Abstract

Drawing from the LEGA-C data set, we present the spectroscopic view of the stellar population across a large volume- and mass-selected sample of galaxies at large look-back time. We measure the 4000 Å break ($D_{n4000}$) and Balmer absorption line strengths (probed by Hδ) from 1019 high-quality spectra of $z = 0.6–1.0$ galaxies with $M_e = 2 \times 10^{10} M_{\odot}$ to $3 \times 10^{11} M_{\odot}$. Our analysis serves as a first illustration of the power of high-resolution, high signal-to-noise ratio continuum spectroscopy at intermediate redshifts as a qualitatively new tool to constrain galaxy formation models. The observed $D_{n4000}$–EW(Hδ) distribution of our sample overlaps with the distribution traced by present-day galaxies, but $z \sim 0.8$ galaxies populate that locus in a fundamentally different manner. While old galaxies dominate the present-day population at all stellar masses $>2 \times 10^{10} M_{\odot}$, we see a bimodal $D_{n4000}$–EW(Hδ) distribution at $z \sim 0.8$, implying a bimodal light-weighted age distribution. The light-weighted age depends strongly on stellar mass, with the most massive galaxies $>1 \times 10^{11} M_{\odot}$ being almost all older than 2 Gyr. At the same time, we estimate that galaxies in this high-mass range are only $\sim$3 Gyr younger than their $z \sim 0.1$ counterparts, at odds with purely passive evolution given a difference in look-back time of $>5$ Gyr; younger galaxies must grow to $>10^{11} M_{\odot}$ in the meantime, or small amounts of young stars must keep the light-weighted ages young. Star-forming galaxies at $z \sim 0.8$ have stronger Hδ absorption than present-day galaxies with the same $D_{n4000}$, implying larger short-term variations in star formation activity.

Key words: galaxies: evolution – galaxies: high-redshift – galaxies: stellar content

1. Introduction

The Sloan Digital Sky Survey (SDSS; York et al. 2000) produced one of the most valuable legacy data sets for galaxy evolution studies. From the strengths and shapes of spectral lines, the SDSS spectra provide diagnostics for fundamental physical properties of individual galaxies: ages and metal content of stellar populations, star formation rates (SFRs), metallicity in the interstellar medium (ISM), and internal dynamics. Furthermore, with hundreds of thousands of spectra, the SDSS has characterized various galactic scaling relations (Brinchmann et al. 2004; Tremonti et al. 2004; Gallazzi et al. 2005, to name a few). This information shaped our understanding of the formation of galaxies.

Despite its tremendous success, the SDSS is mainly confined to the nearby universe. The median redshift of the SDSS spectroscopic main sample is $z \sim 0.1$, which corresponds to $\sim$1 Gyr of look-back time (Strauss et al. 2002). On the other hand, deep wide-field optical and near-infrared (NIR) imaging surveys have pushed the census of galaxy population to $z \sim 4$ (Marchesini et al. 2009; Ilbert et al. 2013; Muzzin et al. 2013). From photometric studies, we have constructed the growth history of the stellar mass density as a function of cosmic time. We know that $\sim$90% of stars form after $z \sim 2$ and about half of stars formed since $z \sim 1$ (Rudnick et al. 2003; Muzzin et al. 2013; Madau & Dickinson 2014). The relative abundance of quiescent and star-forming galaxies also evolves with cosmic time. At low redshifts, massive galaxies are mainly quiescent, while at $z \sim 2$, star-forming galaxies become the dominant population at all masses (Ilbert et al. 2010; Muzzin et al. 2013). These observations show that the stellar population in high-redshift galaxies is very different from local galaxies. However, we have not yet understood the processes driving the assembly of stellar masses and shaping the star-forming properties of galaxies throughout cosmic time.

Spectroscopic redshift surveys, such as DEEP2 (Newman et al. 2013), zCOSMOS (Lilly et al. 2007), VVDS (Le Fèvre 2013), or VIPERS (Guzzo et al. 2014; Garilli et al. 2014), have gathered tens of thousands of galaxy spectra using multiobject
spectrographs on 8–10 m class telescopes, thereby pushing the spectroscopic census of galaxy population to \( z \sim 1 \) and beyond. In order to obtain a large number of spectra, these surveys need to compromise on the signal-to-noise ratio or spectral resolution in exchange for sample sizes. They provide a profound resource for studying the star formation and ISM properties through emission lines. However, the quality of these spectra is usually not good enough to constrain the ages and metallicities of stars in individual galaxies through the stellar continuum. So far, our understanding of stellar populations of galaxies at \( z \sim 1 \) and beyond only comes from studies with sample sizes of a few dozen, mainly massive and quiescent galaxies (Kelson et al. 2001; Treu et al. 2005; van der Wel et al. 2005; Jørgensen & Chiboucas 2013; van de Sande et al. 2013; Choi et al. 2014; Gallazzi et al. 2014; Belli et al. 2015; Onodera et al. 2015). This is far from representative of the galaxy population at that epoch.

To achieve both the depth and sample size required for characterizing the stellar content in the early universe, we carry out the Large Early Galaxy Astrophysics Censuses (LEGA-C) survey (van der Wel et al. 2016). The LEGA-C survey will obtain \( \sim 3000 \) \( K_s \)-band-selected spectra at \( z \sim 1 \) with typical signal-to-noise ratio (S/N) of 20 \( \text{Å}^{-1} \). The quality of the spectra allows us to characterize the stellar populations of individual galaxies and galaxies as a population, akin to what has been achieved by the SDSS (Kauffmann et al. 2003a; Brinchmann et al. 2004; Gallazzi et al. 2005).

In this paper, we present measurements of two age-sensitive absorption line indices, the equivalent width of \( \text{H}\delta \) absorption [EW(\( \text{H}\delta \))] and the \( D_4 \) index, of 1019 galaxies selected from the LEGA-C survey. For a simple stellar population (SSP), the \( D_4 \) index increases monotonically with time. On the other hand, the EW(\( \text{H}\delta \)) increases rapidly in the first few hundreds of megayears when the O- and B-type stars fade and the A-type stars dominate the spectrum. The EW(\( \text{H}\delta \)) then decreases afterwards when A-type stars also fade. For a composite stellar population, the peak strength of the \( \text{H}\delta \) absorption depends on whether the SFR varies rapidly or changes smoothly. These two spectral features have been extensively used as diagnostics for the age of the stellar population and to discern recent star formation histories (SFHs; Kauffmann et al. 2003a; Le Borgne et al. 2006; Kauffmann 2014; Maltby et al. 2016).

In the local universe, Kauffmann et al. (2003b) showed that both the \( D_4 \) and EW(\( \text{H}\delta \)) of galaxies exhibit bimodal distributions, suggesting a bimodality in the light-weighted stellar ages. On average, lower mass galaxies have smaller \( D_4 \) and larger EW(\( \text{H}\delta \)), which indicate younger stellar populations. Furthermore, for star-forming galaxies, low-mass galaxies have stronger \( \text{H}\delta \) absorption, and the scatter of EW(\( \text{H}\delta \)) at fixed \( D_4 \) is larger than massive star-forming galaxies. These features suggest that low-mass star-forming galaxies have more bursty SFHs (Kauffmann et al. 2003a; Kauffmann 2014).

Recent spectroscopic surveys has pushed the census on the stellar ages of galaxies to higher redshifts. Similar to galaxies in the local universe, the \( D_4 \) of galaxies varies with the stellar mass, and the bimodal distribution is in place up to \( z \sim 1 \) (Vergani et al. 2008; Haines et al. 2017). Studies on the EW(\( \text{H}\delta \)) are limited, targeting mainly quiescent galaxies and through stacked spectra (Shudek et al. 2017). Because of the typically low S/N or low spectral resolution of high-redshift spectroscopic surveys, the uncertainty of EW(\( \text{H}\delta \)) measurements on individual galaxies is too large and the emission line infilling cannot be estimated, preventing accurate constraints on recent star formation activity.

In this paper, we show that the individual LEGA-C spectrum contains precise age information for both star-forming and quiescent galaxies. With over 1000 galaxies, we are able to describe the average age and the patterns of recent star formation activities at a look-back time of \( \sim 7 \) Gyr. We describe the galaxy sample and the quality of the spectral index measurements in Section 2. In Section 3, we present the distribution of \( D_4 \) and EW(\( \text{H}\delta \)) at \( z \sim 0.8 \) and the comparison to SDSS galaxies at \( z \sim 0.1 \). We discuss the implications of our results in Sections 4 and 5. We summarize the paper and point out future directions in Section 6.

2. Data and Analysis

2.1. The LEGA-C Sample at \( z \sim 0.8 \)

The LEGA-C survey is a four-year survey using the VIMOS (Le Fèvre et al. 2003) mounted on the 8 m Very Large Telescope to obtain rest-frame optical spectra of \( \sim 3000 \) \( K_s \)-band-selected galaxies mainly at \( 0.6 \leq z \leq 1.0 \). Each galaxy receives \( \sim 20 \) hr of integration at a spectral resolution of \( R \sim 3500 \). The typical continuum S/N is 20 \( \text{Å}^{-1} \).

This study is based on the first two years of data of the LEGA-C survey. The primary sample of the LEGA-C survey consists of those galaxies brighter than \( K_s = 20.7–7.5 \times \log((1+z)/1.8) \) and with redshifts \( 0.6 \leq z \leq 1.0 \) (van der Wel et al. 2016). From the LEGA-C primary sample, we then select galaxies with stellar mass \( 10.3 \leq \log(M_*/M_\odot) \leq 11.5 \) to make a mass-limited sample. The lower mass limit ensures that the \( K_s \)-band magnitude limit of the LEGA-C survey does not introduce a strong bias against red galaxies at the low-mass end. We also require that the spectra cover the wavelength range for measuring the \( D_4 \) and EW(\( \text{H}\delta \)). We then exclude galaxies detected in X-ray, whose spectra are usually contaminated by the active galactic nucleus.

In total, 1050 galaxies fulfill the redshift and stellar mass criteria. We then also require a minimum median S/N = 5 \( \text{Å}^{-1} \) between rest-frame wavelengths 4000 \( \text{Å} \) and 4300 \( \text{Å} \). This S/N cut excludes 31 galaxies, or \( \sim 3\% \) of the sample. The spectral indices of these low-S/N spectra are mostly unphysical; therefore, we decide to exclude them from the sample. The majority of these galaxies are bright enough in the \( K_s \) band to be included in the survey, but have red colors and faint optical magnitudes, resulting in low-S/N spectra. They tend to have axis ratios <0.5. These galaxies are likely edge-on galaxies whose optical light is attenuated because of the inclination. We have also included these galaxies and repeated our analysis in the paper, and the results are not affected. The final sample contains 1019 galaxies from the 1550 galaxies.

We derive galaxy stellar masses by fitting the observed multiwavelength spectral energy distributions (SEDs) from the UltraVISTA catalog (Muzzin et al. 2013) using the FAST code (Kriek et al. 2009). The SED templates are from the Bruzual & Charlot (2003) stellar population synthesis models with exponentially declining SFRs. We adopt a Chabrier (2003) initial mass function (IMF) and the Calzetti et al. (2000) dust extinction law. The SFRs are estimated from the UV and IR luminosities, following the prescription of Whitaker et al.
The emission-line subtraction has little effect on $D_{n4000}$ and the $\delta_{4000}$ index. Both indices are measured from emission-line-subtracted spectra.

Both corrections are well understood, as the $K_s$-band flux is the only factor that determines the probability that a galaxy is part of the LEGA-C survey (van der Wel et al. 2016). We refer to the forthcoming Data Release paper for details (C. Straatman et al. 2018, in preparation). We apply the completeness correction when comparing the LEGA-C sample to the completeness-corrected SDSS sample (see Section 2.3).

2.2. Measuring $D_{n4000}$ and EW($H\delta$) from LEGA-C Spectra

In this paper, we measure two stellar absorption line indices: the 4000 Å break, $D_{n4000}$, and the equivalent width of the Balmer absorption, EW($H\delta$). To separate the stellar continuum from the ionized gas emission, we model the observed spectrum using the Penalized Pixel-Fitting (pPXF) method (Cappellari & Emsellem 2004) with the updated Python routines (Cappellari 2017). Each galaxy spectrum is fit by a combination of two templates representing the stellar and the gas emission. The stellar template is a linear, optimal nonnegative combination of Vazdekis (1999) SSP models with the Medium resolution INT Library of Empirical Spectra (MILES; Sánchez-Blázquez et al. 2006) empirical stellar spectra and Girardi et al. (2000) isochrones. All emission lines are fit as a single kinematic component, that is, with the same velocity and velocity dispersion, but the strength of each line is a free parameter. We refer to Bezanson et al. (2018) for the detailed fitting process and Figure 2 for an example.

We adopt the definition of the $D_{n4000}$ in Balogh et al. (1999) and the $H\delta_a$ index in Worthey & Ottaviani (1997) as our EW($H\delta_a$). Both indices are measured from emission-line-subtracted spectra. The emission-line subtraction has little effect on $D_{n4000}$ but is important for EW($H\delta_a$). Our visual inspection suggests that the fit captures weak emission-line infilling well. Using 25 galaxies observed twice by the LEGA-C survey, we estimate the uncertainty on our emission line strength measurements. We estimate the typical uncertainties of our final $D_{n4000}$ and EW($H\delta_a$) measurements to be $\sim$0.03 and $\sim$0.4 Å, respectively.

In Figure 3(a), we show three galaxies with SSP ages of $\sim$1–2 Gyr (see Section 3). Our spectra clearly differentiate the evolution of the $H\delta$ strength within $\sim$1 Gyr. Figure 3(b) shows three galaxies with older SSP ages of $\sim$2–3 Gyr. The different shapes of the continua can be easily identified by visual inspection and quantified by the $D_{n4000}$ index.

2.3. SDSS Sample at $z \sim 0.1$

From the SDSS DR7 (Abazajian et al. 2009), we first select galaxies from a narrow redshift range $0.04 \leq z \leq 0.14$ ($z_{\text{median}} \approx 0.1$) and mass range $10.3 \leq \log(M_*/M_\odot) \leq 11.5$. We further require a redshift-dependent lower mass limit, $\log(M_*/M_\odot) > 10.6 + 2.28 \times \log(z/0.1)$, the mass-completeness limit of the SDSS spectroscopic sample (Chang et al. 2015).

The SDSS spectra are obtained with a fiber spectrograph, while the LEGA-C spectra are obtained with slits. To make a proper comparison between the two data sets, we first require a $g$-band fiber aperture covering fraction of $\geq 20\%$ from the comparison of the 3 arcsec fiber flux with the total flux to mitigate the bias that fiber spectra sample only the central part of galaxies. We then apply a statistical correction on the $D_{n4000}$ and EW($H\delta$) to account for the age gradients of galaxies. We describe the derivation of the statistical correction in Section 2.4.

We adopt the stellar mass and spectral measurements by the MPA/JHU group (Kauffmann et al. 2003a; Brinchmann et al. 2004; Salim et al. 2007). The stellar masses are estimated by SED fitting, using templates constructed from the Bruzual & Charlot (2003) population synthesis code, assuming a range of SFHs and metallicities with a Chabrier (2003) IMF. The basic assumptions are the same as the templates we used to derive the stellar masses of LEGA-C galaxies.

For the $D_{n4000}$ and EW($H\delta$), we adopt the measurement on the data after subtracting emission lines. To account for volume incompleteness, each galaxy is assigned a weight $1/V_{\text{max}}$, where $V_{\text{max}}$ is the maximum volume for which the galaxy would be included in the sample based on our redshift-dependent lower mass limit. The redshift and mass distributions of the SDSS sample are shown in Figure 1.

Figure 1. Distributions of redshifts and stellar masses of the LEGA-C and SDSS samples. Upper panels: histograms of the LEGA-C sample. Lower panels: distributions of the LEGA-C (blue) and SDSS (white) samples with the completeness correction (see Section 2).
2.4. Estimating the Bias on Indices Introduced by SDSS Fibers

The SDSS fiber spectra probe the central part of galaxies. Recent integral field unit (IFU) surveys have shown that galaxies in the local universe have on average negative age gradients; in other words, galaxy outskirts are younger than the galaxy center (González Delgado et al. 2015; Goddard et al. 2017; Wang et al. 2017). Any redshift evolution is therefore exacerbated if we use SDSS fiber spectra to create a low-redshift baseline sample, as those measurements will be biased toward old ages. In the local universe, age gradients depend on galaxy morphological types, where early-type galaxies have only mild age gradients but late-type galaxies, especially Sa and Sb galaxies, exhibit strong age gradients (González Delgado et al. 2015; Goddard et al. 2017). Estimating the aperture bias by galaxy types is thus necessary.

Wang et al. (2017) measured the $D_{n}4000$ and EW(Hδ) as a function of the effective radius ($R_e$) out to $1.5R_e$ for galaxies in the Mapping Nearby Galaxies at APO (MaNGA, Bundy et al. 2015) survey. They reported the profiles of $D_{n}4000$ and EW(Hδ) as a function of stellar masses and star formation properties of galaxies (Figure 8 in Wang et al. 2017).

Briefly, Wang et al. (2017) presented the index gradients of three types of galaxies, categorized by the equivalent width of H$\alpha$ emission and $D_{n}4000$: “star-forming,” “partially quenched,” and “totally quenched.” The radial profiles of indices of “star-forming” and “partially quenched” galaxies are similar; therefore, we take the average of the two and refer to them as “star-forming” hereafter.

We use the index gradients to derive a statistical correction for our SDSS comparison sample. Using the slopes of $D_{n}4000$ and EW(Hδ) presented in Figure 8 of Wang et al. (2017), we calculate the difference between indices measured from the integrated light within $0.5R_e$ and $1.5R_e$ as the correction to be applied to the SDSS fiber measurements. Assuming a Sérsic $n = 4$ light profile, the two radii enclose $\sim30\%$ and $\sim60\%$ of total light, similar to the median fiber and slit covering fraction of our SDSS and LEGA-C sample, respectively.

We apply the correction of “totally quenched” galaxies to galaxies with weak H$\alpha$ emission (EW(H$\alpha$) $> -1$ Å) and the correction of “star-forming” galaxies to the rest. This scheme is motivated by Figure 11 of Wang et al. (2017), which showed that the integrated EW(H$\alpha$) within $0.5R_e$ serves as a reasonable demarcation between the two types of galaxies.

In summary, the correction to the SDSS sample depends on stellar mass and the equivalent width of H$\alpha$ emission in the fiber (Figure 4). The correction is larger for “star-forming” galaxies than “quiescent” galaxies, qualitatively consistent with the expectation from galaxy morphological types (González Delgado et al. 2015; Goddard et al. 2017). We implicitly assume that all SDSS galaxies have a Sérsic $n = 4$ light profile and the fiber covers out to $0.5R_e$; then we correct the indices to the values as they were observed out to $1.5R_e$. Different Sérsic profiles have little effect; the correction differs by $\sim20\%$ between $n = 1$ and $n = 6$. A more accurate comparison would involve creating mock slit spectra from MaNGA or other local IFU surveys like CALIFA (Sánchez et al. 2012; Walcher et al. 2014) and SAMI (Bryant et al. 2015), mimicking the observing condition and aperture size of the LEGA-C survey (Bezanson et al. 2018).

The corrected $D_{n}4000$ is smaller and EW(Hδ) is larger than the measured values (Figure 4). Galaxies shift along the locus on the $D_{n}4000$–EW(Hδ) plane in Section 3. We also repeat the
analysis in this paper using uncorrected indices. The inferred stellar age in Section 5 becomes $< 1$ Gyr older. Our main conclusion in the paper does not change.

3. The 4000 Å Break and Balmer Absorption Strength of Galaxies at $z \sim 0.8$

About half of stars in the present-day universe formed since $z \sim 1$ (Dickinson et al. 2003; Rudnick et al. 2003; Ilbert et al. 2010; Muzzin et al. 2013). The stellar population at $z \sim 0.8$ is thus expected to be very different from galaxies in the local universe. With over 1000 high-quality spectra, we are able to construct the distributions of $D_n4000$ and $\text{EW}(H\delta)$ and, for the first time, the distribution of galaxies on the $D_n4000$--$\text{EW}(H\delta)$ plane at $\sim 7$ Gyr look-back time. In this section, we present the inventories of stars in galaxies of the same stellar masses at two epochs.

3.1. Distribution of $D_n4000$ and $\text{EW}(H\delta)$ as a Function of Stellar Mass

Figure 5 shows the histogram of $D_n4000$ and $\text{EW}(H\delta)$ of the completeness-corrected LEGA-C and SDSS samples in each...
stellar mass bin. The median, 68th, and 95th percentiles of the distribution are listed in Table 1.

At $z \sim 0.8$, the $D_{4000}$ distribution depends on the stellar mass. The median $D_{4000}$ shifts from 1.43 in the low-mass bin to 1.68 in the high-mass bin. The distribution of $D_{4000}$ is narrower in the high-mass bin, as quantified by the 16th and 84th percentiles. There is only a small fraction of galaxies with $D_{4000} < 1.4$, which is the median value of the low-mass bin. This result is in broad agreement with the distribution measured from the VVDS and the VIPERS survey based on lower $S/N$.

### Table 1

| Stellar Mass | $D_{4000}$ | EW($\delta$) |
|--------------|------------|-------------|
| $10.3 < \log(M_*/M_\odot) < 10.7$ | 1.16 | 0.80 |
| $10.7 < \log(M_*/M_\odot) < 11.1$ | 1.21 | 0.90 |
| $11.1 < \log(M_*/M_\odot) < 11.5$ | 1.35 | 1.00 |
| **All** | 1.17 | 0.78 |

| Stellar Mass | $D_{4000}$ | EW($\delta$) |
|--------------|------------|-------------|
| $10.3 < \log(M_*/M_\odot) < 10.7$ | 1.21 | 0.81 |
| $10.7 < \log(M_*/M_\odot) < 11.1$ | 1.26 | 0.91 |
| $11.1 < \log(M_*/M_\odot) < 11.5$ | 1.39 | 1.01 |
| **All** | 1.23 | 0.80 |

Figure 5. Distribution of $D_{4000}$ and EW($\delta$) of LEGA-C (blue, $z \sim 0.8$) and SDSS (white, $z \sim 0.1$) samples with completeness correction. Each panel shows galaxies in 0.4 dex stellar mass bins. The error bars indicate the 16th, 50th, and 84th percentiles of the distributions. At fixed stellar mass, LEGA-C galaxies have on average smaller $D_{4000}$ and larger EW($\delta$), indicating younger populations. At $z \sim 0.8$, the distributions of both $D_{4000}$ and EW($\delta$) depend on stellar mass.
spectrum (Vergani et al. 2008; Haines et al. 2017). At $z \sim 0.1$, the $D_n4000$ distribution depends less on mass, with peaks at $D_n4000 \approx 1.8$ at all masses. The major difference is that the tail to low $D_n4000$ vanishes, as can be seen from the 2.5th and 16th percentiles in Table 1.

Figure 5(b) shows for the first time the distribution of $EW(H\delta)$ at $z \sim 0.8$. Similar to the distribution of $D_n4000$, the $EW(H\delta)$ distribution at $z \sim 0.8$ also depends strongly on the stellar mass. In the low-mass bin, the $EW(H\delta)$ distributes around $EW(H\delta) \approx 4$ Å. In the high-mass bin, the median shifts to $EW(H\delta) \approx 0$ Å, and there are very few galaxies with $EW(H\delta) > 4$ Å. On the other hand, the distributions at $z \sim 0.1$ center at $EW(H\delta) \approx -1$ Å for all masses. Similarly, the tail to the younger end (larger $EW(H\delta)$) vanishes in the high-mass bin.

3.2. The $D_n4000$–$EW(H\delta)$ Plane

Figure 6 shows LEGA-C galaxies on the $D_n4000$–$EW(H\delta)$ plane. Overall, galaxies at $z \sim 0.8$ are located along a diagonal sequence on the $D_n4000$–$EW(H\delta)$ plane. As the stellar mass increases, the population moves from the top left toward the bottom right corner of the panel, that is, larger $D_n4000$ and smaller $EW(H\delta)$, indicating an overall older stellar population in more massive galaxies (Kauffmann et al. 2003b; Studek et al. 2017).

In Figure 6(a), galaxies are color-coded according to the specific star formation rate (sSFR), the SFR divided by the stellar mass. The sSFR and $D_n4000$ are correlated such that galaxies with high sSFRs also have small $D_n4000$. The correlation between the sSFR and $D_n4000$ is qualitatively similar to the correlation found for galaxies at $z \sim 0.1$ (Brinchmann et al. 2004).

Figure 6(b) shows again the LEGA-C galaxies. Star-forming galaxies and quiescent galaxies in the UVJ two-color classification scheme (Muzzin et al. 2013) are plotted in blue and red, respectively. The star-forming/quiescent classification based on the UVJ colors and sSFR, adopting $sSFR = 10^{-10}$ yr$^{-1}$ as demarcation, is in good agreement. On the $D_n4000$–$EW(H\delta)$ plane, the star-forming and quiescent galaxies can be roughly separated by $D_n4000 \approx 1.55$ or $EW(H\delta) \approx 2$ Å.

Figure 6(c) shows the density contours of LEGA-C galaxies with the completeness correction in blue and SDSS galaxies in black. For galaxies with $10.3 < \log(M_*/M_\odot) < 11.5$, the LEGA-C distribution is double-peaked, with a valley located at $D_n4000 \approx 1.55$ and $EW(H\delta) \approx 2$ Å, corresponding to the separation between star-forming and quiescent galaxies. This bimodal distribution of galaxies on the $D_n4000$–$EW(H\delta)$ plane is also present in the nearby universe with similar demarcation (Kauffmann et al. 2003b).

Galaxies at $z \sim 0.8$ and $z \sim 0.1$ occupy a qualitatively similar locus on the $D_n4000$–$EW(H\delta)$ plane but populate this locus differently. At $z \sim 0.1$, the distribution peaks at $D_n4000 \sim 1.9$ and $EW(H\delta) \sim -2$ Å. On the contrary, quiescent galaxies at $z \sim 0.8$ have on average smaller $D_n4000$ and larger $EW(H\delta)$. Also, there are very few galaxies at $z \sim 0.8$ with $D_n4000 > 1.9$ or $EW(H\delta) < -2$ Å. Furthermore, Figure 6(c) shows that the distribution of LEGA-C galaxies extends to higher $EW(H\delta)$, especially for galaxies with small $D_n4000$. Previous studies based on principal component analyses of spectra also suggest a higher fraction of galaxies with strong $H\delta$ at higher redshifts (Wild et al. 2009; Rowlands et al. 2018).

4. The Strong H$\delta$ Absorption at $z \sim 0.8$

Figure 7 shows the distribution of $EW(H\delta)$ in four narrow $D_n4000$ bins for galaxies with $D_n4000 \lesssim 1.5$, where star-forming galaxies dominate the population. Except for the lowest $D_n4000$ bin, the $EW(H\delta)$ distributions of galaxies at $z \sim 0.8$ extend to larger $EW(H\delta)$ and are on average broader. We fit a Gaussian profile to each $EW(H\delta)$ distribution and list the best-fit parameters in Table 2.

The strong Balmer absorption lines in star-forming galaxies are usually interpreted as evidence for a rapidly declining SFR in the last $\lesssim 1$ Gyr. An illustration is shown in Figure 6(d). We plot Bruzual & Charlot (2003) evolutionary tracks of four different SFHs with solar metallicity: an SSP and three exponential-decay SFHs with 0.5, 2, and 4 Gyr decaying time $\tau$. The strength of the H$\delta$ absorption increases after the O- and B-type stars fade away and the A-type stars dominate the optical spectrum. Rapidly declining SFHs, for example, SSP or $\tau = 0.5$ Gyr, will elevate the $EW(H\delta)$ at $D_n4000 \lesssim 1.5$ for several hundred megayears compared to a more gently declining SFH. Thus, the higher $EW(H\delta)$ suggests that the SFHs of $z \sim 0.8$ star-forming galaxies change more rapidly than in low-$z$ star-forming galaxies.

Based on observed evolution of the star-formation main sequence (MS), Leitner (2012) derived analytic formulae for average SFHs of star-forming galaxies. We can thus calculate the average declining rate of the SFHs in the 1 Gyr period prior to $z \sim 0.8$ and $z \sim 0.1$. Adopting the parameterized MS evolution $\psi(M_*, z) \propto M_*^{4+\alpha}(1 + z)^{\beta}$ with $\alpha = 3.45$ and $\beta = -0.35$ (Karim et al. 2011, see also Damen et al. 2009; Oliver et al. 2010; Fumagalli et al. 2012) and the analytic formulae in Leitner (2012), we find the average SFHs of star-forming galaxies in the 1 Gyr period prior to $z \sim 0.8$ and $z \sim 0.1$ can be approximated by the $\tau$ model with $\tau \approx 2$ Gyr and $\tau \approx 4$ Gyr, respectively.

Exponentially declining SFH models with $\tau \approx 2$ Gyr and $\tau \approx 4$ Gyr occupy very similar loci on the $D_n4000$–$EW(H\delta)$ plane; therefore, the increase in average SFR from $z \sim 0.1$ to $z \sim 0.8$ does not explain the stronger H$\delta$ absorption at $z \sim 0.8$. Instead, the strong H$\delta$ absorption implies that the SFHs of individual galaxies have stronger time variabilities than the average evolution of the star formation MS at $z \sim 0.8$. A star-forming galaxy may experience starburst events while it stays in the MS or oscillate up and down within the MS in a timescale shorter than the evolution of average sSFR. Galaxies with recent, rapidly declining SFHs will have stronger Balmer absorptions and deviate from the main locus on the $D_n4000$–$EW(H\delta)$ plane for a few hundred megayears and create an excess at large $EW(H\delta)$, and the $EW(H\delta)$ distribution becomes broader (Kauffmann et al. 2003a).

The high-variability SFHs in star formation galaxies at higher redshifts are also suggested by the cosmological zoom-in simulations. The Feedback in Realistic Environments (FIRE; Hopkins et al. 2014) showed that all galaxies at high redshifts ($z \gtrsim 1$) have bursty SFHs, while massive, $\sim L_*$ galaxies settle to steady SFHs at $z \lesssim 1$ (Orr et al. 2017; Sparre et al. 2017; Faucher-Giguère 2018). The strong time variability of SFHs has been observed in local dwarf galaxies by comparing SFHs derived from H$\alpha$ and FUV emission, which trace different timescales (Weisz et al. 2012). The large scatter of the $EW(H\delta)$
in low-mass galaxies at \( z \sim 0.1 \) is another sign of bursty SFHs (Kauffmann et al. 2003a; Kauffmann 2014). At \( z \sim 0.7 \), Guo et al. (2016) used \( \mathrm{H} \beta \) and FUV and found that the SFRs of low-mass galaxies (\( M_\star < 10^{9.5} \, M_\odot \)) have stronger time variability than galaxies at low redshifts. This redshift evolution is in qualitative agreement with numerical simulations. Our result provides evidence that the SFRs of higher mass galaxies at \( z \sim 0.8 \) also vary in a short timescale. The rapidly changing SFRs left imprints on the stellar population through the \( \mathrm{H} \delta \) absorption, which lasts for a longer timescale of a few hundred megayears, and the difference between \( z \sim 0.8 \) and \( z \sim 0.1 \) is visible on the \( D_{4000} - \mathrm{EW}(\mathrm{H} \delta) \) plane.

Figure 6. Distribution of LEGA-C and SDSS galaxies on the \( D_{4000} - \mathrm{EW}(\mathrm{H} \delta) \) plane in different stellar mass bins. (a) The colored dots are individual LEGA-C galaxies, color-coded by sSFR. Galaxies with \( sSFR < 10^{-10} \, \text{yr}^{-1} \) are in red. The \( D_{4000} \) correlates with sSFR, where high-sSFR galaxies have small \( D_{4000} \). The cross in the bottom left corner is the typical uncertainty. The \( \mathrm{EW}(\mathrm{H} \delta) \) uncertainty is smaller than the \( \mathrm{EW}(\mathrm{H} \delta) \) distribution at \( D_{4000} \), so our measurements resolve the recent star formation histories of individual galaxies through \( \mathrm{EW}(\mathrm{H} \delta) \). (b) The same LEGA-C galaxies as in panel (a), color-coded by the star-forming/quiescent classification in the UVJ two-color scheme. The star-forming galaxies and quiescent galaxies are roughly separated by \( D_{4000} \approx 1.55 \) and \( \mathrm{EW}(\mathrm{H} \delta) \approx 2 \, \AA \). (c) Distributions of completeness-corrected LEGA-C and SDSS samples. Blue solid contours represent the LEGA-C sample, and the dashed contours represent the SDSS sample. Contour levels are at 0.05, 0.20, 0.40, and 0.80 times the peak value for each sample. The LEGA-C sample exhibits a bimodal distribution on the \( D_{4000} - \mathrm{EW}(\mathrm{H} \delta) \) plane, while the SDSS sample does not. (d) An illustration of how a galaxy evolves on the \( D_{4000} - \mathrm{EW}(\mathrm{H} \delta) \) plane with different SFHs. Four SFHs are shown (top to bottom): SSP, 0.5, 2, and 4 Gyr \( \tau \) decaying time. All models are with solar metallicity. The models with 2 and 4 Gyr \( \tau \) decaying time occupy almost the same loci. The contour levels are the same as those in panel (c).
subsolars, with an average log($Z_n/Z_\odot$) = −0.21 (Gallazzi et al. 2014). We have compared the loci of the Bruzual & Charlot (2003) models of solar and subsolar metallicity ($Z_n/Z_\odot$ = 0.4) with various SFHs on the $D_n4000$–EW($H\delta$) plane. We find that the subsolar metallicity does not produce larger EW($H\delta$) at fixed $D_n4000$.

Alternatively, dust can alter both the $D_n4000$ and EW($H\delta$). The $D_n4000$, which is essentially a color index, will in general be larger when the dust attenuation is more severe (MacArthur 2005). The effect of dust on the EW($H\delta$) depends on the dust geometry. The EW($H\delta$) will be boosted up if the dust is distributed mainly around the birth clouds of young stars. In this case, the featureless continuum of hot stars is obscured, and the Balmer absorption feature from intermediate-age stars becomes more prominent. On the other hand, the diffuse interstellar dust has little effect on the measured EW($H\delta$) (MacArthur 2005).

If the difference in the EW($H\delta$) distribution is entirely due to the dust attenuation, galaxies at $z \sim 0.8$ must have a birth-cloud V-band attenuation $A_V \approx 2$ mag larger than that of SDSS galaxies to elevate the EW($H\delta$) by ~1 Å (MacArthur 2005). On the other hand, if we artificially decrease the $D_n4000$ of LEGA-C galaxies by ~0.07, the EW($H\delta$) distributions at fixed $D_n4000$ match that of the SDSS galaxies better. This shift in $D_n4000$ indicates that LEGA-C galaxies have $A_V$ more than 1.5 magnitudes larger than SDSS galaxies, assuming the Cardelli et al. (1989) extinction law. In either case, such a heavy extinction is inconsistent with previous studies, which found that the dust extinction of star-forming galaxies at $z \sim 0.8$ is similar to or only slightly higher than galaxies at $z \sim 0.1$ of the same stellar mass (Garn & Best 2010; Garn et al. 2010; Zahid et al. 2013; Leslie et al. 2018, see also Sobral et al. 2012; Domínguez et al. 2013; Kashino et al. 2013 for results up to $z \sim 1.6$).

In summary, the large EW($H\delta$) can only be explained by a rapidly changing SFR at $z \sim 0.8$. Changes in metallicity and dust attenuation cannot explain it. A full analysis incorporating SFR, metallicity, and dust requires using more spectral features, that is, full spectral fitting or combining with multiwavelength photometry (e.g., Pacifici et al. 2012, 2013). We will present the SFHs of individual galaxies at $z \sim 0.8$ constructed from the LEGA-C spectra in forthcoming papers (Chauke et al. 2018; C. Pacifici et al. 2018, in preparation).

### Table 2

| $D_n4000$ | $A_{\text{fit}}$ | $A_{\text{SSP}}$ |
|-----------|------------------|------------------|
| $1.1 < D_n4000 \leq 1.2$ | 5.23 ± 0.13 | 0.07 ± 0.13  |
| $1.2 < D_n4000 \leq 1.3$ | 5.34 ± 0.11 | 0.12 ± 0.01  |
| $1.3 < D_n4000 \leq 1.4$ | 4.36 ± 0.10 | 0.14 ± 0.01  |
| $1.4 < D_n4000 \leq 1.5$ | 3.73 ± 0.17 | 0.12 ± 0.01  |

Note. The Gaussian model is $A \times \exp[-(\text{EW}(H\delta) - \text{EW}(H\delta)_0)^2/(2 \times \sigma(H\delta)^2)]$.

## 5. Stellar Ages from $D_n4000$ and EW($H\delta$)

The $D_n4000$ and EW($H\delta$) are commonly used as proxies for the light-weighted stellar ages. Figure 8(a) shows again the distribution of LEGA-C galaxies on the $D_n4000$–EW($H\delta$) plane, together with Bruzual & Charlot (2003) evolutionary tracks of SSP and exponential-decline SFHs with $\tau = 0.5, 2$, and 4 Gyr with solar metallicity. For the stellar mass range discussed in this paper, a solar-metallicity population is a good approximation for galaxies at both $z \sim 0.1$ and $z \sim 0.8$ (Gallazzi et al. 2014).

Motivated by the evolutionary tracks in Figure 8(a), we combine $D_n4000$ and EW($H\delta$) to construct the distribution of galaxies along the ridge line of the diagonal distribution on the $D_n4000$–EW($H\delta$) plane. We compute a spectral age index as $15 \times D_n4000$–EW($H\delta$)–20.5. This new index represents the distribution on the $D_n4000$–EW($H\delta$) plane projected onto the ridge of LEGA-C contours (the black line in Figure 8(a)). The ridge of LEGA-C contours tracks closely the $\tau = 2$ Gyr model as well as the SSP model for old populations. If galaxies evolve as the model SFHs, galaxies of the same age have the same spectral age index. A larger index corresponds to an older...
Figure 8. (a) Distribution of LEGA-C galaxies on the Dn4000–EW(Hδ) plane, overplotted with model evolutionary tracks. The contours are the same as those in Figure 6(c), and model tracks are the same as those in Figure 6(d). The τ = 2 Gyr and τ = 4 Gyr models overlap with each other. Time steps of 0.5, 1, 2, 4, 8, and 12 Gyr are marked with black circles, gray squares, and white triangles for the SSP, τ = 0.5 Gyr, and τ = 2 Gyr models, respectively. The black line indicates the ridge line of the distribution. (b) Spectral age index as a function of time with different SFHs. The definition of the age spectral index is given in Section 5. The red, green, and blue curves represent the SSP, τ = 0.5 Gyr, and τ = 2 Gyr SFHs, respectively. The same time steps as in panel (a) are labeled. (c, d, e, f) Distributions of the spectral age index of LEGA-C galaxies (blue) and SDSS galaxies (white). Galaxies with older stellar populations have larger indices. The SSP ages are labeled on the top of each panel, assuming a solar metallicity. The solid curves are the best-fit two-Gaussian models of the LEGA-C sample. The error bars indicate the 16th, 50th, and 84th percentiles of the distributions.

| log(M*/M☉)          | 2.5% | 16% | 50%  | 84%  | 97.5% |
|---------------------|------|-----|------|------|-------|
| LEGA-C, z ~ 0.8     |      |     |      |      |       |
| 10.3 < log(M*/M☉) < 10.7 | -9.3 | -7.1 | -2.9 | 3.7  | 7.2   |
| 10.7 < log(M*/M☉) < 11.1 | -8.4 | -4.8 | 1.1  | 5.5  | 8.4   |
| 11.1 < log(M*/M☉) < 11.5 | -5.1 | -0.1 | 4.1  | 6.7  | 9.2   |
| All                 | -9.1 | -6.2 | -1.1 | 4.8  | 7.9   |
| SDSS, z ~ 0.1       |      |     |      |      |       |
| 10.3 < log(M*/M☉) < 10.7 | -7.7 | -2.4 | 6.5  | 9.7  | 11.7  |
| 10.7 < log(M*/M☉) < 11.1 | -6.3 | 0.8  | 7.4  | 10.0 | 11.9  |
| 11.1 < log(M*/M☉) < 11.5 | -2.8 | 5.0  | 8.6  | 10.5 | 12.1  |
| All                 | -7.3 | -1.1 | 7.1  | 9.9  | 11.8  |
stellar population. The constant $-20.5$ is chosen so that the zero point falls between the bimodal distribution (e.g., $D_n4000 \approx 1.55$ and EW(Hα) $\approx 2$ Å; Kauffmann et al. 2003b; Haines et al. 2017). The spectral age indices can be translated into ages according to Figure 8(b) based on different SFHs.

Figure 8(c) shows the distributions of the spectral age indices of the SDSS and the LEGA-C sample. Figures 8(d), (e), and (f) show the distributions in each stellar mass bin. The corresponding SSP ages are labeled on the top of the panels. The median, 68th, and 95th percentiles of the distribution are listed in Table 3. We note that the SSP ages should be interpreted with care. For star-forming galaxies, a single number of a luminosity-weighted age may not be a good quantitative age diagnostic (Zibetti et al. 2017, Chauke et al. 2018). On the other hand, for very old stellar populations, the spectral indices evolve little with time (see Figure 8(b)) and thus are not sensitive to stellar ages. Also, we assume a solar metallicity for all galaxies. The age would be underestimated if galaxies have subsolar metallicities and vice versa. The spectral age indices and the corresponding SSP ages are slightly affected by the dust extinction. Assuming a typical extinction at $z \sim 1$, we estimate a <0.5 Gyr effect on the SSP ages for both star-forming and quiescent galaxies. To compare the age difference between $z \sim 0.8$ and $z \sim 0.1$, the effect of dust is likely minimal because of the similar amount of extinction in both populations (Sobral et al. 2012; Dominguez et al. 2013; Kashino et al. 2013; Gallazzi et al. 2014).

At $z \sim 0.8$, the age increases with stellar mass. The mass-dependent stellar ages support the downsizing galaxy formation, where more massive galaxies formed in earlier times (Thomas et al. 2010), and this archaeological trend is already in place in the first half of cosmic time. The oldest galaxies with $M_*/M_\odot > 10^{11}$ are $\sim 5$ Gyr old, indicating that they form at $z \geq 3$. The formation redshifts are similar to those $z > 3$ quiescent galaxies spectroscopically confirmed recently (Gobat et al. 2012; Straatman et al. 2015; Glazebrook et al. 2017).

The distribution of the spectral age indices of the LEGA-C sample is double-peaked: the distribution of the spectral age index is better fit by a two-Gaussian model than a single Gaussian model. Using the F-test, we find that for the entire population and the two lowest mass bins, the null hypothesis that a two-Gaussian model provides no better fit than a one-Gaussian model is rejected with a probability of 0.01. On the other hand, the highest mass bin does not appear as a clear bimodal distribution as in other mass bins. The overall bimodal spectral age index distribution implies a bimodal light-weighted stellar age distribution. Figure 9 shows the fraction of galaxies with old stellar population (spectral age index >0) as a function of stellar masses. At $z \sim 0.8$, the fraction of the old population changes sharply with the stellar mass, from $\leq 40\%$ at the lowest mass bins to $>80\%$ at the highest mass bin. At log($M_*/M_\odot$) $\approx 10.8$, the old and young populations have similar number densities. This result is in broad agreement with several previous studies that classify galaxies using either broadband colors (Bundy et al. 2006; Pozzetti et al. 2010; Davidzon & Bolzonella 2013; Muzzin et al. 2013) or $D_n4000$ (Vergani et al. 2008; Haines et al. 2017).

Using the SSP age inferred from the spectral age index, we find that the massive galaxies (log($M_*/M_\odot$) > 11.1) at $z \sim 0.8$ are on average $\sim 3$ Gyr younger than massive galaxies at $z \sim 0.1$. The difference in galaxy ages is smaller than the age difference of the universe between the two epochs ($\sim 5.5$ Gyr).

Purely passive evolution of the massive galaxies at $z \sim 0.8$ cannot reproduce the massive galaxy population at $z \sim 0.1$. The current analysis assumes that massive galaxies at the two epochs both have solar metallicities. The conclusion does not change if we instead use supersolar metallicities (Jorgensen et al. 2017). Furthermore, if massive galaxies at lower redshifts are slightly more metal-rich, as suggested by previous studies (Choi et al. 2014; Gallazzi et al. 2014), the inferred age difference will be even smaller, further strengthening our result. The conclusion is consistent with Gallazzi et al. (2014), who derived ages using both SSP and composite stellar populations. Massive galaxies at high redshifts need to acquire younger stars from either star formation or by merging with other younger galaxies. Alternatively, lower mass galaxies at $z \sim 0.8$ need to grow their stellar masses and become young massive galaxies at $z \sim 0.1$ (Bell et al. 2004; Gallazzi et al. 2014). Obtaining the stellar metallicities of both star-forming and quiescent galaxies will help to constrain the evolutionary routes (Choi et al. 2014; Gallazzi et al. 2014).

6. Conclusions and Future Work

We measure the $D_n4000$ and EW(Hα) of 1019 galaxies at $0.6 \leq z \leq 1.0$ with $10.3 \leq \log(M_*/M_\odot) \leq 11.5$ using the first two years of data of the LEGA-C survey. With a typical S/N of $\sim 20$ Å$^{-1}$ and a spectral resolution $R \approx 3500$, we can separate the absorption features of the stellar continuum from the emission lines from the ISM, accurately quantifying the stellar population in both star-forming and quiescent galaxies. We show the distributions of $D_n4000$ and EW(Hα) as a function of stellar mass and, for the first time, where galaxies at $z \sim 0.8$ are located on the $D_n4000$–EW(Hα) plane for both individual galaxies and galaxies as a population.

At $z \sim 0.8$, galaxies exhibit a bimodal distribution on the $D_n4000$–EW(Hα) plane. The star-forming and quiescent populations can be roughly separated by $D_n4000 = 1.55$ and EW(Hα) = 2 Å as in the local universe. The majority of galaxies with log($M_*/M_\odot$) $\leq 10.7$ are star-forming galaxies and populate the upper left corner on the $D_n4000$–EW(Hα) plane. As the stellar mass increases, galaxies have on average...
larger D_4000 and smaller EW(Hδ), indicating a progressively older stellar population. At log(M_*/M_☉) ≥ 11.1, most galaxies have already moved off the red sequence at z ∼ 0.8 and occupy mainly the lower right corner on the D_4000–EW(Hδ) plane.

Using D_4000 and EW(Hδ) as age indicators, we find that at z ∼ 0.8, more massive galaxies have older stellar populations than less massive ones, confirming the downsizing galaxy formation scenario. The oldest massive galaxies at z ∼ 0.8 are consistent with forming at z ∼ 3.

The ages of galaxies at z ∼ 0.8 and z ∼ 0.1 are inconsistent with a passive evolution scenario even for massive galaxies. Massive galaxies at z ∼ 0.8 need to acquire young stars either from star formation in galaxies or by merging with other young galaxies, or lower mass galaxies at z ∼ 0.8 need to grow masses and become younger massive galaxies at z ∼ 0.1.

At fixed D_4000, star-forming galaxies at z ∼ 0.8 have on average stronger Hδ absorption, and the distribution of EW(Hδ) is wider than galaxies at z ∼ 0.1. This feature indicates that the SFRs in star-forming galaxies at z ∼ 0.8 vary rapidly. The SFRs of individual galaxies change in a timescale shorter than the average evolution of the star-formation main sequence. Star-forming galaxies at z ∼ 0.8 may experience starburst events more often or oscillate up and down within the main sequence.

We will derive the stellar ages of individual galaxies using all available spectral features, taking into account the effects of metallicity, dust attenuation, and complex SFHs (Gallazzi et al. 2014). We have carried out a full spectral fitting to reconstruct the SFHs of individual galaxies (Chauke et al. 2018). These stellar age estimates of galaxies at ∼ 0.7 Gyr look-back time will provide new constraints on galaxy formation models.

This work was based on observations made with the ESO Telescopes at the La Silla Paranal Observatory under program ID 194-A.2005 (LEGA-C Public Spectroscopy Survey). This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program (grant agreement No. 683184).
