Abstract

Investigation of the structure of the Standard Model effective potential at very large field strengths opens a window towards new phenomena and can reveal properties of the UV completion of the SM. The map of the lifetimes of the vacua of the SM enhanced by nonrenormalizable scalar couplings has been compiled to show how new interactions modify stability of the electroweak vacuum. Whereas it is possible to stabilize the SM by adding Planck scale suppressed interactions and taking into account running of the new couplings, the generic effect is shortening the lifetime and hence further destabilisation of the SM electroweak vacuum. These findings have been illustrated with phase diagrams of modified SM-like models. It has been demonstrated that stabilisation can be achieved by lowering the suppression scale of higher order operators while picking up such combinations of new couplings, which do not deepen the new minima of the potential. Our results show the dependence of the lifetime of the electroweak minimum on the magnitude of the new couplings, including cases with very small couplings (which means very large effective suppression scale) and couplings vastly different in magnitude (which corresponds to two different suppression scales).

1 Introduction

The discovery of the 126 GeV scalar particle, which in the light of available data can be identified with the Standard Model Higgs boson, and absence of experimental signature of any new physical state in the LHC experiments makes it important to search for possible windows towards new phenomena within the Standard Model itself. One of the possible windows is the investigation of the structure of the effective potential in the Standard Model which has been the subject of considerable activity [1][2][3][4][5][6][7][8]. The study of the renormalisation group improved effective SM potential has revealed an interesting structure at field strengths higher than approximately $10^{11}$ GeV and new minima at superplanckian field strenghts. The upshot depends critically on the precise value of the measured Higgs mass and on the measured value of the top quark Yukawa coupling. In particular, one finds that for the central value of the top mass and for the central value of the measured Higgs mass the physical electroweak symmetry breaking minimum becomes metastable with respect to the tunneling from the physical EWSB minimum to a deeper minimum located at superplanckian

values of the Higgs field strength. The computed lifetime of the metastable SM Universe turns out larger than the presently estimated age of the Universe, however the instability border in the space of parameters $M_{\text{top}} - M_{\text{higgs}}$ looks uncomfortably close and this suggests that the result is rather sensitive to various types of modifications that can be brought in by the BSM extensions. The question about stability of the SM vacuum in the presence of ultraviolet completions at or below the planck scale is the central point of this note. In the paper [1] higher order operators have been added to the scalar potential of the neutral higgs field. The operators are suppressed by suitable powers of the Planck scale and for sensible values of the new couplings they were found to modify significantly the behaviour of the potential near the Planck scale. It has been shown and illustrated by examples in [1], that Planck scale operators can indeed produce a minimum near the Planck scale, however they can also destabilize the SM metastable minimum with respect to the tunneling to a deeper minimum at high field strengths. Here we study the question further, making a more complete map of the vacua in the SM extended by nonrenormalisable scalar couplings. taking into account the running of the new couplings and going beyond the standard assumptions taken when calculating the lifetime of the metastable vacuum. Usually, one uses certain quasi-analytic approximations of the effective potential, [10], for the purpose of calculating the tunneling rate. In particular, one uses as the departure point the calculation for the quartic-like form of the effective potential at large field strengths, while in the modified scalar potential it is the order 6 or order 8 coupling which naively dominates the potential in the large field domain. It is important to check the validity of such approximation and to search through a relatively wide scope of new couplings to find the actual behaviour of the scalar potential. The ultimate tool in this case is the direct numerical analysis, which however is not so straightforward because of the flatness of the effective potential. In this paper we present currently available results of such extended analysis of the modified SM scalar potential. In general, we confirm that it is relatively easy to destabilize the SM with the help of the Planck scale suppressed scalar operators. However, there exists choices of higher-dimensional couplings which meta-stabilize the SM vacuum.

2 New interactions

In what follows we shall assume the Lagrangian of the Standard Model augmented by two higher dimensional interactions $\lambda_6$ and $\lambda_8$ suppressed by a large mass scale $M$ which give us modified SM potential of the form (similar to [1]):

$$V = -m^2 \phi^2 + \frac{\lambda}{4} \phi^4 + \frac{\lambda_6}{6!} \frac{\phi^6}{M^2} + \frac{\lambda_8}{8!} \frac{\phi^8}{M^4}. \quad (2.1)$$

It is well known that effects of radiative corrections to SM couplings on the vacuum are large and so these couplings require precise determination [2]. We have used two-loop running of the SM parameters [5] and computed one-loop corrections to the new interactions. The correction to the running of the quartic Higgs coupling is of the form

$$\Delta \beta_\lambda = \frac{\lambda_6}{16\pi^2} \frac{m^2}{M^2}, \quad (2.2)$$
and its contribution is negligible for $m \ll M$. One-loop beta functions of new couplings take the form

$$\begin{align*}
16\pi^2 \beta_{\lambda_6} &= \lambda_8 \frac{m^2}{M^2} + 15\lambda_6 \lambda + 6\lambda_6 \left( \frac{9}{4} g_2^2 + \frac{9}{20} g_1^2 - 3y_t^2 \right) , \\
16\pi^2 \beta_{\lambda_8} &= 35\lambda_6^2 + 28\lambda_8 \lambda - 8\lambda_8 \left( \frac{9}{4} g_2^2 + \frac{9}{20} g_1^2 - 3y_t^2 \right) .
\end{align*}$$

(2.3)

Figure 1 shows an example of running of the new couplings and Figure 2 shows the resulting potential with $\lambda_6(M_p) = -1$, $\lambda_8(M_p) = -0.1$ and suppression scale $M = M_p$. We could use a more usual electroweak basis used in SM [11] which means nonrenormalisable couplings of the form

$$\begin{align*}
V_{\text{nonr}} &= \frac{\lambda_6}{6!} |H^\dagger H|^3 + \frac{\lambda_8}{8!} |H^\dagger H|^4 .
\end{align*}$$

(2.4)
This gives slightly different coefficients than those in (2.3) due to contributions from three additional scalars
\[
16 \pi^2 \beta_{\lambda_6} = \frac{10}{7} \lambda_6 \frac{m^2}{M^2} + 18 \lambda_6 6 \lambda - 6 \lambda_6 \left( \frac{9}{4} g_2^2 + \frac{9}{20} g_1^2 - 3 y_t^2 \right),
\]
(2.5)
\[
16 \pi^2 \beta_{\lambda_8} = \frac{7}{5} 28 \lambda_6^2 + 30 \lambda_6 6 \lambda - 8 \lambda_8 \left( \frac{9}{4} g_2^2 + \frac{9}{20} g_1^2 - 3 y_t^2 \right),
\]
which agrees with [12]. However we have checked that difference between (2.3) and (2.5) has negligible impact on our results here and in the following sections.

3 Tunneling rate

To calculate the expected lifetime of a metastable vacuum present in potential \( V(\phi) \) we use the standard formalism of finding a bounce solution [13] [14] which in the \( O(4) \) symmetric case depends only on \( s = \sqrt{x^2 + x_4^2} \). This means solving an equation of motion of the form
\[
\ddot{\phi} + 3 \frac{\dot{s}}{s} \dot{\phi} = \frac{\partial V(\phi)}{\partial \phi},
\]
(3.1)
with a dot denoting a derivative with respect to \( s \). The boundary conditions are \( \dot{\phi}(0) = 0 \), so that the solution is non-singular at \( s = 0 \), and \( \phi(\infty) = \phi_{\min} \) so that it corresponds to the decay of the metastable vacuum positioned at \( \phi_{\min} \). We then calculate the euclidean action of the bounce given by
\[
S_E = \int d^4x \left\{ \frac{1}{2} \sum_{\alpha=1}^4 \left( \frac{\partial \phi(x)}{\partial x^\alpha} \right)^2 + V(\phi(x)) \right\} = 2\pi^2 \int ds s^3 \left( \frac{1}{2} \dot{\phi}^2(s) + V(\phi(s)) \right),
\]
(3.2)
which allows us to calculate decay probability of a volume \( d^3x \)
\[
dp = dt d^3x \frac{S_E^2}{4\pi^2} \left| \frac{\det[-\partial^2 + V''(\phi)]}{\det[-\partial^2 + V''(\phi_0)]} \right|^{-1/2} e^{-S_E}.
\]
(3.3)

To calculate the expected lifetime we simply integrate that probability assuming size of the universe \( T_U = 10^{10} \) yr in the spatial directions and define the expected lifetime \( \tau \) as time at which decay probability is equal to 1. We also approximate the determinant and normalization prefactor by another dimensionfull quantity encountered in our problem, namely \( \phi_0 = \phi(0) \). The error introduced that way is small compared to uncertainty in determination of action, because lifetime depends only on fourth power of \( \phi_0 \) while its dependence on action is exponential,
\[
\frac{\tau}{T_U} = \frac{1}{\phi_0^4 T_U} e^{S_E}.
\]
(3.4)

In the following sections we will present known analytical approximations and compare their results with our numerical solution. As the suppression scale we use the Planck mass, \( M = M_P \), unless stated otherwise (see: the Lowering the magnitude of the suppression scale section below).
### 3.1 Analytical solution

Possibly the simplest scheme for estimating the vacuum’s lifetime, often conjectured for the SM (e.g. \cite{2}), amounts to calculating the quantity in (3.4) as

$$\frac{\tau}{T_U} = \frac{1}{\Lambda_B^4 T_U} \frac{8 \pi^2}{3} \frac{1}{|\lambda_{\text{eff}}(\Lambda_B)|},$$  

(3.5)

where $\lambda_{\text{eff}}(\phi) = \frac{V_{\text{eff}}(\phi)}{\phi^4}$, $V_{\text{eff}}$ being the effective potential, and $\Lambda_B$ denoting a renormalisation scale that minimises $\lambda_{\text{eff}}$. This approach utilises the fact that for a wide range of energy scales, $\lambda_{\text{eff}}$ is close to a constant negative value $\approx -0.014$. Bounce solution for the simple quartic potential of the form $-|b| \phi^4$ is known \cite{10} and its action is exactly $\frac{8 \pi^2}{3} \frac{1}{|b|}$. Thus, taking minimum of $\lambda_{\text{eff}}$, one estimates the action of a true bounce from below. Simultaneously, the picked $\Lambda_B$ value serves as the only characteristic scale for the bounce since the quartic potential is classically scale invariant.

Simplifying further, we approximate $\lambda_{\text{eff}}$ only by the RGE-improved quasiquartic coupling $\lambda_4(\phi) + \frac{4}{6!} \frac{\lambda_6}{M_P^2} \phi^2 + \frac{4}{8!} \frac{\lambda_8}{M_P^4} \phi^4$, neglecting both the mass term and running of the field itself in the tree-level $V_{\text{eff}}$. We use two approaches. Firstly we also completely ignore the RGE-running of $\lambda_6$ and $\lambda_8$. Then we include them in the set of RGE equations and make them scale dependent according to (2.2) and (2.3).

When $\lambda_6$ and $\lambda_8$ do not run, $\lambda_{\text{eff}}$ does not have a global minimum for $\lambda_8 < 0$. Thus we can calculate the value (3.5) only for the range of positive $\lambda_8$’s. The lhs of Figure 3 shows a contour plot of $\log_{10} \frac{\tau}{T_U}$ for $-1 < \lambda_6 < 1$ and $0 < \lambda_8 < 1$. In the region where $\lambda_6$ is negative enough, $\lambda_{\text{eff}}$ develops new minimum (as compared to SM) at scales close to $M_P$ and the exponent in (3.5) becomes small, rendering the vacuum short-lived.

![Figure 3: Decimal logarithm of lifetime of the universe in units of $T_U$ as a function of the nonrenormalisable $\lambda_6$ and $\lambda_8$ couplings, calculated with formula (3.5). For $\lambda_6$ and $\lambda_8$ kept constant (left panel) and $\lambda_6$ and $\lambda_8$ scale dependent and satisfying their one-loop RGE’s (right panel).](image_url)

Next we include the running of $\lambda_6$ and $\lambda_8$. It has small influence on the position of the $\log_{10} \frac{\tau}{T_U} = 0$ contour. The novelty is that now, even when put negative at the Planck scale, $\lambda_8$ eventually becomes positive and so $\lambda_{\text{eff}}$ possesses global minimum, thus enabling us to use the formula (3.5) in...
wider range of $\lambda_8$’s. The right panel of Figure 3 shows the plot of $\log_{10} \tau_T$ for the values of $\lambda_6(M_P)$ and $\lambda_8(M_P)$ between $-1$ and $1$ as put at the Planck scale. The region where $\lambda_{\text{eff}}$ does not develop a global minimum at the renormalisation scale lower than $M_P^2$ was excluded (white color).

Another way of breaking the scale invariance of quartic potential (originally presented in [10] and recently used in [1]) would be to sew it with a linear function

$$
V_\eta(\phi) = \begin{cases} 
-\frac{b_\eta}{\eta^4} \phi^4, & \phi \leq \eta \\
-\frac{b_\eta}{\eta^4} \eta^4 - K (\phi - \eta), & \phi > \eta,
\end{cases} \quad (3.6)
$$

where $b_\eta = \frac{-V_{\text{eff}}'(\eta)}{\eta^4} = \frac{-\lambda_{\text{eff}}'(\eta)}{\eta^4}$. One then still needs to choose the sewing point $\eta$ and the slope parameter $K$, to approximate the effective potential. It is conceivable to sew the two functions at any point, on the plot of $V_{\text{eff}}$ on left hand side of Figure 2.4. Evidently certain level of arbitrariness is present in choosing the bounce this way.

Moreover, no special bounce solution is singled out unless the ratio of derivatives at $\eta$, $-\gamma = \frac{b_\eta \eta^3}{K}$, falls into the region $0 < -\gamma < 1$, [10]. The action of a bounce is then given by $S_\eta = \frac{8\pi^2}{3} \frac{1}{b_\eta} (1 - (\gamma + 1)^4)$, and its starting point, $\phi_0 = \eta(2 + \gamma)$, lies in the linear part of $V_\eta$. In the case when $-\gamma \geq 1$, all the bounce solutions lie in the quartic part of $V_\eta$ only and the effect of sewing it with the linear function amounts again to arbitrarily choosing the value of quartic coupling $\lambda_{\text{eff}}(\eta)$ (and the scale of the bounce $\Lambda_B = \eta$) in (3.5).

One could be tempted to destabilise the vacuum by a steep linear function (large $K$) but generally, in order for $V_\eta$ to seemingly reproduce the shape of $V_{\text{eff}}$ near the global minimum, one has to put $-\gamma$ close to 1 and $\eta$ of the order of $M_P$. It follows that the main effect of lowering the action in (3.4) by the unrenormalisable operators comes from the increase of $|\lambda_{\text{eff}}|$, just like in the previously described scheme.

As a check, we have calculated the $\log_{10} \tau_T$ (for nonrunning $-1 < \lambda_6 < 1$, $0 < \lambda_8 < 1$), putting $-K = V_{\text{eff}}''(\eta)$ and $\eta$ equal to the potentials inflection point ($V_{\text{eff}}''(\eta) = 0$). The results were qualitatively similar to the ones presented above: in particular the $\log_{10} \tau_T = 0$ contour remained practically unmoved.

### 3.2 Numerical result

The numerical procedure we used is based on finding solutions to the equation of motion (3.1), by an overshot/undershot method. First we solve starting from the true vacuum at very small $s = \epsilon$ and expanding the solution into a series to get

$$
\phi \approx \phi_0 + \epsilon \frac{\partial V(\phi)}{\partial \phi} \bigg|_{\phi = \phi_0},
$$

$$
\dot{\phi} \approx \frac{\epsilon}{4} \frac{\partial V(\phi)}{\partial \phi} \bigg|_{\phi = \phi_0}.
$$

Than we use simple bisection to find $\phi_0$ for which $\phi(\infty)$ is the electroweak minimum.
Next we solve the equation of motion again, this time starting from the electroweak minimum. We first expand the field and potential around the minimum

\[ \phi \approx \phi_{\text{min}} + \phi_{\infty}, \]

\[ \frac{\partial V(\phi)}{\partial \phi} \approx m^2 \phi_{\infty}. \]

(3.8)

Thus we get a simplified equation of motion which is solved by modified Bessel functions, so we can express the initial conditions as

\[ \phi_{\infty} = A \frac{K_1(s)}{s}, \]

\[ \phi_{\infty}' = -A \frac{K_2(s)}{s}. \]

(3.9) (3.10)

These conditions are solved to obtain \( \phi_{\infty}' \) as a function of \( \phi_{\infty} \). We then again use simple bisection to find \( \phi_{\infty} \) which minimizes the field derivative at a very small \( s = \epsilon \) near the true vacuum.

Numerical problems arise in this scenario because standard model potential is very flat and the change induced by the new couplings appears only around the Planck scale, so we have to solve the equation of motion through sixteen orders of magnitude in the field \( \phi \). For this reason it is very hard to choose numerical values of \( \epsilon \) and \( \infty \) for parameter \( s \) such that the bisection converges to the desired solution. Hence we only required that one of the above methods converged at any given point.

The resulting lifetimes are shown in Figure 4 for constant couplings \( \lambda_6 \) and \( \lambda_8 \).

Figure 4: Decimal logarithm of lifetime of the universe in units of \( T_U \) as a function of constant couplings \( \lambda_6 \) and \( \lambda_8 \).
We can distinguish 3 different areas in Figure 4. The first one with both new couplings positive corresponds to the SM potential stabilised by new interactions at the Planck scale. The resulting lifetimes are very close to SM one, because the bounce solution with SM potential starts at field values smaller than Planck mass ($\phi_0 < M_p$). The second region with $\lambda_8 < 0$ corresponds to a potential unbounded from below, and as we can see a quickly decaying bounce solution appears when $\lambda_8$ becomes negative. The last region with positive $\lambda_8$ but negative $\lambda_6$ corresponds to a stabilized potential with a new minimum around the Planck scale which can be approximated with an analytical solution described in the previous section.

To further increase the accuracy of above prediction we solved the equation of motion (3.1) numerically taking into account the 1-loop running of $\lambda_6$ and $\lambda_8$ from equation (2.3) together with 2-loop Standard Model RGEs. The resulting lifetimes are shown in Figure 5.

![Figure 5: Decimal logarithm of lifetime of the universe in units of $T_U$ as a function of running couplings $\lambda_6$ and $\lambda_8$ calculated at the scale $M$.](image)

Examples of running of new couplings in Figure 1 show that their values can change significantly, but the most important qualitative difference comes from the $\lambda_6^2$ contribution to the running of $\lambda_8$ (see equation (2.3)). In Figure 1 we see that for large enough $\lambda_6$ it can stabilize the potential by pushing $\lambda_8$ to positive values not far above the Planck scale, when $\lambda_8(M_p)$ is negative but has small enough modulus. This effect bends the metastability curve in Figure 5 towards more negative $\lambda_8$ near edges of the plot where $|\lambda_6|$ is large.

### 3.3 Comparison of different methods

Figure 6 shows comparison of results obtained using the methods described above. The analytical approximation is accurate enough for qualitative analysis, however more careful numerical analysis results in a larger stability region. The same can be said about the effect of taking into account
running of nonrenormalisable couplings, where sufficiently large contribution from $\lambda_6$ to running of $\lambda_8$ can save otherwise unstable vacua.

Figure 6: Contours corresponding to metastability boundary ($\tau = T_u$) obtained using four different methods.

4 Standard Model phase diagram

To illustrate effects of new nonrenormalisable operators on Standard model vacuum stability in Figure 7 we show the well known standard model phase diagram (see for example [2]) and the same diagram after including new operators, respectively $\lambda_6(M_p) = -1/2, -1$ and $\lambda_8(M_p) = 1, 1/2$.

Figure 7: Standard Model phase diagram (left panel), the same diagram after including new operators $\lambda_6(M_p) = -1/2$ and $\lambda_8(M_p) = 1$ (middle panel) and $\lambda_6(M_p) = -1$ and $\lambda_8(M_p) = 1/2$ (right panel). The white region corresponds to absolute stability, and the black line marks the instability border.

Above plots clearly show that nonrenormalisable interactions suppressed by the Planck mass can drastically change the SM phase diagram, by pushing electroweak vacuum towards the instability region.
5 Lowering the magnitude of the suppression scale

In this section we will discuss how lowering the suppression scale $M$ in (2.1) changes our results. To analyse this problem qualitatively it is enough to use the analytical approximation we presented in section 3.1. When nonrenormalisable operators are positive, lowering the suppression scale $M$ corresponds simply to making the potential positive not far above $M$. The action (the exponent in (3.5)) increases because the position of the minimum of $\lambda_{eff}$ shifts towards smaller energy scales and the value of $|\lambda_{eff}|$ decreases, which is shown in Figure 8.

![Figure 8: Scale dependence of $\lambda_{eff}$ with $\lambda_6 = \lambda_8 = 1$ for different values of suppression scale $M$. The lifetimes corresponding to suppression scales $M = 10^8, 10^{14}, 10^{16}$ are, respectively, $\log_{10}(\tau_u) = \infty, 1302, 581$ while for the Standard Model $\log_{10}(\tau_u) = 540$.](image)

In the case with positive $\lambda_8$ and negative $\lambda_6$ this dependence is smaller as shown in Figure 9. The new minimum is deeper and changing the scale changes $\lambda_{eff}$ by a small fraction of its value so the resulting lifetimes are much less scale dependent. In fact, in this case scale dependence of lifetime comes mostly from the prefactor in (3.5), because the size of the bounce is $\phi_0 \approx \mu_{min} \propto M$. 

10
Figure 9: Scale dependence of $\lambda_{eff} = \frac{V}{\phi^4}$ with $\lambda_6 = -1$ and $\lambda_8 = 1$ for different values of suppression scale $M$. The lifetimes corresponding to suppression scales $M = 10^8, 10^{12}, 10^{16}$, are, respectively, $\log_{10}(\tau_{UV}) = -45, -90, -110$ while for the Standard Model $\log_{10}(\tau_{UV}) = 540$.

The last possibility is a potential unbounded from below which again corresponds to quickly decaying solutions, that depend on $M$ very much like in the previous case. Because their action is very close to zero, the actual dependence of the corresponding lifetime comes from the size of the bounce in the prefactor of (3.4).

5.1 Superplanckian suppression and two different suppression scales

Conclusions about the behaviour of the models with the suppression scale larger than the Planck scale and with two different suppression scales can be drawn from Figures 4 and 6 looking at the regions where both or one of the couplings $\lambda_6$ and $\lambda_8$ are much smaller than 1. One can see that even there various effects are possible depending on signs of each coupling.

6 Summary

In this paper we have made a map of the vacua in the SM extended by nonrenormalisable scalar couplings, taking into account the running of the new couplings and going beyond the standard assumptions taken when calculating the lifetime of the metastable vacuum. Usually, one uses certain quasi-analytic approximations of the effective potential, [10], for the purpose of calculating the tunneling rate. In particular, one uses as the departure point the calculation for the quartic-like form of the effective potential at large field strengths, while in the modified scalar potential it is the order 6 or order 8 coupling which naively dominates the potential in the large field domain. It is important to check the validity of such approximation and to search through a relatively wide scope of new couplings to find the actual behaviour of the scalar potential. The ultimate tool in this case is the direct numerical analysis, which however is not so straightforward because of the flatness of the effective potential. In this paper we present currently available results of such extended analysis.
of the modified SM scalar potential. It turns out that the simplified analytical approach represents reasonably well the actual numerical results. In general, we confirm that it is relatively easy to destabilise the SM with the help of the Planck scale suppressed scalar operators. While it is possible to stabilise the SM by adding such higher dimensional interactions and taking into account running of the new couplings, the generic effect is shortening the lifetime and hence further destabilisation of the SM electroweak vacuum. This conclusion has been illustrated with the phase diagrams of modified SM-like models. It has been demonstrated that effective stabilisation can be achieved by lowering the suppression scale of higher order operators while picking up such combinations of new couplings, which do not deepen the new minima of the potential. Our results show the dependence of the lifetime of the electroweak minimum on the magnitude of the new couplings, including cases with very small couplings (which means very large effective suppression scale) and couplings vastly different in magnitude (which corresponds to two different suppression scales).
