years, great efforts have been made to identify markers for minimally invasive early diagnosis and/or monitoring of disease. The expression of epithelial cell adhesion molecules has been used primarily to detect CRC cells in the hematopoietic milieu, and the detection of circulating cancer cells is a promising approach, although its diagnostic/prognostic role needs to be established[79]. The detection of cancer-related RNA molecules in plasma has recently been proposed as a marker of cancer onset and outcome, and ongoing studies indicate that circulating microRNAs may be biomarkers for the early detection of CRC[80,81]. Within this framework, recent studies suggest that cell-free circulating TERT mRNA is also a potential marker of disease.

Transcripts of TERT have been detected in the plasma of patients with different tumours, including CRC[82,83]. In a series of CRCs (stage I to stage IV), the TERT mRNA levels in plasma were related to those in tumours[85] (Figure 2B). In addition, while 95% of patients with tumours had detectable cell-free circulating TERT, aged-matched controls were negative in almost all cases[59]. This finding suggests that TERT levels in plasma reflect those in tumours. Very promising findings have been reported in patients with rectal cancer who underwent chemoradiotherapy (CRT) prior to surgery; plasma TERT was significantly decreased in patients who underwent a complete pathologic response, but remained unchanged or increased in patients who did not respond to CRT[84] (Figure 2C). These findings also suggest that circulating TERT is a useful marker for monitoring the response to therapy. However, further studies with a prospective design and with a large sample sizes are required to clearly define the prognostic role of telomerase in CRC patients and to ascertain the cut-off values and reliability of circulating TERT as a marker for monitoring disease outcome and response to therapy.

**CONCLUSION**

Besides extensive heterogeneity in the molecular and biological features of CRC, chromosomal instability plays a key role in the early steps of carcinogenesis. The majority of studies agree that telomere shortening is an early event in the oncogenetic process and that telomere erosion...
Table 3 Telomerase as a marker of disease in colorectal cancer

| Ref. | Cases | Main findings |
|------|-------|---------------|
| Engelhardt et al⁹⁴, 1997 | 80 (50 CRCs, 20 polyps, 10 colitis) cancerous and 50 CRC patient-matched non-cancerous mucosa specimens | Telomerase activity
Absent in normal tissues
Higher in CRCs than in non-neoplastic lesions
Higher in late-stage than in early-stage tumours |
| Tatsumoto et al⁹⁵, 2000 | 100 CRC and patient-matched non-cancerous mucosa specimens | Telomerase activity
Higher in CRC than in adjacent non-cancerous mucosa
Detectable in adjacent non-cancerous mucosa derived from intestinal crypt basal cells
Not correlated with CRC stage or grade
Has prognostic value for OS and DFS (high telomerase activity: poor prognosis) |
| Niiyama et al⁹⁶, 2001 | 140 CRC and patient-matched non-cancerous mucosa specimens; 20 adenomas | TERT mRNA and telomerase activity
Higher in CRCs than in adenomas
Higher in adenomas than in normal mucosa |
| Naito et al⁹⁷, 2001 | 66 (50 adenomas, 6 mucosal carcinomas, 10 invasive carcinomas) specimens | Positive correlation between TERT mRNA and telomerase activity
TERT levels increase with adenoma-carcinoma sequence |
| Gertler et al⁹⁸, 2002 | 57 CRC and patient-matched non-cancerous mucosa specimens | Both CRC and adjacent non-cancerous mucosa are positive for TERT
TERT levels lower in tumours than in non-cancerous mucosa in most cases
TERT levels not correlated with tumour stage
TERT has prognostic value for OD and DFS (high telomerase activity: poor prognosis) |
| Kawanishi-Tabata et al⁹⁹, 2002 | 122 CRCs, stage II (52 colon, 70 rectum) | 80% of CRC are telomerase-positive
Higher percentage of telomerase-positive tumours in the colon than in the rectum |
| Ghori et al⁰⁰, 2002 | 30 CRCs and 20 patient-matched non-cancerous mucosa specimens | High telomerase activity: Good prognosis
Telomerase activity
Higher in CRCs than in adjacent non-cancerous mucosa
Correlated with Duke's stage |
| Boldrini et al⁰¹, 2002 | 36 CRC and patient-matched non-cancerous mucosa specimens, 8 adenomatous polyps, 9 dysplastic polyps | Telomerase activity
Absent in normal mucosa and adenomas
Higher in CRCs than in dysplastic polyps
Higher in late-stage than in early-stage tumours |
| Maláska et al⁰², 2004 | 41 CRC and patient-matched non-cancerous mucosa specimens | Telomerase activity
Present in 83% of CRCs
Absent or at very low level in normal mucosa
Higher in metastatic tumours |
| Boldrini et al⁰³, 2004 | 43 CRCs | TERT levels and telomerase activity higher in tumours with mutated TP53
Telomerase activity increases with tumour progression (Duke's stage)
Higher percentage of telomerase-positive tumours in the colon than in the rectum
Telomerase activity has prognostic value for DFS (high telomerase activity: poor prognosis) |
| Sanz-Casla et al⁰⁴, 2005 | 105 CRCs | TERT levels increase with adenoma-carcinoma sequence
Higher in CRCs than in adjacent non-cancerous mucosa
Absent in normal tissues
Telomerase activity |
| Garcia-Aranda et al⁰⁵, 2006 | 91 CRC and patient-matched non-cancerous mucosa specimens | Telomerase activity
Present in 81% of CRCs
Present at very low levels in 15% of normal samples
Not correlated with tumour progression
No prognostic value |
| Vidaurreta et al⁰⁶, 2007 | 97 CRCs | Telomerase activity
Present both in MSI and MSS tumours
Has prognostic value for OS (high telomere activity: poor prognosis) |
| Bautista et al⁰⁷, 2007 | 108 rectal cancer and patient-matched non-cancerous mucosa specimens | Telomerase activity
Higher in rectal cancer than in normal mucosa
Not correlated with tumour stage and grade
Has prognostic value for DFS and OS |
| Terrin et al⁰⁸, 2008 | 85 CRC and 42 patient-matched non-cancerous mucosa specimens, 49 plasma samples | TERT levels
Higher in CRCs than in adjacent non-cancerous mucosa
Increase with tumour stage and grade
Not correlated with MSI status
Not correlated with tumour location
Plasma TERT levels correlated with tumour TERT levels |
| Valls Bautista et al⁰⁹, 2009 | 6 cases, each with cancer, polyps and normal mucosa; 8 polyps and normal mucosa | Telomerase activity
Increases with adenoma-carcinoma sequence
Elongation of the 3'OH of telomere by telomerase may increase Malignant potential of cancer cells
Telomerase activity has prognostic values for OS (telomerase activated without 3'OH shortened telomeres: poor prognosis) |
| Kojima et al¹⁰, 2011 | 106 CRC and paired adjacent non-cancerous mucosa specimens | Plasma TERT levels correlated with tumour TERT levels
Higher circulating TERT levels in stage IV tumours
No correlation between telomerase expression and prognosis |
leads to genetic instability. Telomerase, which maintains telomere length and preserves the cell’s replicative potential, is activated during the adenoma-carcinoma sequence and its activity increases during tumour progression.

While most studies do not confirm the prognostic role of telomere length, there is general agreement that high levels of TERT and/or telomerase activity are associated with poor prognosis. Emerging data also suggest that circulating TERT levels reflects tumour TERT levels. Overall, there is sufficient evidence to indicate that telomerase is a useful marker for monitoring and predicting disease outcome. A caveat to the use of telomerase as a marker is the availability of simple and reliable assays to quantify telomerase expression and/or activity. The use of reliable assays will allow researchers to compare data and to define useful cut-off values to discriminate between patients at low and high risk of disease progression. Further studies with a prospective design and large

Figure 2  Representative panels of telomere length and telomerase reverse transcriptase levels. A: Relative telomere length in tumours (K) and adjacent mucosa (N) according to tumour stages I (30 samples), II (45 samples), III (29 samples), and IV (29 samples). The cases included those reported in Rampazzo et al[41]. Telomere length was significant shorter in tumours than in adjacent mucosa (P < 0.0001) at all tumour stages, but telomere lengths did not significantly differ with tumour stage. Relative telomere length was estimated using real-time polymerase chain reaction (real-time PCR)[41]; B: Telomerase reverse transcriptase (TERT) levels in tumours (K) and adjacent mucosa (N) according to tumour stages I (K: 25 samples, N: 17 samples), II (K: 35 samples; N: 10 samples), III (K: 15 samples; N: 5 samples), and IV (K: 30 samples; N: 22 samples). The cases included those reported in Terrin et al[55]. TERT levels were significantly higher in tumours than in adjacent mucosa and significantly increased (P < 0.01) with tumour stage. TERT levels were estimated using real-time PCR[41,55]; C: Plasma TERT levels before and after the chemoradiotherapy prior to surgery in responders (35 samples) and non-responders (42 samples) with rectal cancer. The cases included those reported in Pucciarelli et al[84]. TERT levels in plasma were estimated using real-time PCR[84]. Boxes and whiskers: 25th-75th and 10th-90th percentiles, respectively; the median is the central line in each box.

Bertorelle R et al. Telomeres, telomerase and colorectal cancer

| TERT levels: |
|------------------------|
| Increase with tumour stage and grade |
| Not correlated with MSI status |
| Not correlated with tumour location |
| Have prognostic value for OS and for both OS and DFS for stage II patients (high TERT levels: poor prognosis) |

CRC: Colorectal cancer; DFS: Disease free survival; OS: Overall survival; TERT: Telomerase reverse transcriptase; MSI: Microsatellite instability.
Bertorelle R et al. Telomeres, telomerase and colorectal cancer

sample sizes are required to clearly define the prognostic role of telomerase and to ascertain its reliability as a circulating biomarker for the minimally invasive monitoring of disease and the response to therapy.
