Vacuolar-type ATPases (V-ATPases) exist in various cellular membranes of many organisms to regulate physiological processes by controlling the acidic environment. Here, we have determined the crystal structure of the \( A_3B_3 \) subcomplex of V-ATPase at 2.8 Å resolution. The overall construction of the \( A_3B_3 \) subcomplex is significantly different from that of the \( \alpha_2\beta_3 \) sub-domain in \( F_{\alpha}F_{\gamma} \) ATP synthase, because of the presence of a protruding ‘bulge’ domain feature in the catalytic A subunits. The \( A_3B_3 \) subcomplex structure provides the first molecular insight at the catalytic and non-catalytic interfaces, which was not possible in the structures of the separate subunits alone. Specifically, in the non-catalytic interface, the B subunit seems to be incapable of binding ATP, which is a marked difference from the situation indicated by the structure of the \( F_{\alpha}F_{\gamma} \) ATP synthase. In the catalytic interface, our mutational analysis, on the basis of the \( A_3B_3 \) structure, has highlighted the presence of a cluster composed of key hydrophobic residues, which are essential for ATP hydrolysis by V-ATPases.

Introduction

The vacuolar-type ATPases/synthases (V-ATPases) are widely distributed in many organisms and are involved in a variety of physiological processes (Forgac, 2007). The eukaryotic V-ATPases function as proton pumps that are involved in the acidification of cellular compartments such as the Golgi apparatus or lysosomes. In addition, some prokaryotes, such as the thermophilic eubacterium, \( T. thermophilus \), contain a member of the family (or homologue) of the V-ATPases in their membranes (Yokoyama et al, 1990; Yokoyama and Imamura, 2005). The prokaryotic V-ATPase is made up of a simpler subunit composition than the eukaryotic enzymes, but each subunit shows significant sequence similarity to its eukaryotic counterpart (Tsutsumi et al, 1991; Yokoyama et al, 2003). For instance, the A subunit of \( T. thermophilus \) shows 49% sequence identity and 67% similarity to its human counterpart (Supplementary Figure S1A).

The V-ATPases and \( F_{\alpha}F_{\gamma} \)-ATPases (\( F_{\alpha}F_{\gamma} \)), which function as ATP synthases in mitochondria, chloroplast and most bacteria, are evolutionarily related and use a similar rotary catalytic mechanism that couples ATP hydrolysis/synthesis in the water soluble part of \( F_{\gamma} \) or \( V_{\gamma} \) with proton translocation across the membranes in the hydrophobic domain of \( F_{\alpha} \) or \( V_{\alpha} \) (Yoshida et al, 2001; Forgac, 2007). The isolated Escherichia coli \( F_{\gamma} \), which has the subunit stoichiometry \( \alpha_2\beta_3\gamma_{5\delta} \), hydrolyses ATP with high cooperativity between the three catalytic sites contained in the \( \beta \) subunits at the \( \alpha/\beta \) interfaces. The crystal structure of bovine \( F_{\gamma} \) revealed remarkable asymmetry in the conformation and nucleotide occupancy at the \( \alpha/\beta \) interfaces, consistent with the binding change model for rotary catalysis (Boyer, 1993; Abrahams et al, 1994). In the binding change model, a central \( \gamma \) subunit is surounded by an \( \alpha_2\beta_3 \) cylinder, with the \( \beta \) subunits at three catalytic interfaces bearing an ATP or ADP analogue. In this structure, two of the \( \beta \) subunits (\( \beta_3 \), \( \beta_3 \)) at catalytic interfaces bearing nucleotides are in closed conformations, and the third \( \beta \) subunit, which is free of bound nucleotides (\( \beta_3 \)), has an open conformation. Sequential conformation change of each \( \beta \) subunit (closed to open) during turnover is coupled to rotation of the \( \gamma \) subunit. In reverse, rotation of the \( \gamma \) subunit, which is driven by the proton motive force, drives sequential conformational changes in the \( \beta \) subunits, resulting in ADP phosphorylation and release of product ATP from the enzyme.

Analysis of single particles by electron microscopy has indicated that the overall features of \( V_{\gamma} \) are nearly identical to
those of F₁. The A and B subunits also share ~25% amino-acid sequence identity with the β and α subunits of F₁, respectively. In particular, the ATP-binding regions of the catalytic A subunits in V₁ and the β subunits in F₁ are highly conserved. However, sequence alignment of the A subunit with the β subunit revealed that an additional non-homologous region is present in the A subunit of V₁ (Forgac, 2007). Earlier mutagenesis studies have suggested that the non-homologous region likely has an important function in energy coupling between the V₁ and V₀ moieties (Shao et al., 2003).

The V₁ of T. thermophilus is composed of an A₃B₃ cylinder and the D and F subunits (Yokoyama and Imamura, 2005). Experimental evidence for rotation in V₁ has been obtained by direct visualization of polystyrene beads attached to the D or F subunit, indicating that V₁ catalyses ATP hydrolysis using a binding change mechanism similar to that of F₁ (Imamura et al., 2003, 2005). On the basis of analogy with F₁ and several mutagenesis studies on V-ATPases, it has been proposed that ATP hydrolysis occurs at three catalytic sites sequentially, each located at the ‘B–A interface’, one of two interfaces between the A and B subunits (Yokoyama and Imamura, 2005; Forgac, 2007). Most residues in this site, including a P-loop motif responsible for nucleotide binding, are from the A subunit. The other interface, between the A and B subunits, is called the ‘A–B interface’. The P-loop motif is not conserved in the B subunit and the isolated B subunit of T. thermophilus V-ATPase did not bind nucleotides, unlike the isolated A subunit (Yokoyama et al., 1998; Imamura et al., 2006). An active ATP analogue was, however, shown to modify the B subunit, which has been interpreted as possible nucleotide binding to the A–B interface (Manolson et al., 1985; Vasilyeva and Forgac, 1996).

Here, we present the X-ray structure of the V-ATPase A₃B₃ complex from T. thermophilus. The overall structure shows clear differences from that of the αβ sub-domain in F₁ because of the presence of a protruding ‘bulge’ domain, belonging to the A subunit. Comparisons with the F₁ structure, in addition to mutagenesis studies at the B–A and A–B interfaces, have highlighted the importance of some hydrophobic residues in catalysis. We have also re-examined the reported nucleotide binding to the B subunits (supported by chemical modification), using a reactive ATP analogue. Our X-ray structure also reveals many similarities and differences between the F₁ and V₁ at the catalytic interface, which contribute to a further understanding of the rotary catalytic mechanism of these ATPases.

### Results and discussion

#### Structure determination of the A₃B₃ subcomplex

The A₃B₃ complex, which does not contain nucleotides, was prepared as described earlier. The mutant A₂B₃ complex, in which all cysteine residues (A/C28, C255, C508, B/C265) were substituted with serine residues, was used for crystallization. The structure of A₃B₃ was solved by molecular replacement, using partial structures of the A and B subunits from archaebacteria (PDB codes 1VDZ and 2C61, respectively) as search models. The crystallographic asymmetric unit contains two AB dimers, which are virtually structurally identical. Extensive remodelling was required for both the A and B subunit structures, because the isolated subunit structures were considerably different from those in the complex, particularly in the region of the subunit interfaces (Supplementary Figure S2). Accordingly, the A₃B₃ complex structure provides much new information about the structures of the subunit interfaces, which are described below. The structure was refined using the data up to 2.8 Å resolution. The data collection and refinement statistics are summarized in Table I. A small fraction of the crystal (15%) is twinned with a twinning operator of (−l, −k, l) and this contribution was included during the final refinement of the model (Supplementary Figure S3). The average B-factors for the N-terminal, the bulge, the central α/β and the C-terminal domains of the A subunit are 18.0/18.0, 22.5/22.4, 29.6/29.6 and 46.3/46.3 Å², respectively (two numbers represent the values for two different A subunits in the asymmetric unit). The average B-factors for the N-terminal, the central α/β and

the C-terminal domains of the B subunit are 20.2/20.2, 29.1/29.1 and 46.5/46.5 Å², respectively. As indicated by the average B-factors, the C-terminal domains of the both A and B subunits are rather disordered and it was not possible to model side chains accurately. Other details are described in Materials and methods.

**Overall structure**

Figure 1 shows the top (A) and side (B) views of the A₃B₃ complex crystal structure. The three catalytic A subunits and three catalytic B subunits are arranged alternately as in F₁. Both A and B subunits are nucleotide free in the crystal structure. The six A and B subunits in the complex are related by an approximate six-fold symmetry, which is highlighted by the N-terminal β-barrel domains (shown as blue ribbons). This six-fold symmetry, however, breaks down because of protruding structures from the A subunits (shown as red ribbons), which makes the A₃B₃ complex a triangular shape in the top view. This protruding structure, referred to as the bulge hereafter, is encoded by the ‘non-homologous region’ of the A subunit that is not conserved in F₁. In the side view, perpendicular to the molecular three-fold axis, the A₃B₃ complex structure does not have the orange-like spherical shape of the F₁ (Abrahams et al, 1994). The main structural differences between the V-ATPase A₃B₃ complex and the β₅β₃ sub-domain in F₁ are observed in two regions in the A subunit. One is the bulge mentioned above and the other is the presence of three longer helices in the C-terminal domain facing the Vₒ domain in the membrane. The A₃B₃ complex maintains a large internal cavity, which should accommodate a part of the DF central shaft in the full complex. The diameter of the cavity is larger than those observed for the β₅β₃ sub-domain in F₁ because all A subunits in the complex are present in an ‘open’ conformation as described below.

**B subunit structure and the non-catalytic A–B interface**

The B subunit in the A₃B₃ complex consists of the N-terminal β-barrel domain (5–79), the central α/β domain (80–373) and the C-terminal domain (374–464), as shown in Figure 2. Secondary structure elements of A and B subunits are summarized in Supplementary Figure S4. The B subunit has been suggested to be the non-catalytic subunit, equivalent to the F₁-α subunit (Manolson et al, 1985; Vasilyeva and Forgac, 1996; Forgac, 2007). This was examined by comparing the B subunit structure with α and β subunit structures of yeast F₁, respectively (Kabaleeswaran et al, 2006; PDB ID: 2HLD). In the F₁ structure, all three α subunits adopt similar conformations, whereas the β subunits are in three distinct conformations, namely β₂, β₃ and β₄ (Abrahams et al, 1994). Using the Cα atom positions, the whole B subunit can be superimposed onto the best fit α and β (β₂) subunits with r.m.s.d. values of 1.7 and 1.9 Å, respectively, when the molecule 2 of 2HLD is used. This means that the nucleotide-free B subunit structure is more similar to the α subunit structure with bound AMPPNP than to the nucleotide-free β subunit (β₂) structure. The similarity of these two subunits is highlighted when their domains are compared. The N-terminal β-barrel, central α/β and C-terminal domains of the B subunit can be superimposed onto the respective domains of the α subunit, with r.m.s.d.s of 1.7, 1.3 and 1.6 Å, respectively.

It has been thought that the B subunit could contain a nucleotide-binding site because it is modified by the ATP analogue of 3-O-(4-benzoyl) benzoyladenosine 5′-triphosphate (Bz-ATPase) or 2-azido-ATP (Manolson et al, 1985). On the other hand, the structure of the potential nucleotide-binding site of the B subunit in the A–B interface is very different from that observed in the β-α interface of F₁, which binds a non-catalytic nucleotide. Unlike the non-catalytic α subunit, the P-loop sequence (GXXXXXGKT/S, also known as ‘Walker motif A’) is not conserved in the B subunit.
A subunit structure

The structure of the A subunit is shown in Figure 2A. The A subunit consists of four domains: the N-terminal β-barrel domain (1–72), the non-homologous domain including the bulge (113–184), the central α/β domain (205–441) and the C-terminal domain (442–565). The A subunit is the catalytic subunit of the V-ATPases and is equivalent to the F₁-β subunit. As shown in Figure 2C and Table II, structures of the A and the β subunits are similar except for the presence of an additional bulge of eight β-strands and a larger C-terminal α-helical bundle in the A subunit. The bulge is connected to the nucleotide-binding domain through an extended linker (A185–204), which starts in the space between the N-terminal and the bulge domains and runs down the surface of the A₃B₃ complex (Figure 2A; Supplementary Figure S4A). Both the bulge and this extended linker are encoded by the so-called ‘non-homologous’ region of sequence (Shao et al., 2003). Interestingly, the residues within this linker (A/P188, A/P194 and A/P204) are conserved among V-ATPases (Supplementary Figure S1A). Substitution of the equivalent residues in yeast V-ATPase results in a change in coupling efficiency (Shao et al., 2003). These results suggest that the linker region is involved in the interaction between the peripheral stalk (composed of the E and G subunits) and the A₃B₃ complex.

The presence of longer helices, including α13–α16 in the C-terminal domain, distinguishes the domain structure from that of the equivalent F₁-β subunit (Figure 2D; Supplementary Figure S3A). This structure is also conserved in the isolated A subunit of Pyrococcus horikoshii (Maegawa et al., 2006), indicating that this is a general feature observed among V-ATPase structures.

The A subunit superimposes well onto the structure of the F₁-β₇ subunit, but not onto those of the β₇ and β₁ subunits (Figure 2C and D). This is because of conformational differences around the nucleotide-binding site of nucleotide-free (βₒ) and nucleotide-bound β subunits (Menz et al., 2001). A similar conformational change should be induced in the A subunit by nucleotide binding and/or interaction with the central rotor. That is, we predict that the lower part of the nucleotide-binding domain (205–245, 405–441) will rotate upwards, together with the C-terminal domain (442–565), as one group. This conformational change should act to place side chains critical for catalysis into the correct positions and

alanine causes the complete loss of ATP binding to the α subunit, resulting in a dramatic loss of steady-state ATP hydrolytic activity (Matsui et al., 1997). In contrast, a double mutant of V₁ (B/N161/A (equivalent to α/T176) and B/E162A (equivalent to α/A177)), which eliminates hydrophilic residues on the loop region, shows a comparable ATP-hydrolysis rate to that of the wild-type V₁ (Table II). These mutations did not affect the profile of ATP hydrolysis of V₁ either (Supplementary Figure S6). In conclusion, it is unlikely that the B subunit binds a nucleotide at the A–B interface in a similar manner to that of the α subunit. The chemical modification of the B subunit by nucleotide analogues can be explained as a modification of the B subunit residues in the catalytic B–A interface, but not in the A–B interface. As discussed below, we found a conserved B/Y331 at the nucleotide-binding site in the B–A interface, which is the likely target of this modification.

Figure 2 Structures of the A and B subunits in the complex. (A) A subunit structure. The β-barrel (A1–72) and the C-terminal (A442–565) domains are shown in blue and green, respectively. The bulge domain (A113–184), the extended linker (A185–204), the P-loop (A222–250) and the hydrophobic loop (A374–407) are highlighted in red, purple, magenta and cyan, respectively. The conserved proline residues in the extended linker are shown in purple and labelled. These proline residues have been reported to be important for the coupling efficiency of yeast V-ATPase (Shao et al., 2003). (B) B subunit structure. The β-barrel (B5–79) and the C-terminal (B374–464) domains are shown in blue and green, respectively. Tyrosine 331 in the B subunit is shown in sky blue. (C) A subunit (red) superimposed on the β₁ subunit of the yeast F₁. (D) A subunit (red) superimposed on the β₀ (blue) subunit of the yeast F₁.

Figure 3 compares the structures of the P-loop equivalent region in the B subunit and of the nucleotide-bound P-loop in the yeast F₁ αE subunit. The P-loop has a unique main-chain structure, which allows five amide protons within the loop to form hydrogen-bonding interactions (shown in blue in Figure 3B) with the triphosphate group of bound ATP. The equivalent loop in the B subunit shows a totally different main-chain conformation, which by analogy does not allow the formation of these hydrogen bonds (Figure 3A and C). This is presumably because the P-loop equivalent region in the B subunit lacks flexible glycine residues and includes an insertion of a proline residue, which does not have an amide group. In addition, several residues known to be involved in nucleotide binding at the β₁–α interface (β/Y368, β/R372, α/Q172, α/Q432, α/P367, the bovine F₁ residue numbering is used hereafter) are missing in the A₃B₃ complex. In the F₁ structure, the side chains of α/Q172, α/K175, α/T176 in the P-loop region interact with the diphosphate group of ATP-Mg at the β₁–αE interface. Substitution of these residues with

b superimposed on the Tyrosine 331 in the B subunit is shown in sky blue. (B374–464) domains are shown in blue and green, respectively. The bulge domains (A222–250) and the hydrophobic loop (A374–407) are highlighted in red, purple, magenta and cyan, respectively. The conserved proline residues in the extended linker are shown in purple and labelled. These proline residues have been reported to be important for the coupling efficiency of yeast V-ATPase (Shao et al., 2003). (B) B subunit structure. The β-barrel (B5–79) and the C-terminal (B374–464) domains are shown in blue and green, respectively. Tyrosine 331 in the B subunit is shown in sky blue. (C) A subunit (red) superimposed on the β₁ subunit of the yeast F₁. (D) A subunit (red) superimposed on the β₀ (blue) subunit of the yeast F₁.
conformations for nucleotide binding, as we discuss in the following section.

Regulatory disulphide bond formation between conserved cysteine residues in the A subunit (A/C261 and C539 in yeast V-ATPase) has been proposed (Feng and Forgac, 1994). The equivalent cysteine residues in the T. thermophilus A subunit are A/S232 and A/S539 (mutated from A/C539), respectively. In our open structure of A subunit, the distance between the hydroxyl oxygen atom of A/S232 and the sulfur atom of A/C507 is 26 Å apart. It is, therefore, unlikely that a disulphide bridge exists between them. However, it is possible that side chain of A/S232 might be proximate to that of A/C507 when the A subunit adopts the closed conformation. Disulphide bond formation between two different subunits is unlikely because the relevant residues are more than 60 Å apart.

### The catalytic B–A interface

The nucleotide-binding sites are located in the interface between the B and A subunits. The site is mainly composed of the residues from the A subunit, but some from the B subunit are also essential. The nucleotide-binding domain of the A subunit shows high sequence similarity to that of F₁, including the P-loop, which is responsible for coordination of phosphate moieties of ATP (Supplementary Figure S1A). Figure 4 shows a structural comparison between the nucleotide-binding sites of the V₁ B–A interface and the aE–bE interface in the yeast F₁. As expected, the binding site in the B–A interface is similar to that in the aE–bE interface in the F₁, including the P-loop. For example, the A subunit structure confirmed that residues A/K234 and A/T235 are placed in similar positions to those of the b/K162 and b/T163 residues of the b subunit, respectively. The superposition of both interfaces, however, identified some significant differences (Figure 4). Electron density maps calculated during the determination of the yeast F₁ structure allowed identification of density attributed to bound inorganic phosphate (P<sub>i</sub>). However, equivalent analysis indicates that the B–A interface in the present structure is P<sub>i</sub>-free (Figure 4B). In the yeast F₁ structure, the bound P<sub>i</sub> was coordinated by residues b/K162 (equivalent to A/K234), b/R189 (A/R258), b/D256 (A/D325), b/R260 (A/R329), α/R373 (B/R360) and β/N257 (A/S326). In contrast, the A-subunit structure shows that all arginine residues are orientated away from the putative P<sub>i</sub>-binding site, leaving the site much more open and structurally less favourable for P<sub>i</sub> binding (Figure 4B).

### Table II Effect of mutagenesis on the ATP hydrolysis activity of V₁/F₁

The ATP hydrolysis activities of each mutant enzyme were measured by the enzyme-coupling assay. Each value represents the average of 3–5 replicates. The V₁ contains the TSSA mutation as described in Materials and methods. Note that the residue numbers of bacillus PS3 F₁ are on the basis of the bovine F₁ system.

---

**Figure 3** Structures of the P-loop equivalent region in the B subunit and of the nucleotide-bound P-loop in the yeast F₁ α₅ subunit. (A) Structure of the P-loop equivalent region in the B subunit. (B) Structure of the P-loop of the yeast F₁α₂ subunit. The bound AMP-PNP molecule and the magnesium ion are shown. Hydrogen bonds are shown in light blue, whereas coordination links to the magnesium ion are shown in yellow. (C) Superposition of (A) and (B). Only protein atoms are shown.
We have also compared the B–A interface structures of V-ATPase with the nucleotide-bound $\gamma_{B}-\beta_{B}$ interface of the yeast F1. Figure 5 shows that most of the key residues for nucleotide binding and catalysis are conserved, except for $\alpha_{F}/S344$ (B/Y331), which will be discussed below. As our V-ATPase structure is nucleotide free, we have performed some mutational studies to confirm that this is the catalytic site of the V1. The subunit stoichiometry of mutated F1/V1 has been confirmed by SDS–PAGE (Supplementary Figure S5). A/E257 is well conserved in the A subunits among species and is thought to be equivalent to residue $\beta/\gamma$ on the ATPase (Supplementary Figure S1A). In F1, the side chain of $\beta/\gamma$ is appropriately positioned close to the nucleophilic water molecule at the $\alpha_{B}^{-}\beta_{B}$ interface, promoting an inline nucleophilic attack on the terminal $\gamma$-phosphate moiety of the substrate ATP. The mutation of A/E257 in V1 to aspartate or glutamine resulted in almost complete loss of ATP-hydrolysis activity (Table II), consistent with earlier results with the yeast V-ATPase (Liu and Kane, 1996). The guanidinium moiety of $\gamma/\gamma$ at the $\alpha_{B}$ interface in the F1 has a critical function in catalysis by stabilizing the negative charge of the $\gamma$-phosphate group in the transition state. The mutation of B/R360, equivalent to $\gamma/\gamma$, to lysine or leucine causes complete loss of ATP-hydrolysis activity in V1 (Table II), as does the equivalent mutation of $\gamma/\gamma$ in F1. Residues in the adenine-binding pocket, as identified in the F1 $\beta$ structure, are well conserved in the subunit A structure from V1. Accordingly, the mutation of A/F419, which is equivalent to $\gamma/\gamma$, to glutamate causes a complete loss of ATP-hydrolysis activity (Table II). Taken together, these mutation results confirm that the catalytic sites of F1 and V1 are closely related.

We have, however, observed one interesting and important difference in the nucleotide-binding sites of two ATPases. The residue $\alpha_{F}/S344$ is well conserved in F1 among species, and in the elucidated structures, it lies in close proximity to the catalytic water interacting with $\beta/\gamma$ at the $\alpha_{B}^{-}\beta_{B}$ interfaces (Abrahams et al., 1994). Thus, the $\alpha/\gamma$ residue has been thought to be critical for catalysis (Abrahams et al., 1994; Menz et al., 2001; Dittrich et al., 2004). However, the serine residue is not conserved at the identical position in the B subunit of V1 (Supplementary Figure S1B). Instead, the conserved tyrosine residue (B/Y331) is located at the identical position. Mutation of residue B/Y331 to serine, alanine or leucine reduced the ATPase activity of V1 by >99% (Table II). In contrast, the mutant protein B/Y331F showed comparable activity (ca 45% of residual activity) to that of the wild-type protein. These results are consistent with earlier mutational studies of the yeast V-ATPase (Liu and Kane, 1996). Therefore, an aromatic side chain in this position seems essential for the ATP-hydrolysis activity of V1.

Interestingly, we have also identified an aromatic side chain (B/Y311), which is located next to $\alpha_{F}/S344$, and which occupies the equivalent position in the $\alpha_{B}^{-}\beta_{B}$ interface in the structure of F1. This $\beta/\gamma$ residue can react with hydrophobic chemical modifiers such as NBF-Cl or $\delta$-azide ATP (Yoshida and Allison, 1990; Garin et al., 1994), even though the residue lies ~7 Å away from the adenine pocket (Abrahams et al., 1994). Moreover, the serine residue is conserved among V1 proteins (A/S345 in the Thermus V1), at the equivalent position to residue $\beta/\gamma$ in F1. It seems that the B/Y331-A/S385 pair in the V1 has the same function as the $\alpha/\gamma$-Y311 pair in the F1 with swapped positions.

To prove this hypothesis, we designed several mutational studies. As expected, the A/S385A substitutions caused
complete loss of ATPase activity of the V1 (Table II). Similar to α/S344 in the F1, A/S385 possibly coordinates a catalytic water molecule at the nucleotide-bound B–A interfaces. β/Y311 of F1 at the equivalent position to A/S385 was also mutated using the F1 from the thermophilic bacillus PS-3. Both β/Y311S and β/Y311A substitutions significantly decreased the ATP-hydrolysis activity of F1, but the β/Y311F substitution showed weak effect on the activity (Table II). In conclusion, the pair of a serine and an aromatic residue seems essential for catalysis in both F1 and V1.

**Importance of hydrophobic residues at the B–A interface**

It is not immediately obvious how aromatic residues such as B/Y331 and β/Y311 can be involved in ATP hydrolysis. Our A3B3 structure enables us to compare the catalytic interfaces of both ATPases. By combining the structural information and mutational studies, we have studied the importance of these hydrophobic residues. Figure 6 compares the surroundings of these hydrophobic residues in the V-ATPase (A) and nucleotide free and bound F1 structures (open (B) and closed (C) conformations, respectively). In the F1, nucleotide binding induces a conformation change, which relocates the β132–173 region, including the P-loop, towards the β330–464 region, including the C-terminal domain and its linker to the central α/β domain (Figure 6B and C). In this closed conformation, the side chains from both regions, including residues β/F155, β/A158, β/I310, β/Y311, β/F313 and β/F326 form a hydrophobic cluster at the interface (Figure 6C). For example, β/F155 and β/A158, which are associated with the P-loop, move into contact with β/F326 and β/P313, respectively. This P-loop closes the catalytic site, defined by these hydrophobic residues and facilitates the correct alignment of water molecules and residues essential for catalysis. Computer simulations show that ATP hydrolysis at the catalytic site of the F1 requires a multi-centre proton alignment of water molecules and residues essential for catalysis. For example, the aromatic side chains of β/F155 and β/F326, which show stacking orientations in the closed form of F1, are replaced by A/P227 and A/L400 in the V-ATPase. β/A158 in the P-loop is replaced by A/F230, which is highly conserved in the V-ATPases. If the closed form of the V1 is similar to that observed for the F1, then residue A/F230 should move into proximity with A/P387 and B/Y331 to form a hydrophobic cluster, in which the residues interact very differently from those in the F1. This idea is strongly supported by the result that the substitution of A/F230 by alanine caused nearly complete loss of the ATPase activity of V1 (Table II). In conclusion, the formation of a hydrophobic cluster has a critical role in catalysis for both the V1 and F1 rotary motors. Observed differences in the cluster possibly affect the stability of the closed conformations of the α and β subunits, thus affecting the open-closed transition of these catalytic subunits during rotary catalysis.

Interestingly, similar hydrophobic cluster formation has been reported in the sarcoplasmic reticulum Ca2+-ATPase (Yamasaki et al., 2008), which is a P-type ion transporting ATPases that catalyses Ca2+ transport coupled with ATP hydrolysis. The crystal structures of the E1P Ca2+-2 and E2P states of the Ca2+-ATPase showed that a hydrophobic cluster is formed at the interface between the phosphorylation (P) and actuator (A) domains, during the transition between the two states (Olesen et al., 2007). The cluster is formed by seven residues, including Y122, which are located on the interface, and mutational studies on the residues in the cluster indicate that the formation of the hydrophobic cluster is critical for the catalytic cycle of the Ca2+-ATPase. Their proposal suggests our idea that hydrophobic cluster formation is important for the ATPase reaction in rotary ATPases.

**Materials and methods**

**Purification, crystallization and structure determination**

The A3B3 subcomplex overexpressed in *E. coli* BL21-CodonPlus (DE3)-RP (Stratagene) was purified, as described earlier (Imamura et al., 2003). The purified A3B3 complex was supplemented with a final concentration of 100 mM MgCl2 and concentrated to a protein concentration of 10 mg/ml using a Centricon 100k concentrator (Millipore). Crystals were obtained by the vapour diffusion method in a hanging drop with the reservoir solution, 11.5% (w/v) PEG 8000, 0.1 M Tris–HCl (pH 7.5), 5% (v/v) MPD and 100 mM MgCl2. By adding 20% glycerol, the reservoir solution was used to flash freeze the crystals in liquid nitrogen. X-ray data were collected at 100 K using an ADSC Quantum-4 CCD detector with a wavelength of 0.933 Å and 0.5° oscillation steps over a range of 120° at the ESRF.

![Figure 6 Hydrophobic cluster formation in the catalytic interfaces of V- and F-ATPases.](image-url)
ID14-2 beamline (Grenoble, France). The data set was processed to 2.8 Å resolution using the programs Denzo and Scalepack (Otwinowski and Minor, 1997) and the CCP4 program suite (Collaborative Computational Project, Number 4, 1994). The crystal belonged to the space group P2₁, with unit cell dimensions a = b = 199.4 Å and c = 179.0 Å. The average B-factor estimated from the Wilson plot was 62.5 Å². The 2.8 Å resolution structure of the A₅B₅ subcomplex was solved by molecular replacement with Phaser (McCoy et al, 2007), using partial structures of the A and B subunits from archa (PDB code 1VDZ and 2CGI) as search models (Masegawa et al, 2006; Schafer et al, 2006). A single solution with two AB heterodimers located close to the crystallographic three-fold axis was identified (Supplementary Figure S3A and B). The two dimers were related by a translational symmetry, which is confirmed by peaks at (0.66, 0.03, 0.02) in the native Patterson map. Preliminary rigid body and restrained refinement with REFMAC5 (Murshudov et al, 1997) gave residuals R = 0.44 and Rfree = 0.48 for this solution. Model bias was minimized by solvent flattening using RESOLVE (Terwilliger, 2000) using ‘prime-and-switch’ phasing and two-fold NCS averaging. The resulting electron density maps were readily interpretable and clearly showed areas with structural differences. Manual adjustments to the model were made using COOT (Emsley and Cowtan, 2004) and O (Jones et al, 1991). Model refinement was carried out using CNS (Brunger et al, 1998) and REFMAC5 with TLS (Painter and Merritt, 2006). We found that a small fraction of the crystal (15%) is twinned with a twinning operator (−h, −k, l) and this contribution was included in the final stage of the refinement using REFMAC5 (Supplementary Figure S3C). This improved the values of the residuals, R and Rfree to 25.0% (from 27.3%) and 28.1% (from 32.8%), respectively.

Biochemical assay

The V₁ of T. thermophillus and F₁ of thermophilic Bacillus PS-3 were expressed in E. coli and purified by earlier described procedures. We thank S Hayashi, T Ikekami and Y Suzuki for critical discussion, members of Hisabori and Yoshida laboratories, Diamond MPL and ICORP in Odaiba for help and advice, T Yano for laboratory management and encouragement. This work was partly supported by Grants-in-Aid from the Ministry of Education, Science, Sports and Culture of Japan to KY (No. 21023009 and 21370042), Targeted Proteins Research Program (TPRP) (B-37, to KY), Welcome Trust to MI, and a Cancer Institute of NSW fellowship (MJM). We thank a referee who suggested the possible twinning problem of the structure.
