ABSTRACT

A sample of 25 IR-bright planetary nebulae (PNe) towards the Galactic bulge is analysed through 8–13\,\mu m spectroscopy. The classification of the warm-dust emission features provides a measure of the C/O chemical balance, and represents the first C/O estimates for bulge PNe. Out of 13 PNe with identified dust types, 4 PNe have emission features associated with C-based grains, while the remaining 9 have O-rich dust signatures. The low fraction of C-rich PNe, $\lesssim30\%$, contrasts with that for local PNe, around $\sim80\%$, although it follows the trend for a decreasing frequency of C-rich PNe with galactocentric radius (paper I). We investigate whether the PNe discussed here are linked to the bulge stellar population (similar to type IV, or halo, PNe) or the inner Galactic disk (a young and super-metal-rich population). Although 60\% of the PNe with warm dust are convincing bulge members, none of the C-rich PNe satisfy our criteria, and they are probably linked to the inner Galactic disk. In the framework of single star evolution, the available information on bulge PNe points towards a progenitor population similar in age to that of local PNe (type I PNe are found in similar proportions), but super-metal-rich (to account for the scarcity of C-rich objects). Yet the metallicities of bulge PNe, as inferred from [O/H], fail to reach the required values - except for the C-rich objects. It is likely that the sample discussed here is derived from a mixed disk/bulge progenitor population and dominated by type IV PNe, as suggested by Peimbert (1992). The much higher fraction of O-rich PNe in this sample than in the solar neighbourhood should result in a proportionally greater injection of silicate grains into the inner Galactic medium.

Key words: planetary nebulae: general – infrared: ISM: lines and bands – ISM: abundances – stars: evolution – stars: AGB and post-AGB.

1 INTRODUCTION.

Planetary nebula (PN) compositions reflect the initial composition and nuclear processing undergone by their progenitors, and provide valuable information on the end point of evolution for populations of intermediate mass stars in various galactic environments. Ratag et al. (1997) have published an extensive abundance analysis of PNe towards the Galactic bulge, providing helium, oxygen and nitrogen abundances. The results are surprising as many bulge PNe have high N/O ratios, which is characteristic of Peimbert type I PNe. The temptation to link the high N/O ratio in the bulge with the high progenitor masses of type I PNe, in excess of 2–3\,M$_\odot$, is countered by growing evidence that the bulge and halo are coeval (Ortolani 1995). In an addendum to his review on PNe, Peimbert (1992) favours a link with halo PNe (type IV, defined by a very low metallicity), which sometimes have N/O ratios within the range of type I PNe. However, carbon is conspicuously absent from the previous abundance analyses, and the C/O chemical balance is also a function of progenitor mass.

The C/O abundance ratio in PNe is usually calculated from gas phase abundances, through fine structure emission lines of C and O ionised up to three times. But the bright C lines are [C\,\text{ii}] $\lambda$2326, [C\,\text{iii}] $\lambda$1908, [C\,\text{iv}] $\lambda$1550, and extinction is severe at such short wavelengths. As the lines of sight to the bulge are usually affected by strong extinction, no C abundances are available for bulge PNe. However, the C/O chemical balance
can be inferred from the 8–13\(\mu\)m warm dust signatures, through the identification of the grain type. Silicate emission corresponds to oxygen-rich environments, SiC emission is typical of carbon-rich environments, while the unidentified infrared (UIR) emission bands are associated with a strong overabundance of carbon relative to oxygen (e.g. Barlow 1983, Roche 1989, see also Casassus et al. 2001a, paper I).

In this article we analyse a sample of bulge PNe through their dust signatures. We present 8–13\(\mu\)m spectra for a sample of 18 PNe observed towards the Galactic bulge (which meet the bulge-membership criteria of Acker et al. 1991), and analyse these, together with 7 objects previously reported by Roche (1987). We determine the dominant dust emission features in terms of grain emissivities, thus deriving the C/O chemical balances. Section 2 contains a description of the observations. A compilation of the data available for the sample of bulge PNe with 8–13\(\mu\)m spectra, together with a discussion on the criteria for bulge membership, is presented in Section 3. In Section 4 we interpret the available information on bulge PNe. In the framework of single star evolution, the rarity of C-rich PNe and the high frequency of N-enrichment links the ‘bulge’ PNe with the inner Galactic disk rather than with the bulge stellar population. But the O abundances in bulge PNe do not reach the required super-metal-rich values. The failure of single star evolution models in accounting for bulge PNe is thus highlighted. Section 5 summarises our conclusions.

## 2 8–13\(\mu\)m SPECTRA OF PNE TOWARDS THE GALACTIC BULGE

The objects selected were required to satisfy the following criteria,

- good detection by IRAS at 25 \(\mu\)m, and 12 \(\mu\)m flux in excess of \(0.5\) Jy, or high upper limits,
- diameters less than \(10''\), and almost all \(< 5''\),
- listed as likely bulge PNe in the Strasbourg-ESO catalogue (Acker et al. 1992), i.e. \(-10 < l < 10\), \(-10 < b < 10\), \(F(6\,\text{cm}) < 100\) mJy.

The spectra were acquired during July 23–26 1990, using UCLS at UKIRT, with the 40 l/mm grating and an aperture of 4.5 arcsec in diameter. The linear array of 25 Si:As photoconductive detectors was oversampled two times. Flux calibration was relative to standard stars through their dust signatures. We present 8–13\(\mu\)m spectra, together with the identified PNe, as well as the emission line fluxes.

Table 1: List of objects observed with UCLS at UKIRT in July 1990. Emission line fluxes are \(10^{-15} \text{ W m}^{-2}\).

| M1-29 | 359.1–1.7 | 1.9 | 3.0 |

sample). The spectra for PNe in Table 2 which are not listed in Table 1 are published in Roche (1987). The column under ‘comments’ contains the best fit parameters to the 8–13\(\mu\)m continua, with the notation of paper I, leading to a classification of dust signatures in terms of the dominant component (see Table 3 in paper I):

\[
F_\lambda = \sum_i a_i \epsilon_i(\lambda) B(\lambda, T_i) / B(10\mu m, T_i),
\]

where we sum over grain types, each with an emissivity \(\epsilon_i\), and where \(B(\lambda, T_i)\) is a Planck function at temperature \(T_i\). The free parameters are \(a_i\) and \(T_i\), the relative contribution of each grain type being \(a'_i = a_i / \sum_j a_j\). In this classification, a superposition of silicate emission and the UIR bands is classified as O-rich, because all ‘O’ PNe classified in this way have gas phase C/O < 1 (in the sample discussed here, only M3-38 shows such a superposition).

The proportion of PNe with C-based grains is smaller for PNe with longitudes towards the bulge than in the disk population:

| Bulge | Disk |
|---|---|
| \(R < R_0\) | \(R > R_0\) |
| 31 \(\pm\) 13\% | 70 \(\pm\) 9\% |
| 86 \(\pm\) 7\% |

\(a\) \(R_0 = 8.5\) kpc corresponds to the solar circle (Kerr & Lynden-Bell 1986).

There is a striking difference between the bulge PN sample compared with local PNe (see paper I for a discussion on the dust signatures in local PNe). This may be interpreted either as support for linking the PNe in Table 2 with the bulge stellar population, or as a strong metallicity dependence in the PN compositions. By contrast central star properties (Tylenda et al. 1991), or other nebular abundances (Section 5 below), have not
Landscape Table to go here

Table 2:
Figure 1: 10 µm spectra of the PNe listed in Table 1. The abscissae are the wavelengths in µm, and the ordinates the flux density in 10^{-15} W m^{-2} µm^{-1}. Fits to the dust emission continua are shown by the solid lines (fit parameters are in Table 2). Bright emission lines of [A\textsc{iii}], [S\textsc{iv}] or [Ne\textsc{ii}] at 9.0, 10.5 and 12.8 µm are excluded from the fitting procedure.

Figure 2: The ratio of UCLS to IRAS 12 µm flux as a function of IRAS flux. Open and filled circles correspond to O-rich and C-rich objects respectively, while crosses denote weak continuum PNe.

convincingly been demonstrated to reflect the broadly varying bulge and local galactic environments.

Does the IR-bright selection criterion preferentially select silicate nebulae? As shown in paper I, the fraction of flux emitted in the 12 µm band, $F(12 \mu m)/F_{\text{IRAS}}$, is about 25% and independent of dust emission type. No particular bias towards silicate nebulae is expected, and moreover the bulge sample is subject to the same selection effects as the disk sample in paper I. In spite of a lower $F(12 \mu m)/F_{\text{IRAS}}$ of ~ 10%, ‘weak’ nebulae are found in a proportion of 48% in the bulge sample, against 27% in the disk. The higher proportion of ‘weak’ nebulae is probably because the Galactic bulge sample is at a greater average distance from the sun, and hence fainter than the disk sample, but also many bulge PNe have upper limits only in the 12 µm band.

It is noteworthy that the 11-13 µm flux measured from the ground with the UCLS is in many cases substantially lower than that measured by IRAS. The average 12 µm flux ratio is 0.36, but this varies from 0.67 for C-rich objects, 0.48 for O-rich objects and 0.17 for PNe with weak continua, as shown in Fig. 3 (objects with IRAS upper limits at 12 µm are excluded, but those with uncertain detections are included). While source extension beyond the UCLS aperture and pointing errors may account for some of this difference, it seems that in the objects with weak continua, line emission and/or very strongly-rising continua beyond 13 µm must provide the bulk of the emission, if the 12 µm IRAS fluxes are accurate in this crowded region.
3 BULGE MEMBERSHIP AND GAS PHASE ABUNDANCES

Due to the lack of accurate distance indicators for PNe, bulge membership cannot be determined with certainty, but it is strengthened if the following criteria are met:

- Criterion A. The bulge is the site of large velocity dispersions, in contrast to the near-circular orbits in the Galactic disk. If a PN is associated with the Galactic disk, the maximum line of sight velocity towards the bulge would be of the order of the velocity dispersion for 1M⊙ stars in the solar neighbourhood, or about σ ~ 80 km s⁻¹ (from the age-velocity dispersion relation in Wielen 1977). In the extreme case of placing the PNe on the inner side of the molecular ring (galactocentric radius R ~ 2.5 kpc), bulge membership is strengthened if the deviation from circular rotation is greater than σ.

- Criterion B. PNe with distances beyond 6 kpc are bulge members. When available, we used the statistical distances from Zhang (1995), which are averaged between an ionised mass-radius distance scale, and that distances from van de Steene and Zijlstra (1995), or the distances computed by Maciel (1987) but without the kinematical distinctions (i.e. log(N/O) > −0.3 in type I PNe, −0.3 > log(N/O) > −0.6 in type Ia PNe, and −0.6 > log(N/O) in type IIb PNe), and the gas-phase abundances are mostly taken from Ratag et al. (1997). Note however that the agreement between different data sets for the few objects in common (Ratag et al., 1997, Cuisinier et al. 2000, Webster 1988), which are generally faint and reddened, is rather poor. There appears to be a high proportion of type I PNe in the bulge sample, 25% of the total, or 30% of the PNe which satisfy criteria A and B for bulge membership. This value is close to the proportion of type I PNe in compact and infrared bright Galactic disk PNe, 29 ± 6%. Cuisinier et al. (2000) obtain similar distributions for N/O ratios in bulge and local PNe, considering the small number statistics. In fact, although their interpretation points towards a marked difference with local PNe, their data shows 23% type I objects, and with a continuous range of N/O values, like the Galactic disk PNe. There is also a large population of type IIa nebulae in the bulge, 33% in this sample, compared to ~12% in the disk (in the sample of paper I).

As an example of the uncertainties affecting the gas phase abundances, consider the case of M 2-29: ground based spectra yielded [O/H] = −1.4 dex, making M 2-29 the most metal poor PN so far, but Torres-Peimbert et al. (1997) reported [O/H] = −0.5 dex from HST FOS spectra of a knot close to the central star. Are the HST results typical of the whole nebula? Would density and temperature inhomogeneities also affect the abundance determinations of other bulge PNe? Although we will consistently refer to the work by Ratag et al. (1999), the gas-phase abundances can only be viewed as rough indicators.

The distribution of oxygen abundances listed in Table II for the 10 objects with warm dust emission and known [O/H], is [O/H] = −0.3 ± 0.4 dex (in terms of the mean and 1σ spread and for a solar abundance of 7.4 × 10⁻⁶, Grevesse & Anders 1989). In the Galactic disk PNe discussed in paper I, the distribution of oxygen abundances for the objects with warm dust emission, is [O/H] = −0.52 ± 0.26 dex for R > R⊙, two objects with such a superposition and known C/O ratio. Ratag et al. (1997) report a high N/O ratio for M 3-38.

Table II also contains a summary of the observational data on bulge PNe with 8–13μm spectra. Nitrogen enrichment is classified according to Peimbert (1978), with the sub-types from Faundez-Abans and Maciel (1987) but without the kinematical distinctions (i.e. log(N/O) > −0.3 in type I PNe, −0.3 > log(N/O) > −0.6 in type Ia PNe, and −0.6 > log(N/O) in type IIb PNe), and the gas-phase abundances are mostly taken from Ratag et al. (1997). Note however that the agreement between different data sets for the few objects in common (Ratag et al., 1997, Cuisinier et al. 2000, Webster 1988), which are generally faint and reddened, is rather poor. There appears to be a high proportion of type I PNe in the bulge sample, 25% of the total, or 30% of the PNe which satisfy criteria A and B for bulge membership. This value is close to the proportion of type I PNe in compact and infrared bright Galactic disk PNe, 29 ± 6%. Cuisinier et al. (2000) obtain similar distributions for N/O ratios in bulge and local PNe, considering the small number statistics. In fact, although their interpretation points towards a marked difference with local PNe, their data shows 23% type I objects, and with a continuous range of N/O values, like the Galactic disk PNe. There is also a large population of type IIa nebulae in the bulge, 33% in this sample, compared to ~12% in the disk (in the sample of paper I).

As an example of the uncertainties affecting the gas phase abundances, consider the case of M 2-29: ground based spectra yielded [O/H] = −1.4 dex, making M 2-29 the most metal poor PN so far, but Torres-Peimbert et al. (1997) reported [O/H] = −0.5 dex from HST FOS spectra of a knot close to the central star. Are the HST results typical of the whole nebula? Would density and temperature inhomogeneities also affect the abundance determinations of other bulge PNe? Although we will consistently refer to the work by Ratag et al. (1999), the gas-phase abundances can only be viewed as rough indicators.

The distribution of oxygen abundances listed in Table II for the 10 objects with warm dust emission and known [O/H], is [O/H] = −0.3 ± 0.4 dex (in terms of the mean and 1σ spread and for a solar abundance of 7.4 × 10⁻⁶, Grevesse & Anders 1989). In the Galactic disk PNe discussed in paper I, the distribution of oxygen abundances for the objects with warm dust emission, is [O/H] = −0.52 ± 0.26 dex for R > R⊙, two objects with such a superposition and known C/O ratio. Ratag et al. (1997) report a high N/O ratio for M 3-38.
DISCUSSION ON THE PROGENITOR MASSES OF PNE TOWARDS THE BULGE

The much smaller fraction of C-rich PNe in the bulge compared to the disk must reflect the change in the stellar populations between the two regions. The main factors that affect the production of C-rich PNe are the initial composition and the age of the stellar population; in old populations the stars sufficiently massive to produce C-rich PNe (≥ 1.5 M⊙) will have evolved beyond the PN stage. In this Section we examine the consequences of linking the progenitor population of PNe towards the bulge to the inner Galactic disk or to the bulge stellar population.

4.1 Expected frequencies of C-rich PNe for various progenitor populations

It appears that the Galactic metallicity gradient is at the root of the trend for an increasing fraction of C-rich PNe beyond the solar circle (Casassus & Roche 2001, paper II), and it could be thought that a natural explanation for the rarity of C-rich bulge PNe may be an extrapolation of the Galactic disk trends to even more metal-rich environments. However, the distribution of oxygen abundances listed in Table 2 does not reach the required values. Also surprising is the fact that C-rich PNe, common in low metallicity environments, are found at rather high [O/H] in the bulge sample.

We now examine the consequences of assuming bulge PN progenitors have diffused off the inner galactic disk, but are otherwise similar to those of local PNe, and investigate the predictions of single star evolution using the synthetic AGB model proposed by Groenewegen & de Jong (1993), modified to include the results of Forestini & Charbonnel (1997, as described in paper II). We considered three cases for the initial compositions of the progenitor population. The first two had initial metalicities normally distributed about Z = 0.02 and Z = 0.03, with an arbitrary ZFWHM = 0.005. The third had a distribution following the observed [O/H] distribution in the objects in our sample i.e. with log(Z/0.02) ~ [O/H] = −0.3 ± 0.4 dex, and bounded by −1 dex and +0.2 dex. Initial compositions were approximated by a metallicity-scaled solar mix, except for O, for which we also considered 16O = 16O⊙(Z/0.02)^1/7, which is obtained by eliminating R from log(Z/0.02) = −0.07(R−R⊙) and log(16O/0.02) = −0.01(R−R⊙) (the oxygen gradient inferred from B stars, as reported by Smartt et al. 2000).

A power law initial mass spectrum, p(M) dM ∝ M^{−κ} dM, whose exponent κ was varied between 2 and 8, is taken to represent the progenitor population. The mass spectrum of PN progenitors is given by N(M) dM = SFR[t(M)] IMF(M) dM where t(M) is the time of birth for a progenitor of mass M. For a constant star formation rate (SFR), the Salpeter (1955) initial mass function (IMF) leads to κ = 2.35. For progenitors linked to the inner Galactic disk, in a conservative estimate the probability for a given star to diffuse off the plane would be proportional to the progenitor’s lifetime, or about M^{−2}. Assuming randomly distributed star formation bursts behave on average as a constant SFR gives κ = 4.35 for a Salpeter IMF. Actually, diffusion off the galactic disk is probably a cumulative process, and using the square of the lifetime may be more adequate, thereby giving κ = 6.35. Whether there were more/less bursts in the past than today can be taken into account by increasing/decreasing κ. If the progenitors are coeval with globular clusters, then SFR is best approximated as a delta function at t = 0. We would have AGB stars at the 0.8 M⊙ turnoff only (see below), and κ goes to infinity. However, this case is excluded by adopting a minimum initial mass of 1.2 M⊙ for the progenitors of compact and IR-bright PNe, as in paper II, our purpose being to test whether the bulge and local PNe are similar stellar populations.

The resulting properties of the synthesised bulge PN population can be seen in Figure 3. The hypothesis that the bulge and local PNe are similar stellar populations predicts far too many C-rich objects in the bulge beyond the PN stage. In this Section we examine the consequences of an increasing fraction of C-rich PNe inferred from B stars, as reported by Smartt et al. 2000.

† One underlying assumption is that the diffused population samples all masses, excluding the case of just one very recent burst (say in the inner 100 pc). The objects discussed here are distributed uniformly over the central 10°.

dinates) as a function of initial mass (in M$_\odot$), for the
model presented in paper II (at solar metallicity). The
grey scale grows darker from the M to S to C phases.

ratio that would be observed in the synthetic populations: M stars on the early AGB are bound to contam-
inate the star counts, and for a steeper $\kappa$, C stars are
increasingly improbable. For $Z = 0.03$, the predicted
ratio is $C/M< 0.04$, while for $Z = 0.02$ we obtain
$C/M< 0.22$, and $C/M< 0.35$ for the bulge metallicities.
Higher metallicities are associated with very low values
of the $C/M$ star ratio. The rarity of bulge C stars is
naturally explained by their very short lifetimes, as il-
lustrated in Figure 4. The very occurrence of this phase
is sensitive to the progenitor’s mass, resulting from an
interplay of mass loss in the stellar envelope and the
thermal pulses (especially around $\sim 2$ M$_\odot$).

N-enrichment is firmly established to be a func-
tion of progenitor mass, in the case of the Galactic
disk population. Thus the statistics of N/O ratios sug-
gests the bulge PNe are derived from a population sim-
ilar in age to local PNe (if they have similar progeni-
tors). Although the highest N/O ratios, and hence the
most massive progenitors, may be deficient in bulge PNe
(Cuisinier et al. 2000), the upper end of the 1–8 M$_\odot$
mass range is very infrequent, and derived differences
with local PNe should be negligible (we avoid discus-
sion of the predicted distribution of PN N/O ratios, as
the frequency of N-enrichment in disk PNe is not un-
derstood, see Section 2.2 in paper II).

For single star evolution to account for the com-
positions of bulge PNe, a super-metal-rich and young
progenitor population is required, i.e. an environment
typical of the inner Galactic disk. But the oxygen abun-
dances reported for bulge PNe, taken as one stellar
population, are on average slightly subsolar, and simi-
lar to the disk objects. Thus, assuming the bulge and
local PNe have similar progenitors (and assuming the
reported [O/H] values are accurate), cannot reproduce
the properties of the bulge sample when taken as one
stellar population.

4.2 Are the bulge PNe all type IV?

The overall picture gathered to date points at an old
bulge, composed of stars no more massive than about
0.8 M$_\odot$ with significant scatter in metallicity about the
solar value (Ortolani et al. 1995, Idiart et al. 1996,
Bruzual et al. 1997, Barbuy, Bica & Ortolani 1998,
Feltzing & Gilmore 2000). But this result is not un-
challenged. Conclusions preferring a younger bulge have
been reached (Holtzman et al. 1993, Kiraga, Paczynski
& Stanek. 1997). In fact, although the results by Or-
tolani et al. (1995) have found strong support, they refer
to the bulk of the bulge; some observations suggest the
existence of an intermediate mass population‡. Frogel
(1999) summarises his work on a bulge population less
than $\sim$1 Gyr old: although there is no solid evidence
for a young population in Baade’s window, a mix of
young and old populations is found towards the inner
bulge (fields less than 1° from the Galactic centre), as
evidenced by an increase in luminous AGB stars.

A long standing problem related to the existence of
an intermediate mass population in the bulge is the lack
of C stars. Blanco, Blanco & McCarthy (1978) detected
only one C star in 310 M stars. Azzopardi, Lequeux &
Rebeiro (1991) reported a list of 33 C stars detected
towards the bulge, but their properties are puzzling. Al-
though the C stars share the same kinematics as bulge
K and M giants, they are too faint to be on the AGB.
The bulge C stars do not seem to be genuine AGB stars,
‡ McWilliam and Rich (1994) estimate that the average mass
of K giants in Baade’s window can be no less than 1.1 M$_\odot$. The
distribution of periods of LPV stars in the bulge has been inter-
preted as evidence for a population with ZAMS masses in excess
of 1.3 M$_\odot$ (Harmon and Gilmore 1988), but this has recently been
shown by Frogel & Whitelock (1998) to merely reflect a metallicity
effect in an old population.
and could be dwarf C stars (dCs) along the line of sight to the bulge. dCs are observed to have low metallicities (Harris et al. 1998), and are most likely produced through binary evolution with $Z < 0.5Z_\odot$ (De Kool & Green 1995), making them members of the local population of spheroid dwarfs. Thus the lack of genuine AGB C stars is characteristic of the bulge.

The principal piece of information brought by the warm dust emission features of PNe in the direction of the bulge is that the proportion of C-rich nebulae is dramatically lower, only $\sim 30\%$ against $\sim 78\%$ in local PNe. In an extension of the method applied to disk PNe in papers I and II, we showed in section 4.1 that such a low fraction of C-rich nebulae and the nitrogen enrichment reported by Ratag et al. (1997) require a young and metal-rich population, with $Z \sim 0.03$. Yet on average the bulge and local PNe have similar metallicities, although the four C-rich object in the bulge sample are found at rather high $[O/H]$, and none is a definite bulge member.

Two alternatives should be considered:

(i) The bulge PNe with warm dust could be related to the type IV PNe in Peimbert’s classification, i.e. halo PNe with peculiar abundances. The case of BB-1 (or PN G108.4-76.1), studied by Peña et al. (1993), merits attention as it is metal poor ($O$ is underabundant relative to solar by one order of magnitude), has a velocity of $\sim 200$ km s$^{-1}$, and is nonetheless enriched in carbon and nitrogen, log(C/O)=+1, log(N/O)=+0.2.

(ii) The bulge PNe with warm dust are similar to the local population, but with higher metallicity and linked to the inner regions of the Galactic disk. A mechanism remains to be found by which such a population would diffuse off the Galactic plane.

Aspects of both alternatives seem applicable to the bulge PNe. The C-rich PNe are most likely metal-rich and foreground objects, and the lack of counterpart C stars is natural in metal-rich environments (the C phase would occur only at the very end of AGB evolution, and could possibly be linked with PN ejection).

Another piece of information is provided by the lack of metallicity dispersion in Baade’s window M giants, about a mean slightly larger than the solar value (Frogel & Whitford 1987, Terndrup et al. 1991). The dispersion in metallicity for M giants is at most a factor of 2 in $[\text{Fe/H}]$, about $<\text{[Fe/H]}>= +0.3$, in contrast with the large spread in metallicity of Baade’s window K giants, $\sim 1$ dex in $[\text{Fe/H}]$ about $<\text{[Fe/H]}> = -0.3$. Is the bulk of the M giants observed towards Baade’s window from a young population, with uniformly high metallicity, linked to the inner Galactic disk?

Similar to the superposition of the populations traced by the K and M giants in Baade’s window, there could be a superposition of two population in the bulge PNe, one linked to the inner disk and the other to the old bulge.

5 CONCLUSION

The C/O chemical balance for a sample of PNe towards the Galactic bulge has been established through the 8–13 $\mu$m dust emission features. Out of 15 PNe with identified dust types, 4 PNe have C-based grains. The very low fraction of C-rich PNe is in contrast with the local PNe, and the bulge PNe probably form a different population. However, none of the C-rich PNe is an unquestionable bulge member. The fraction of C-rich nebulae among ‘bona fide’ bulge PNe could be much lower.

In the framework of single-star evolution, the properties of the bulge PN sample appear to be derived from a young and metal-rich population, linking the ‘bulge’ PNe to the inner Galactic disk. However, the distribution in metallicity of the bulge warm dust PNe follows that of Baade’s window K giants, with a similar mean to solar neighbourhood PNe. It is difficult to reconcile the C/O balance inferred from the dust emission with a single bulge PN population. We are thus inclined to follow the suggestion by Peimbert (1992) that the bulge PNe are predominantly type IV, although contamination from Galactic disk objects is likely. In this context the C-rich PNe towards the bulge are linked to the inner Galactic disk, and the lack of counterpart C stars is a natural property of metal-rich environments.

We find that M2-29, usually classified as a type IV PN with $Z\sim 0.0008$, shows silicate emission. It seems, however, that the ground-based $[O/H]$ determinations could be in error (Torres-Peimbert et al. 1997). In the light of the significant uncertainties linked with the gas-phase abundances, discriminating between a bulge or a disk origin for ‘bulge’ PNe based on their $[O/H]$ values may be premature. It would be interesting to obtain 8–13 $\mu$m spectra of the type IV PNe listed by Peimbert (1992) to investigate dust production at low metallicities.
