Abstract

Studies on the nutritional status of vegetarians in Spain are lacking. Prevention of vitamin B$_{12}$ deficiency is the main concern, as dietary sources are of animal origin. The present study aimed to evaluate vitamin B$_{12}$ and folate status of Spanish vegetarians using classical markers and functional markers. Participants were adult and healthy lacto-ovo vegetarians (forty-nine subjects) and vegans (fifty-four subjects) who underwent blood analyses and completed a FFQ. Serum vitamin B$_{12}$, homocysteine (Hcy), methylmalonic acid (MMA), erythrocyte folate and haematological parameters were determined. The effects of the type of plant-based diet, and the intake of supplements and foods were studied by a FFQ. Mean erythrocyte folate was 1704 (SD 609) nmol/l. Clinical or subclinical vitamin B$_{12}$ deficiency was detected in 11 % of the subjects (MMA>271 nmol/l) and 33 % of the participants showed hyperhomocysteinaemia (Hcy>15 µmol/l). Regarding plant-based diet type, significantly higher Hcy was observed in lacto-ovo vegetarians compared with vegans ($P=0.019$). Moreover, use of vitamin B$_{12}$ supplements involved an improvement of vitamin B$_{12}$ status but further increase in erythrocyte folate ($P=0.024$). Consumption of yoghurts was weakly associated with serum vitamin B$_{12}$ adequacy ($P=0.049$) and that of eggs with lower Hcy ($P=0.030$). In conclusion, Spanish vegetarians present high folate status but vitamin B$_{12}$ subclinical deficiency was demonstrated using functional markers. The lack of influence of dietary sources on functional markers and the strong effect of vitamin B$_{12}$ supplement intake emphasise the need of cobalamin supplementation in both lacto-ovo vegetarians and vegans.

Key words: Vitamin B$_{12}$; Folate; Vegetarians; Vegans; Supplementation

Plant-based diets have been reported to provide several health benefits, reducing the risk of atherosclerosis, CHD, type 2 diabetes and the metabolic syndrome$^{[1,2]}$. However, these diets may also increase the risks of nutritional deficiencies$^{[3–5]}$.

Vitamin B$_{12}$, or cobalamin, acts as a cofactor of the enzymes methionine synthase, acting in the conversion of homocysteine (Hcy) to methionine, and methylmalonyl-CoA mutase, that produces succinyl-CoA from methylmalonyl-CoA, the active form of methylmalonic acid (MMA)$^{[6]}$. These reactions are involved in the methionine cycle and the folate cycle, both essential for DNA and RNA synthesis, erythropoiesis and the production of neurotransmitters$^{[1,7,8]}$. Therefore, deficiencies of vitamin B$_{12}$ and folate can result in neurological damage, due to an inhibition of the formation of the myelin sheath, and megaloblastic anaemia$^{[1]}$.

Clinical deficiency of vitamin B$_{12}$ can cause megaloblastic anaemia, which is characterised by high mean corpuscular erythrocyte volume (MCV) and erythrocyte distribution width, and low erythrocyte count$^{[9,10]}$. Nevertheless, an early detection of vitamin B$_{12}$ deficiency is a challenge, as there is not a single standard marker but several markers should be analysed for diagnosis$^{[11]}$. In this regard, although serum vitamin B$_{12}$ has been widely used to assess cobalamin deficiency, it can remain normal under functional deficiency conditions and

false positives and negatives are common\(^{12,13}\). A more specific marker of functional vitamin B\(_{12}\) deficiency is Hcy, which increases under cellular vitamin B\(_{12}\) deficiency. Nevertheless, Hcy is also elevated under deficiencies of folate or vitamin B\(_{6}\) and by diets rich in methionine\(^{6,14–16}\). Hyperhomocysteinaemia (HHcy) promotes the formation of active oxygen species and the release of inflammatory mediators, and therefore it is considered a risk factor for CVD\(^{16–18}\). Finally, MMA represents the most specific marker for vitamin B\(_{12}\) deficiency, as it is independent of folate status and increases in cobalamin deficiency conditions before the appearance of clinical signs\(^{6,19}\).

Cobalamin is synthesised exclusively by bacteria and archaea, but it is accumulated along the food chain, and animal foods including meat, milk, eggs, fish and shellfish are considered the main dietary sources\(^{1,20}\). Other food sources are scarce and include several mushroom species like shiitake (\textit{Lentinula edodes}), black trumpet (\textit{Craterellus cornucopioides}) and golden chanterelle (\textit{Cantharellus cibarius}), and certain algae and cyanobacteria such as \textit{Chlorophyllum} and spirulina (\textit{Arthrospira platensis}). These are frequently used to produce tablets consumed as cobalamin supplements by vegetarians and particularly vegans\(^{20}\). Nevertheless, it has been observed that these supplements also contain high amounts of inactive analogues of vitamin B\(_{12}\)\(^{21–23}\). Therefore, vitamin B\(_{12}\) deficiency is considered an extended problem for vegetarians, especially for vegans, if nutritional cobalamin supplements are not consumed\(^{6,24}\).

Very limited information exists on the nutritional status of vegetarians in Spain\(^{20}\). It is estimated that they represent at least 1.5% of the Spanish population\(^{20}\). In the present study we evaluate the vitamin B\(_{12}\) and folate status of Spanish vegetarians using markers of clinical deficiency (serum vitamin B\(_{12}\) and haematological markers) and subclinical deficiency (Hcy, MMA and erythrocyte folate), constituting the first complete study on vitamin B\(_{12}\) and folate status in this population. The associations of the studied markers with the type of diet (lacto-ovo vegetarian or vegan), and the intake of vitamin B\(_{12}\)-rich products and supplements were also addressed.

Materials and methods

\textbf{Study design and participants}

The study followed a cross-sectional design. Healthy lacto-ovo vegetarian or vegan adults (age \(\geq 18\) years) were recruited through advertisements in web pages in the area of Madrid, Spain. Exclusion criteria were: occasional meat or fish consumption, diagnosed digestive, renal, haematological, endocrine or oncological diseases, eating disorders, pregnancy, lactation and menopause. Subjects who had donated blood in the 3 months prior to the study were also excluded. A total of 207 subjects were initially interested, of which forty-four declined to participate and fifty-eight did not meet the inclusion criteria. In all, 105 volunteers were selected, and finally 103 completed the study and underwent all the biochemical analyses. None of the selected volunteers reported any diagnosed illness and they did not consume any medication in the days prior to blood extraction.

The present study was conducted according to the guidelines laid down in the Declaration of Helsinki and all procedures involving human subjects were approved by the Clinical Research Ethics Committee of Hospital Puerta de Hierro (Majadahonda, Spain) under the reference number 06.17 and the Ethics Committee of the Spanish National Research Council (CSIC). Written informed consent was obtained from all the participants.

\textbf{Procedure, blood sampling and biochemical assays}

Volunteers attended the Human Nutrition Unit of ICTAN-CSIC between 08.00 and 08.30 hours after a 12 h fasting period. Height of the subjects was measured, and body weight, body composition and BMI were obtained using the body composition monitor Tanita BC-601 (Tanita Ltd). Blood samples were collected in Vacutec Z Serum Sep Clot Activator and K3 EDTA tubes (Greiner Bio-One GmbH). Serum was separated by centrifugation in a Jouan CR-312 centrifuge (Jouan Ltd) at 1000 \(g\) for 15 min and stored at \(-80^\circ\)C. Vitamin B\(_{12}\) and Hcy were analysed in 100 \(\mu l\) and 20 \(\mu l\) of serum, respectively, by competitive immunoassay of direct chemiluminescent technology in an ADVIA Centaur XP autoanalyzer (Siemens Healthineers). Serum samples for MMA determination were prepared by solid-phase extraction using Bond Elute strong anion exchange cartridges (100 mg bed/1 ml) from Agilent. The analysis was performed using a liquid chromatography–tandem MS method previously optimised by our research group\(^{25}\). Erythrocyte count, erythrocyte distribution width, packed cell volume, MCV, Hb and mean corpuscular Hb (MCH) were determined in whole blood using an ADVIA 2120 flow cytometer (Siemens Healthineers). Erythrocyte folate was analysed from whole-blood samples that were refrigerated, diluted 1:25 in folate lysing agent (Beckman Coulter, Inc.), mixed, protected from light for 90 min, and finally measured by an automated chemiluminescent immunoassay in a UniCel DxI 800 Immunoassay System (Beckman Coulter, Inc.). The following quality controls from BioRad Laboratories were used: Lyphocheck Immunoassay Plus Control (for vitamin B\(_{12}\) and erythrocyte folate determinations), Lyphocheck Homocysteine Control (for Hcy determination), Lyphocheck Anemia Control (for vitamin B\(_{12}\) determination) and Liquicheck Hematology Control (for erythrocyte count, erythrocyte distribution width, packed cell volume, Hb, MCV and MCH determinations). ClinChek Controls from LETI laboratories were used for MMA determination. Quality controls were within the expected range for all measurements.

\textbf{Definitions}

The proportion of individuals that presented inadequate levels within each group was defined considering the following reference levels of normality: vitamin B\(_{12}\) (150 pmol/l), Hcy (5–15 \(\mu\)mol/l), MMA (<271 nmol/l), erythrocyte folate.
and erythrocyte distribution width were transformed using folate, MCV and MCH were log-transformed, while MMA > 4 were considered. Subjects were considered supplement users if they consumed supplements at least two to five times a month. Food items included in the study of vitamin B12 status were: animal milk, cheese, eggs, yoghurts and vegetable milks. Mushrooms and vitamin B12-rich algae were not considered due to their low rate of consumption (less than 10% of the subjects reported an occasional intake). The consumption of yoghurts was assessed through three different items (natural or flavoured yoghurts, non-fat yoghurts, other yoghurts) and vegetable milks through six items (soya milk, almond milk, oat milk, coconut milk, rice milk and cashew milk).

**Statistical analysis**

**Sample size justification.** Sample size was calculated for the main variable, serum vitamin B12. Previous reports indicate mean values of 209 (SD 47) and 172 (SD 59) pmol/l for lacto-ovo vegetarians and vegans, respectively. Therefore, to detect as significant a difference of 15% between the two diet option groups, an allocation ratio of 1, a two-sided P = 0.05 and statistical power of 0.80, a total of eighty-eight participants was needed. Calculations were performed using G* Power 3. This number was increased by 15% to ensure a sufficient sample size in case several participants decided not to complete the study. Results are presented for 103 volunteers, with forty-nine lacto-ovo vegetarians and fifty-four vegans.

**Data analysis.** Mean and standard deviation were calculated for each of the markers. Normality was studied by the Kolmogorov–Smirnov test and non-normal variables were transformed according to their distribution. Vitamin B12, folate, MCV and MCH were log-transformed, while MMA and erythrocyte distribution width were transformed using the inverse function. The effect of supplementation was only studied for vitamin B12 supplements, as only one volunteer reported the intake of folate supplements and multivitamins were consumed occasionally for only ten individuals. Differences owed to vitamin B12 supplementation and diet option were studied (fixed factors) by general linear models of the transformed variables including sex and age (random factors). The age effect was not significant and therefore this variable was not included in further analyses. According to cut-off levels for each parameter, binomial variables classifying each individual as adequate or inadequate were calculated. These results are presented within diet (lacto-ovo vegetarian or vegan) and supplementation (vitamin B12 supplement user or non-user) groups. Furthermore, we analysed the differences in the frequency of consumption of the studied food items between subjects with adequate levels and subjects with inadequate levels of serum vitamin B12, Hcy and MMA through contingency tables. When independent food items were analysed (animal milk, cheese, eggs), Monte Carlo two-sided tests with 10,000 simulations and a CI of 99% were used to provide reliability to the analysis. Yoghurt items, as well as vegetable milk items, were converted in multiple response sets and considered as food groups for the analysis, which was performed using Pearson’s χ2 tests. Significance was set at P < 0.05 and all the statistical analyses were performed in SPSS 24 (SPSS Inc.).

**Results**

**Population characteristics**

The participating volunteers were young adults, with a mean age of 30.3 (SD 7.7) years, and only two subjects were older than 46 years. Most of the volunteers were women, 78% of the total (Table 1). In relation to diet option, 47.6% of the participants were lacto-ovo vegetarians and 52.4% were vegans. They were normoweight with slightly higher BMI in men than women. Hcy, erythrocyte count, erythrocyte distribution width, packed cell volume and Hb were significantly different between men and women (P < 0.001 in all cases). Vitamin B12 supplements were consumed by 72.8% of the participants.

**Diet and supplementation effects**

Significant differences were found between vitamin B12 users and non-users, with higher levels of vitamin B12 (P < 0.001) and erythrocyte folate (P = 0.024), and lower MMA (P = 0.012) and Hcy (P = 0.015) in volunteers consuming vitamin B12 supplements (Table 2). Vegans presented significantly lower erythrocyte count (P = 0.032) and erythrocyte distribution width (P = 0.003), and higher MCV (P = 0.036) and MCH (P = 0.023) compared with lacto-ovo vegetarians. A significant interaction diet option × supplementation was found for Hb (P = 0.034). Means of all these haematological variables were in the normal range.

Two participants presented vitamin B12 levels below the cut-off value of 150 pmol/l that indicates clinical deficiency (Fig. 1), while eleven subjects presented elevated MMA. HHcy was detected in thirty-three individuals. The prevalence

(>305 nmol/l), erythrocyte distribution width (<14%), MCV (80–96 fl), MCH (>27 pg), Hb (>130 g/l for men and >120 g/l for women), erythrocyte count (>3.6 × 1012/l for men and >4.2 × 1012/l for women) and packed cell volume (>41% for men and >36% for women)\(^{16,27,28}\).
Erythrocyte folate (nmol/l) 1713

chemical biomarkers of vitamin B12 was not found. sev-

eral participants but a clear correspondence with the bio-

table.

of HHcy in vitamin B12 non-users (twelve subjects, 43 % of the group) was higher than in vitamin B12 users (twenty-one subjects, 28 % of the group). Erythrocyte count low values were more frequent in vegans than lacto-ovo vegetarians (fourteen subjects, 25·9 % of vegans, r two subjects, 4·1 % of lacto-ovo vegetarians). MCV was elevated in sixteen subjects, most of them vegans (twelve subjects, 22·2 % of vegans, r three subjects, 6·1 % of vegetarians). Two of these subjects also presented elevated MMA and Hcy. High erythrocyte distribution width was observed mainly in vitamin B12 users (sixteen subjects, 21·3 % of users, r one subject, 3·6 % of non-users).

The number of subjects with inadequate levels in association with the frequency of consumption of dairy products and eggs is presented in Table 3. Serum vitamin B12 sufficiency was associated with the consumption of yoghurts (P = 0·049), and Hcy was associated with egg consumption (P = 0·030). MMA did not present an association with any of the considered food items.

Discussion

This study represents the first complete report on vitamin B12 and folate status in Spanish vegetarians. Results reveal sufficient serum vitamin B12 levels in the studied subjects independently of their diet option, and the prevalence of clinical vitamin B12 deficiency was very low. However, by measuring MMA we detected subclinical deficiency, particularly in the non-users of vitamin B12 supplements. Regarding haematological results, the differences between vegans and vegetarians did not reach significance, and macrocytosis was observed in several participants but a clear correspondence with the biochemical biomarkers of vitamin B12 was not found.

Elevated MMA was detected in more than 10 % of the population, emphasising the utility of this marker to detect subclinical deficiencies. HHcy was found in more than 30 % of the subjects. The metabolic reactions leading to the production of MMA and Hcy require different cobalamin forms (with methylcobalamin acting in the Hcy pathway and adenosylcobalamin in the formation of succinyl-CoA) and occur in different cell compartments (as the methionine and folate cycles occur in the cytoplasm and the synthesis of succinyl-CoA in the mitochondria) (1). In this context, previous research has stated that serum vitamin B12 might be a misleading marker, as the latency period to detect clinical deficiencies is long (11). Therefore, we encourage the use of both MMA and Hcy together with serum vitamin B12, as each of these biomarkers informs about the action of vitamin B12 in different metabolic pathways.

The use of several functional markers is even more important if we consider recent relevant research revealing a relationship between MMA levels and certain genotypes involved in valine catabolism that might affect MMA levels independently of cobalamin status (32). Therefore the use of Hcy to detect subclinical vitamin B12 deficiency through a different pathway is recommended. Consistently, when cobalamin status was assessed considering serum vitamin B12, MMA and Hcy simultaneously, the proportion of subjects with values out of range of at least one of the biomarkers was remarkably higher than the proportion detected by using only serum vitamin B12. The observed results underline the limitations of serum vitamin B12 to detect vitamin B12 deficiency and the need of using several functional markers to detect subclinical deficiencies accurately.

Most of the hyperhomocysteinaemic individuals presented mild HHcy (16–30 μmol/l) while only three volunteers had moderate HHcy (31–100 μmol/l) (10). There is a great variability in the values obtained in European vegetarians; the volunteers in the present study had Hcy levels higher than German

*Differences were analyzed through general linear models. The diet option x vitamin B12 supplementation interaction was only significant for Hb (P = 0.034).

Regarding the influence of methionine on Hcy, protein consumption and methionine levels have been reported to be higher in lacto-ovo vegetarians than vegans, which in a scenario of folate repletion as observed in our study might lead to higher rates of HHcy in lacto-ovo vegetarian subjects under similar vitamin B12 levels. This might explain the higher Hcy levels of lacto-ovo vegetarians compared with vegans detected in this research. It is remarkable that most of the individuals with altered levels of one of the markers only presented Hcy out of range, while MMA was elevated only in eleven individuals. Therefore, we consider that the high intake of methionine with lacto-ovo vegetarian diets might increase circulating Hcy through the methionine cycle, while the formation of MMA and succinyl-CoA would be unaffected. In addition, it should be pointed out that HHcy is a recognised factor of CVD and higher HHcy prevalence has been reported in vegetarians than omnivores, although it seems that vegetarians have lower IHD mortality than non-vegetarians.

In the present study it was clearly shown that vitamin B12 supplement users exhibited higher serum vitamin B12 and erythrocyte folate, as well as lower MMA and Hcy than non-users; thus the obtained results remark the importance of supplementation both for vegans and lacto-ovo vegetarians. These results are consistent with previous literature considering that the recommended intake of vitamin B12 is difficult to achieve by vegetarians if supplements are not consumed, partly because the intake of fortified food items is not enough to provide the required doses of the vitamin.

Considering all the analysed markers, the studied Spanish vegetarians presented sufficient folate and vitamin B12 status due to their general supplementation habit.
contrast with the findings of recent studies on vegetarian Indians, where a prevalence of vitamin B12 deficiency of 70% has been estimated, and more than 50% of the subjects presented deficient levels of serum vitamin B12 and HHcy\(^\text{44,45}\). This may be explained by the differences in vegetarian diet composition and socio-economic status between these two countries\(^\text{46}\). However, comparing our results with those obtained in other European countries, such as Germany, the Netherlands and UK, the differences remain\(^\text{15,33,43}\). We consider that the sufficient vitamin B12 status of our subjects might be mainly caused by the extended use of cobalamin supplements in the Spanish participants, while the proportion of vitamin B12 consumers found in previous research was smaller. Nevertheless, even the non-users of vitamin B\(_12\) supplements presented a better status than the lacto-ovo vegetarian and vegan participants of the above-mentioned reports. The better cobalamin status detected in our study might be explained by a higher consumption of vitamin B12-rich and vitamin B12-fortified food products, and also the age of the volunteers, as vitamin B12 status is usually lower in old individuals\(^\text{1}\).

In this regard, the association of vitamin B\(_12\)-rich food with cobalamin status was studied. The results suggest an improvement of serum vitamin B\(_12\) levels and a tendency to improve Hcy and MMA, associated with the consumption of yoghurts (including yoghurts of animal and vegetable origin, soya yoghurts). Dairy products constitute a source of vitamin B\(_12\) intake, but they have low concentrations of this vitamin and their positive effects on cobalamin status are due to their elevated consumption\(^\text{20}\). In the studied population, however, it can be appreciated that most of the subjects (eighty-seven volunteers) never consumed animal milk, which could explain the absence of an effect on vitamin B\(_12\) markers. It is remarkable that thirty-three of these subjects were lacto-ovo vegetarians. Interestingly, it was also observed that twenty-eight of the hyperhomocysteinaemic individuals (thirty-three subjects, thirteen vegetarians) never consumed animal milk, suggesting a relationship between milk consumption and normal Hcy levels. This tendency was also observed for MMA levels, as ten of the eleven deficient individuals belonged to the group of animal milk non-consumers. Regarding the intake of vegetable milks, it was observed that the consumption of these food items was more frequent than that of animal milk. However, vegetable milks did not have any influence on the analysed biomarkers in this research, probably because these milks were not vitamin B\(_12\)-fortified. Furthermore, an association was detected between a higher consumption of eggs and normal Hcy levels. Although the concentration of cobalamin in eggs is high, its absorption is limited, presenting a low bioavailability, which could explain the lack of association with MMA, a specific marker of vitamin B\(_12\) status\(^\text{20,21}\). It was observed that sixty-three subjects never consumed eggs, representing most of the population, and only nine of these individuals were lacto-ovo vegetarians.

The categorical character of the collected dietary data and the unbalanced proportion of vitamin B\(_12\) users and non-users represent limitations of the study. Further research on the topic considering quantitative dietary data must be done to assess the vitamin B\(_12\) intake through dietary sources, clarify the possible differences in methionine consumption between lacto-ovo vegetarians and vegans, and discover dissimilarities in diet composition with studies developed in other countries. Participants in the present study were not representative of the Spanish vegetarian population. In addition, the influence of polymorphisms in genes involved in the vitamin B\(_12\) and folate routes was not analysed. However, this research also presents several remarkable strengths, including a sufficient number of volunteers recruited, a balanced distribution of lacto-ovo vegetarians and vegans, and the use of both markers of circulating levels and functional status of cobalamin as previous studies.
Adequacy of cobalamin markers regarding food frequency consumption

Table 3. (Number of answers recorded for each food item or food group)

| Food Item          | Frequency of consumption | B$_{12}$ | Hcy | MMA | B$_{12}$ | Hcy | MMA | B$_{12}$ | Hcy | MMA |

B$_{12}$, vitamin B$_{12}$; Hcy, homocysteine; MMA, methylmalonic acid; A, adequate levels; I, inadequate levels (see the ‘Definitions’ section and Table 1).

Conclusions

Vitamin B$_{12}$ status of the studied vegetarian population was generally normal and better than that observed in previous European studies of similar characteristics, while folate status was elevated. The use of both markers of clinical and subclinical deficiency proved to be a useful tool, with 11% of the subjects presenting subclinical deficiency detected by MMA, and relatively common HHcy. Differences associated with diet option were not detected, observing subclinical deficiencies both in lacto-ovo vegetarians and vegans; thus neither dairy products nor eggs appeared to have a benefit in vitamin B$_{12}$ status. The risk of subclinical deficiency in non-users of supplements was higher, emphasising the need of vitamin B$_{12}$ supplementation in vegetarian diets.

Acknowledgements

Ana Salvador is acknowledged for critical review of the manuscript.

The study was supported by a research project financed by Laboratorios Zamdeh (Veggunn study). A. G.-N.’s work contract was funded by the Youth Employment Initiative (YEI) from the European Social Fund (ESF). The funders had no role in the design, analysis or writing of the article.

Contributions of the authors were as follows: M. P. V., conception and design of the work; A. G.-N. and B. Z., sample collection and laboratory analyses; A. G.-N. and L. B., statistical analysis; A. G.-N. and M. P. V., interpretation of results; A. G.-N., writing of the original draft; L. B. and M. P. V., critical revision of the article.
