ABSTRACT

We provide a detailed description of the Herschel/SPIRE Fourier Transform Spectrometer (FTS) Spectral Feature Finder (FF). The FF is an automated process designed to extract significant spectral features from SPIRE FTS data products. Optimizing the number of features found in SPIRE-FTS spectra is challenging. The wide SPIRE-FTS frequency range (447–1568 GHz) leads to many molecular species and atomic fine structure lines falling within the observed bands. As the best spectral resolution of the SPIRE-FTS is ∼1.2 GHz, there can be significant line blending, depending on the source type. In order to find, both efficiently and reliably, features in spectra associated with a wide range of sources, the FF iteratively searches for peaks over a number of signal-to-noise ratio (SNR) thresholds. For each threshold, newly identified features are rigorously checked before being added to the fitting model. At the end of each iteration, the FF simultaneously fits the continuum and features found, with the resulting residual spectrum used in the next iteration. The final FF products report the frequency of the features found and the associated SNRs. Line flux determination is not included as part of the FF products, as extracting reliable line flux from SPIRE-FTS data is a complex process that requires careful evaluation and analysis of the spectra on a case-by-case basis. The FF results are 100 per cent complete for features with SNR greater than 10 and 50–70 per cent complete at SNR of 5. The FF code and all FF products are publicly available via the Herschel Science Archive.

Key words: line: identification – methods: data analysis – techniques: imaging spectroscopy – techniques: spectroscopic – catalogues – submillimetre: general.

1 INTRODUCTION

The ESA Herschel Space Observatory (Herschel; Pilbratt et al. 2010) observed the far-infrared and sub-millimetre (submm) sky from an orbit around the Sun–Earth L2 Lagrangian point, from 2009 May to 2013 April. After an initial six-months of commissioning and performance demonstration, Herschel entered its routine operation phase, during which science and calibration observations were conducted. The Spectral and Photometric Imaging REceiver (SPIRE; Griffin et al. 2010) was one of three focal plane instruments on board Herschel. SPIRE consisted of an imaging photometric camera and an imaging Fourier Transform Spectrometer (FTS). The SPIRE FTS’s two bolometer arrays, Spectrometer Long Wavelength – SLW (447–990 GHz) and Spectrometer Short Wavelength – SSW (958–1546 GHz), provided simultaneous frequency coverage at high (HR; ∼1.2 GHz) and low (LR; ∼25 GHz) spectral resolution, across a wide frequency band in the submm. The bolometric detectors (Turner et al. 2001) operated at ∼300 mK with hexagonally close-packed feedhorn-coupled focal plane optics, providing sparse spatial sampling over an unvignetted field of view of 2 arcmin (Dohlen et al. 2000). Details on the SPIRE FTS data processing and data products are provided in the SPIRE Data Reduction Guide (SDRG), available in the Herschel Explanatory Legacy Library.1 The calibration scheme and the calibration accuracy for the SPIRE FTS are described by Swinyard et al. (2014), Marchili et al. (2017), and Hopwood et al. (2015). Due to repeated referencing of Hopwood et al. (2015), the abbreviation Hop15 is used in further text within this paper.

1The Herschel Explanatory Legacy Library contains all relevant documents for the three Herschel instruments, including SPIRE, available at the following URL: https://www.cosmos.esa.int/web/herschel/legacy-documentation

This paper details the SPIRE FTS Spectral Feature Finder (FF) and the associated products, which are available in the Herschel Science Archive (HSA). The FF is an automated process that finds and fits significant spectral features in all SPIRE FTS observations, and, where appropriate, produces catalogue entries associated with the features found. The main motivation behind developing the FF was as a data mining aid for the HSA. To this end, the FF provides an initial data analysis shortcut, by allowing quick inspection of one or multiple FTS observations and facilitating the search for spectral features of interest in all SPIRE FTS observations. Use of the FF products should not, however, replace the detailed data inspection and hands-on spectral analysis necessary to produce conclusive scientific results. There are three companion papers that discuss aspects of the FF: a radial source velocity paper (Paper II; Scott et al. 2020a, see also Scott et al. 2016a), a line identification paper (Paper III; Benson et al. 2020) which also presents FF results for the off-axis spectra within sparse observations, and a [CI] detection and deblending paper (Paper IV; Scott et al. 2020b).

The FF procedure is presented in Section 2, with details on the Herschel/SPIRE data products and observing modes given in Section 2.1. The main FF steps are provided in Section 2.2 including deriving the initial continuum estimate (Section 2.2.1), the iterative feature finding (Section 2.2.2), incorporating frequency masking (Section 2.2.3), limited fitting line drifts (Section 2.2.4), estimation of the final signal-to-noise ratio (SNR), and removing spurious detections (Section 2.2.5). Details on the goodness of fit (GoF) criteria and data flagging protocols are presented in Section 2.3. The methods to estimate the radial velocities, including compilation of radial velocities from the literature, are presented in Section 2.4. In Section 2.5, we describe a deblending method that improves the final feature results for sources with $^{12}$CO(7–6) and [CI]$^{3}$P$_{1}$ – $^{3}$P$_{1}$ lines. We also perform visual inspection of the FF products, summarized in Section 2.6. The FF data products are presented in Section 3, and Section 4 presents the main FF validation and results, including completeness validation testing (Section 4.1), comparison with an alternative method (Section 4.2), accessing the FF results, including completeness validation testing (Section 4.3), and comparison with known results for SPIRE calibration sources (Section 4.4). Summary and conclusions are provided in Section 5.

The standard and highly processed SPIRE FTS data products have flux density units of Jy for point-source calibrated data, and intensity units of W m$^{-2}$ Hz$^{-1}$ sr$^{-1}$ for extended-source calibrated data. All SPIRE FTS spectra are presented as a function of frequency, in GHz, in the kinematic local standard of rest (LSRk) reference frame. The mnemonics of the two central detectors for the SSW and SLW arrays are $SSD4$ and $SLC3$ (see SPIRE Handbook 2018).

2 THE SPIRE FTS SPECTRAL FEATURE FINDER

The Spectral FF is developed in the Herschel Interactive Processing Environment (HIPE; Ott 2010), version 15. As mentioned in Section 1, the FF routine was developed as a preliminary analysis tool to help identify Herschel FTS products for follow-up investigation. As the FF needs to process a large number of SPIRE FTS observations, it was developed to run automatically, while having enough flexibility to produce reliable results for a wide range of input spectra.

This section details each of the input products used, as well as the FF processing steps, the derivation of radial velocity estimates, and a dedicated check for in-band [CI] fine structure emission. The FF algorithm is depicted by the flowchart in Fig. 1.

2.1 Feature finder input

From operational day (OD) 209 (8 December 2009) to the end of Herschel’s operational phase (OD 1447, 29 April 2013), there are 1802 SPIRE FTS observations available in the HSA, which total 2083.3 h. Before OD 209, SPIRE FTS data are not properly calibrated, as the final instrument settings were still being tested. The highest proportion of observations (~75 per cent by observation time) were taken in sparse, single-pointing mode (i.e. one SPIRE FTS footprint on-sky). Of those, 1162 were observed in HR mode (1455.6 h) and 330 in LR mode (70.2 h). There are 60 of these observations that were taken in a combined mode, where high- and then low-resolution scans are taken (H + LR, 53.6 h, see SPIRE Handbook 2018; Marchili et al. 2016b; Marchili et al. 2017). Table 1 provides a breakdown of the SPIRE Spectrometer observations, including the number of observations, number of unique observing targets, and the hours of associated observing time. This is provided for several observation categories and classifications. All the fully calibrated data products are presented in the HSA as spectral data sets, with one spectrum for each of the bolometer array detectors for sparse mode.

The SPIRE FTS also observed in intermediate (four jiggle positions), fully sampled (16 jiggle positions), and raster mapping modes, which make up ~25 per cent of all observations at 558.4 h of integration time. There are two types of cube products available for mapping observations – the naïve projection (NP) cube and convolution projection (CP) cube. The NP cube values are determined using the mean sum of the data falling within the spatial grid coordinates, and the CP cube values are determined using a weighted mean based on the proportional filling of the respective grid spaxel by the Gaussian beam profile of the associated detector element. See the SDRG for more details on NP and CP cubes and how they are created. Only CP cubes are considered by the FF, primarily because they tend to have higher SNR and do not contain empty spaxels in the middle of the maps as they are generated using more spatial information. There are, however, incomplete spectra at the edges of some CP cubes. These arise from the vignetting of the frequency dependent SPIRE beam (see Makwa et al. 2013) and result in frequency dependent spatial coverage.

Fully calibrated mapping data are presented as hyper-spectral cubes, where the individual spectra have been projected on to equidistant rectangular RA/Dec. grids. There are separate cubes for the long and short wavelength bolometer arrays with spaxels of different spatial extent, where each spaxel contains a single spectrum. The SPIRE Handbook (2018) provides full details of SPIRE FTS observing modes and data products. The primary input to the FF script is an FTS spectrum from either the SLW or SSW array. Standard SPIRE FTS data products, from the HSA, were used for most observations: the standard product generation (SPG) pipeline was run with HIPE version 14.1, and SPIRE calibration tree spire_cal_14.3. The FF works on unapodized (i.e. unsmoothed) versions of the spectra, although for validating the results with an alternative detection method (see Section 4.2) we also use apodized spectra. Both versions are available as standard products from the pipeline. While it is possible

Figure 1. The FF flowchart that summarizes the main FF steps. A detailed description is provided in Section 2.2.
that some of the HPDP data employed in the FF processing falls under a different HPDE processing/calibration scheme, given that the FF outputs line frequency and SNR, and not integrated flux or intensity of spectral features, this was not observed to change the FF output.

The input data (and output products) depend only on observing mode and the spectral resolution of the associated observation.

As introduced earlier, spectral resolutions include LR and HR, respectively, and observing modes include sparse and mapping observations. Table 1 provides an overview of the SPIRE Spectrometer observations available from the HSA and includes a breakdown of the number of observations in these different observing modes, as used within the FF. The table lists observations that were either restricted or otherwise excluded from the FF, as well as those that are included, and corresponding sub-categories. The restricted observations are special calibration observations, with non-standard detector settings, and are limited to eight targets: Uranus, Mars, Neptune, OMC-1, DR 21, IR+10216, 4 Vesta, and Dark Sky. 4

The HPDP observations excluded from the FF search, the Dark Sky observations are excluded, and there are three other featureless Solar system objects (e.g. planets and asteroids) excluded from the FF search: Uranus, 1 Ceres, and 4 Vesta. The results for Neptune, Mars, and Saturn are also not included, as some of these lines are partially resolved and the FF, tuned specifically for unresolved spectral features, does not produce results as good as their existing models. 5 There is also one AFGL 4106 observation excluded from the HR-sparse FF data due to a pointing error.

Commentary on specific categories of SPIRE Spectrometer observation data as related to the FF is provided in Sections 2.1.1–2.1.6.

### 2.1.1 High resolution sparse-mode observations

For high resolution (HR) sparse-mode observations, the FF is configured to process the central detector of each array, as the large majority of these observations are of point-like sources or sources with little spatial extent. The FF processing of the off-axis detectors in sparse HR mode is presented in Paper III.

### 2.1.2 High resolution intermediate and fully sampled mapping observations

For HR intermediate and fully sampled mapping observations (and raster observations), the FF is run on every fully populated spaxel in both the SLW and SSW CP cubes. If the spectrum of any spaxel contains one or more instances of not-a-number (NaN) values, the FF skips that spectrum.

### 2.1.3 Low resolution observations

The FF process is applied to low-resolution (LR) observations, both for sparse and mapping mode. In this case, the iterative SNR loop is skipped and only the continuum parameters are derived for LR observing modes (see Table 2).

### 2.1.4 High + low-resolution observations

The HR + LR observing mode is simply a sequence of HR and LR spectral scans. For the FF run, we treat each part independently and process it as either HR or LR mode, respectively. In Table 1 these observations are included in the corresponding HR section to avoid double counting with respect to observation totals. Within the FF they appear in both the HR and LR sections.

4 Observations of an area of dark sky are set to match the longest science observation on a given observation day. The location of the SPIRE dark sky field is 17h40m12.00s, 69°00′00″.

5 www.cosmos.esa.int/web/herschel/calibrator-models
Due to the frequency dependent beam diameter of the SPIRE source and the extended-source calibrated processing pipelines. For these observations, the FF was run with both the point-source and the extended-source calibrated processing pipelines. Over the course of the Herschel mission, a number of sources with significant spatial extent were observed in sparse observing mode. For these observations, the FF was run with both the point-source and the extended-source calibrated processing pipelines. Due to the frequency dependent beam diameter of the SPIRE FTS (Makiwa et al. 2013), few sources are truly extended over the SPIRE bands and it is not always clear which of these calibration schemes will provide the better FF result. The number of HR sparse observations where the extended source calibration leads to better FF results is given in Table 1, as ‘extended source’ classification.

For some sources, neither the point nor the extended source calibration provide good spectral shape without a discontinuity in the overlap region or unphysical curvatures. In such cases, SECT (Wu et al. 2013) can be used iteratively to optimize the source size and shape in order to minimize the transition between the SLW and SSW data. This improves the spectral shape and continuum significantly, and consequently the feature detection and characterization. For some calibration observations, HPDPs with semi-extended corrections exist (Section 2.1.6) and were used instead of the standard HSA spectra. Therefore, a visual inspection (Section 2.6) was carried out to determine which calibration scheme was optimal for a given observation.

Table 1 lists the number of spectra visually classified as ‘semi-extended’, based on the appearance of the SLW and SSW spectra. The input spectra were not corrected for the source shape and size with SECT, as this was considered outside the scope of the automated FF. The class is nevertheless provided to inform or warn the user that the FF results may be sub-optimal as neither the point nor the extended source calibrations are applicable.

### 2.1.6 The use of highly processed data products

For some observations, including those observing calibration sources, there are expert produced data products, which are alternative or better than the nominal SPG output. Some of those are available as highly processed data products (HPDP). For the FF input we use the following improved products:

1. A pointing offset correction as described by Valtchanov et al. (2014). This correction was only applied, as needed, to a subset of the calibration targets (only for HR sparse mode).

2. A correction for partially extended sources using the semi-extended correction tool (SECT) in HIPE (Wu et al. 2013) (only for HR sparse mode).

3. Subtraction of high background emission using averaged spectra from off-axis detectors within the same observation (only for HR sparse mode).

4. Spectral cubes undergo regridding that excludes the outer ring of vignette detectors (typically for maps of faint sources, only for HR mapping mode).

For each SPIRE spectrometer observation operating in sparse mode, a separate set of background subtracted spectra (BGS) exist, which are obtained by using the HIPE Background Subtraction tool in interactive mode. These HPDPs are used in place of the standard HSA products when FF results are improved, e.g. for faint point-sources embedded in high Galactic cirrus. Meta data in FF products contain the parameters ‘HPD USED’ when a pointing offset correction has been applied, and ‘BGS USED’ when the alternate background subtraction has been employed. The number of observations with these corrections is listed in Table 1 as ‘HPDP correction’ and ‘background subtracted’.

### 2.2 Feature finder algorithm

The FF algorithm is depicted by the flowchart in Fig. 1 and can be divided into four main components: (1) initial fit to the continuum, (2) iterative feature finding, (3) final SNR estimate and reliability checks, and (4) generating parameters for the features found. Each of these components is described in detail within this section.

#### 2.2.1 Initial fit to the continuum

Before starting to search for spectral features in the extracted spectrum, the FF fits a polynomial to the continuum in each of the two spectral bands: SSW and SLW. In order to ensure a good result, all significant features present in the spectrum need to be masked. To that end, the input HR spectrum is resampled on a coarser, 5 GHz, frequency grid (LR spectra are not resampled), and a ‘difference spectrum’ is generated by subtracting adjacent flux values of the resampled spectrum. Discrete jumps in the difference spectrum, greater than 3.5 times the RMS, are interpreted as strong peaks in the unmodified input spectrum. A mask for the original spectrum is then fitted using a width of 30 GHz centred on each of the strong peaks that have been identified. The original masked spectrum is then fitted using a third-order polynomial for HR data and a second-order polynomial for LR data. The reduced polynomial order for the LR case was selected to prevent the potential influence of sinc side lobes on the continuum fit (≈1 GHz resolution for HR cf. ≈25 GHz resolution for LR). The resulting best-fitting model of the continuum is used as a base for the spectral feature finding. In each iteration, newly identified features are added to a total spectral model including the continuum, and during the fitting procedure, the continuum parameters are allowed to vary. Throughout the FF process, fitting is always performed on the original spectrum.

#### 2.2.2 Finding and fitting spectral features

The main finding and fitting of spectral features starts with the modelled continuum and the input spectrum. Each step in the iterative

---

6HPDPs are available in the Herschel Science Centre: https://www.cosmos.esa.int/web/herschel/highly-processed-data-products

7Herschel SPIRE Background Subtracted Spectra DOI: doi.org/10.5270/esa-vrq3lz9.

8Herschel SPIRE Re-Gridded Spectral Cubes DOI: doi.org/10.5270/esa-77n5rc0.
process applied is described as follows:

(1) The SNR spectrum is calculated by dividing the continuum subtracted spectrum by the associated error spectrum. The error spectrum is calculated by the SPIRE FTS pipeline (Fulton et al. 2016) as the weighted standard error of the mean signal from all spectral scans in an observation.

(2) Regions with SNR greater than the iteration threshold are located and peaks are determined by merging all data points above the threshold within a 10 GHz width window per peak.

(3) For each peak, a sinc function profile (see Fig. 2 and the SDRG) is added to the total model (which starts before the first iteration with the polynomial fitted to the continuum, and builds as the process iterates). The width parameter of the sinc function is kept fixed to the unresolved HR instrumental line width of \( \frac{1.2}{\pi} = 0.382 \) GHz. This is because the majority of spectral features in SPIRE FTS HR data are unresolved. Partially resolved sources should be fitted using a sinc convolved with a Gaussian, however, allowing the width to be a free parameter does not generally provide a better fit to a partially resolved line (in practice, trials during the FF development cycle demonstrate that the width hardly changes).

(4) A global fit is performed. The features found are assessed against the following set of metrics and discarded from the total model if:

(a) the line amplitude parameter has the incorrect sign,
(b) the SNR is \(< -500\) (for the negative sweep only),
(c) the fitted position has moved more than 2 GHz from the line’s starting position,
(d) the \(|\text{SNR}|\) is \(< |\text{SNR threshold}|\), or
(e) the feature is within the fringe avoidance regions (10 GHz at the end of the bands).

(5) A check is then performed to reduce the number of multisinc fits to partially resolved lines.

(a) The position of each new feature is compared to features already identified in previous iterations of the algorithm, under the likely assumption the previous features have higher SNRs.

(b) If within 1.2 GHz of any neighbouring feature, the new feature is rejected and the position of the previous feature is set back to its position within the previous global fit.

(c) The position of the existing stronger feature is assumed to be at the peak of a partially resolved or highly blended feature or a feature whose width has been significantly affected by noise.

(6) Surviving features are assumed to be valid with a stable fitted position, so a positional restriction of 2 GHz (i.e. \(5\sigma\)) is applied to their corresponding sinc model for subsequent iterations.

(7) At this point the global fit is repeated.

(a) If the fit succeeds, new features are added to the list of detected features and a mask is applied to the spectrum on either side of the detected feature with a frequency width dependant on the SNR threshold (see Section 2.2.3). No new features are accepted if they fall within a masked frequency region.

(b) If the fit fails, all new features are removed and the results remain unchanged for input into the next iteration at a lower SNR threshold.

(8) A residual is calculated by subtracting the best-fitting total model (including both the identified spectral features and the continuum) from the original spectrum, and it is passed to the next iteration of feature finding. The residual is used for the SNR calculation when searching for new peaks.

(9) Once the loop has cycled through the strongest emission features down to the lowest SNR threshold, the loop is repeated searching for absorption features, again starting with the strongest and working down to the final SNR threshold (by definition, SNRs are negative for absorption features, so the threshold evaluation is performed on the absolute SNR magnitude).

2.2.3 Frequency masking

In order to lessen the number of spurious detections that can occur in the wings of another feature, a spectral frequency mask is created and used during the peak detection and fitting process. The mask is
built upon and updated after each iteration and then carried forward and used in subsequent iterations.

Each masked region is centred on a detected feature, with the masking width dependent on the iteration SNR threshold. The widths for each threshold were determined by the expected side lobe amplitudes of a pure sinc function. For example, Fig. 2 shows the relative strength of the side lobes for an ideal SPIRE FTS instrument line shape (ILS) emission line, with SNR of 100 and a flat associated error of 1. From this example, for features with SNR > 100, the third positive side lobes will appear to have an SNR > 5 corresponding to a frequency difference from the central peak of ~8 GHz. Fig. 2 also shows the empirical SPIRE FTS ILS, which was obtained by stacking CO features from calibration observations of NGC 7027 (Hop15).

In setting a mask-width, some additional considerations are necessary, as in reality the noise spectrum will not be flat and the fit to the feature will not be perfect. Strong and unresolved features, significantly above the random noise, tend to be well fitted. Even a small misalignment of the true feature frequency and the model best fit (e.g. due to the mild asymmetry of the observed empirical SPIRE FTS ILS, Naylor et al. 2016), or widening of the peak (due to velocity dispersion of the source or noise) may leave prominent spectral residuals in the wings.

The iterative mask widths used, and their corresponding SNR thresholds are provided in Table 2. The final two widths (both 2 GHz) may appear overly conservative, however, this is the necessary minimum, due to other constraints in the FF flow (see Section 2.2.4). Here, we have assumed that the new fitted peak amplitudes are not stronger than the previous iteration SNR threshold and that the SNR does not significantly change when the final measurement (and SNR) is calculated (see Section 2.2.5), which is generally true for the strongest features present. To improve the reliability of the FF products by removing false detections, the negative −5 and −3 SNR thresholds are omitted for the absorption feature search.

The right-hand panel of Fig. 2 is a vertically zoomed in view of the left-hand panel which shows more clearly the residual after fitting a sinc to the empirical line profile. This plot indicates that for a strong and unresolved feature, the residual has little influence at SNRs > 5. However, that conclusion does not take into account blending, strong noise features, or partially resolved lines.

2.2.4 Limiting spectral feature drift

The frequency mask for identified features is carried forward to the next iteration. Newly identified features added to the working model are not allowed to have frequencies within the masked regions. This masking, however, does not prevent features from wandering into the forbidden regions during the parametric minimization process within the global fit portion of the FF algorithm. Through empirical study of the minimization routine, the fitting engine (Kester 2004) does not respond well with strict frequency limits imposed upon all new features, with the fit much less likely to converge in such cases. This means that during the global fitting procedure, the fitted position of newly added sinc profiles may drift into the forbidden zone and fit an unwanted side lobe or noise feature. Therefore, to minimize such movement and reduce the number of spurious features, a number of checks are made after the first global fit for new features found. These checks are listed in Section 2.2.5. Any surviving new feature is assumed to be stable enough for its position to be restricted to ±2 GHz about its fitted frequency. A final check for features that have drifted to fit a side lobe of another feature, or if the feature is a partially resolved line, is made after the final global fit. These final checks mean that features may be removed without refitting the total model as their removal has little impact on the final positions and SNRs of the main and neighbouring features.

2.2.5 Removal of spurious side lobe features and estimation of the final SNR

The residual in Fig. 2 was used as a rough guide to set the search region when checking for spurious detections in the wings of strong features, which is carried out after the main loop has completed. Thus, a validation step is performed to characterize each identified feature candidate as either a valid spectral feature, or a false fitting of a side lobe to a prominent spectral feature.

(1) The SNR is calculated as $A_{\text{fit}}/\sigma_A$, where $A_{\text{fit}}$ is the best-fitting amplitude of the spectral feature, and $\sigma_A$ is the standard deviation of the residual spectrum, determined for a spectral region in the neighbourhood of the feature and following localized baseline subtraction.

(2) Although the final SNR threshold is set to 5, the iterative line searching is actually conducted down to an SNR threshold of 3 in the main loop, with the application of an SNR cut off at 5, following the final step of the iterative search. This approach is used to avoid missed features and false positives as the final SNRs for each feature are subject to change during the iterative line search.

(3) Identified features (i.e. with |SNR| ≥ 5) are checked for proximity to other features to see if they are likely fitting a side lobe or peak in the wings of a more prominent feature. The final consideration when checking for wing fitting, is the SNR of the identified main peak compared to that of the potential spurious feature. Considering again the ideal line shown in Fig. 2, the main peak would need to have an SNR greater than 23 for the first positive side lobe to have an SNR above the final SNR search threshold. However, leaving room for blending, partially resolved lines, and noise (and remembering peak positions can move during the global fit), limiting the minimum SNR of the main peak to 10 leads to few side lobe fit features falsely identified as spectral features. The final condition before a feature is labelled as false is the absolute ratio of the main peak to wing SNRs, which is required to be greater than four for the feature to be rejected.

(4) Due to the mild asymmetry in the observed SPIRE FTS ILS (Naylor et al. 2016), the search window is asymmetrically centred about the feature location, starting 2 GHz below and ending 2.5 GHz above the central frequency for all SSW spectral features.

(5) The flagging regions in the SLW array are modified to improve the positive detection of [CI] $^3P_2 - ^3P_1$ fine-structure emission near the $^{12}$CO(7−6) rotational transition feature, against false features fit to sinc side lobes (rest frame ~806.65 GHz, ~809.34 GHz, for $^{12}$CO and [CI], respectively, see Section 2.5, Paper IV, and Scott et al. 2016b). Thus, the SLW search window starts between 1.5 and 2 GHz below (1.5 GHz for the $^{12}$CO(7−6) feature, 2.0 GHz otherwise), and ends 2.5 GHz above the central frequency. This reduced SLW range results in a high success rate of detecting the neutral carbon emission of interest, without leaving spurious wing-fit features. To further improve detection, a dedicated search for the neutral carbon features is performed after the main loop is complete (see Section 2.5 and Paper IV).

(a) For each positive feature there is a search at lower frequencies of the prominent peak. If a more prominent peak is found with SNR > 10, and the SNR$_{\text{strong}}$/SNR$_{\text{weak}}$ ratio is >4
then the weaker peak is labelled as a wing fit and discarded. For a discarded feature, no adjustment is made to the nearby existing features, on the assumption that the discarded wing peak, if any, is significantly weaker than the main peak. In the SPIRE FTS data, typically the [CI] feature is of weaker intensity than the neighbouring CO feature, hence the asymmetric window function for this region of the SLW band.

(b) The search for a stronger peak is then repeated to the higher frequency side, this time using the absolute SNR, so negative features are also considered. The same SNR checks are performed as in the previous step.

After the main loop has completed, the final residual is used to determine the final SNR for each identified feature.

2.3 Goodness of fit and the feature flags

To assess the confidence level of an FF-identified spectral feature, a quality metric has been developed that combines the GoF for each feature found (GoF) with the Bayesian ratio B10 (Bernardo & Smith 1994) of the total model. GoF and B10 are used in conjunction with frequency regions identified as suffering higher than average noise to assign a flag to each feature (FF flag).

2.3.1 Goodness of fit

The $\chi^2$ statistics is commonly used as a GoF metric. It is, however, only appropriate when the associated noise of the data considered is Gaussian in nature. SPIRE FTS data have a high incidence of systematic noise, such as fringing due to residual telescope and instrument emission, and ringing due to the spectral features themselves (i.e. the sinc wings). The ringing is stronger for stronger lines, which leads to $\chi^2$ tending to higher values for higher SNR lines. $\chi^2$ is also sensitive to the continuum. The FF requires a GoF metric that is not sensitive to the continuum or line flux. Such a metric, $r$, can be calculated using a cross-correlation function between fitted feature and total model, as

$$r = \frac{1}{N} \sum_{|v - v_0| < R} \frac{[S(v) - \bar{S}_R][M(v) - \bar{M}_R]}{\sigma_S \sigma_M},$$

where $R$ is the frequency range for the estimation, $v_0$ is the line frequency, $N$ is the number of frequency bins within the frequency range, $S(v)$ is the flux density at frequency $v$, $M(v)$ is the model at frequency $v$, $\bar{S}_R$ and $\bar{M}_R$ are the average flux and model within the frequency range, with $\sigma_S$ and $\sigma_M$ the corresponding standard deviations within the frequency range. Based on testing the FF with spectral simulations and spectra of SPIRE calibration targets, a fit is taken as good for $r > 0.64$ and poor for $r < 0.64$.

The variable $r$ is not sensitive to the continuum, due to the subtraction of local averages. Furthermore, $r$ is not sensitive to line flux, because of division by the standard deviations. Comparing the GoF to the SNR of features found for 150 calibration observations, shows that although there is not a perfect correlation, there is a strong trend of higher $r$ for higher SNR features. Regardless of SNR, $r$ saturates at $\sim 0.95$, which may be due to line asymmetry. Strong features that have low $r$ may be partially resolved and/or suffer from close strong features, i.e. high levels of sinc-wing blending. Similarly, $r$ is not low for all weaker features. These features may be in low noise areas and be relatively isolated, i.e. low levels of sinc-wing/side lobe blending.

2.3.2 Bayesian ratio B10

The second GoF metric for the FF is the Bayesian ratio B10, which we define as follows:

$$B10 = \log P(D|H1) - \log P(D|H0),$$

where $P(D|H1)$ is the evidence for the total model $H1$ with the putative sinc-function feature in and $P(D|H0)$ is the evidence for a model without it. The logarithm of each model evidence is returned by the fitting engine, assuming flat priors on the model parameters and taking into account the noise scale (see Kester 2004 for details). If the two models are equally good at describing the data then $B10$ will be zero. In this case, it is highly likely the feature is spurious. As this is a probabilistic check, no assumption about the noise is made and therefore B10 is insensitive to systematic noise. An empirical threshold on B10 of $-6$ is set such that a B10 difference of $-6$ or greater indicates a true detection, while a difference of less than $-6$ is associated with a spurious detection. The Bayesian ratio test is complimentary to $r$.

Generally, most features are labelled as ‘True’ by B10, if their SNR is greater than 15. B10 tends to fail when assessing the model fitted to a spectrum that has many spectral features, so it is only applied when there are fewer than 35 features found. The algorithm implementation is also time consuming and is therefore turned off for mapping observations, where the FF has to evaluate many more spectra per observation.

Bearing in mind that B10 aims to distinguish between true and false detections, while GoF aims to evaluate the quality of the fit, the results of GoF and B10 were compared for the same 150 calibration observations previously mentioned. For the 1731 features found by the FF, 1259 (70 per cent) were deemed as good detections by both, with 46 (3 per cent) labelled as poor by both. There was disagreement between the two methods for 137 features, while 335 features fell into an ambiguous zone for both. A description of how these two metrics are used together in the FF is in Section 2.3.3 below.

2.3.3 Feature finder flags

The GoF and B10 criteria are combined with ‘noisy’ regions in the frequency range of both detector bands to define a FF flag. The SPIRE FTS sensitivity and 1σ additive error on the continuum (known as the continuum offset) were used along with spurious detections in repeated SPIRE FTS calibration observations of featureless sources to define these ‘noisy’ regions. Fig. 3 shows the point-source calibrated sensitivity and continuum offset taken from Hop15, along with spurious features present in the FF results for Uranus, Ceres, Pallas, and Vesta. There is significant noise seen at the low-frequency end of SLW, due to imperfect instrument thermal background subtraction. Both the sensitivity and continuum offset steeply increase at the edges of the bands. These characteristics are similar for both types of noise and were considered along with the spurious features found for featureless sources, to determine the noisy regions as $< 608.6$ GHz and $> 944.0$ GHz for SLW and $< 1017.8$ GHz and $> 1504.7$ GHz for SSW.

There are four combined FF flags

(i) 0.0: a good fit in a lower noise region,
(ii) 0.1: a good fit in a noisy region,
(iii) 1.0: a poor fit in a lower noise region,
(iv) 1.1: a poor fit in a noisy region,

where the flag for goodness of fit is 0 (a good fit) or 1 (a poor fit). 0.1 is added to this flag if a feature is found within a noisy region. A
Figure 3. Noisy regions (shaded), defined using the SPIRE FTS point-source sensitivity and continuum offset (top and centre, respectively, see Hop15). The bottom panel shows the average spectra, and associated FF results, from SPIRE FTS calibration observations of each of the featureless sources Ceres, Pallas, Vesta, and Uranus (scaled by 10). Although no spectral features were identified above the SNR cutoff thresholds, the 12 low SNR features that were identified are indicated with vertical ticks (as is done in the nominal FF postcards, see Fig. 4) and in the inset histogram (bars with black outline). The inset histogram also shows the FF results on the individual HPDPs for these sources (bars without outline), the distribution of which confirms the FF low-SNR cutoff thresholds.

2.4 Source radial velocity estimate

Here, we briefly describe two different approaches able to provide a source radial velocity estimate for the FF catalogue entries, method 1 is based on the identification of the characteristic $^{12}$CO rotational ladder (rest frequencies for the lines within the CO ladder are provided in the line template at the top of Figs 8 and 10), and method 2 is based on cross-correlation of the FF catalogue with a spectroscopic line template catalogue based on HIFI data and included within HIPE. Both methods are detailed in full in the corresponding companion FF paper (Paper II).

Method 1 relies on the abundance of $^{12}$CO in the interstellar medium and the strong infrared ladder of its rotational transitions. There is also a near even spectral distribution of the $^{12}$CO emission, with a (rest frame) difference between the spectral lines of $\sim 115.1$ GHz, and a variation less than the resolution of HR SPIRE FTS spectra (i.e. $1.2$ GHz). The list of features found after completion of the main loop is searched for the presence of the $^{12}$CO ladder. This is accomplished by searching an array of frequency differences between detected features for elements that are an integer multiple of $\sim 115.1$ GHz. The set of features with the highest number of matches is taken as the most likely $^{12}$CO ladder candidate set. The chosen set of $^{12}$CO candidates are paired with their nearest rest frequency transition and are used to derive a velocity estimate. Candidate features producing high standard deviations in the per-candidate feature velocity estimates are removed. The number of identified $^{12}$CO features remaining is used to assess the quality estimate with more identifications producing a higher quality estimate. When $^{12}$CO is not identified within a candidate spectrum, but there is [N II] emission (the $3P_1 - 3P_0$ transition, rest frequency $1461.13$ GHz) with SNR $> 10$, this feature alone is used to estimate the velocity and the result given an appropriate quality flag.

Method 2 cross-correlates the list of features with a template catalogue (see e.g. Zucker 2003). The template catalogue contains most of the far-infrared characteristic lines for astronomical sources and is available as part of HIPE. The two catalogues are put on the same frequency grid and cross-correlated for a range of radial velocity offsets. The velocity for which the cross-correlation signal is maximized is taken as an initial estimate. Performing an initial line identification using the template catalogue further improves the radial velocity estimate. In some cases, due to degeneracies from the $^{12}$CO ladder or other molecular lines, the highest peak of the cross-correlation is not the actual radial velocity. That is why, out of the five strongest cross-correlation peaks, we select the one that maximizes the number of identified lines.

In addition to the two methods, we also compiled radial velocity estimates from CDS/Simbad data base and a list of radial velocities collected for the HIFI instrument (Beniamatti et al. 2017, private communication) and Wilson et al. (2017). The FF catalogue contains only one radial velocity estimate, its associated uncertainty, and a flagging parameter indicating how the estimate was derived. The FF methods take priority when the resulting radial velocity estimates return metrics indicating high quality. Estimates from external references are used when our methods fail or return low-quality metrics.

Only method 1 is used when estimating radial velocities in mapping observations as this method is more rigorously validated fit is deemed good when both GoF and B10 ‘good’ criteria are met. If there are no B10 results, due to a large number of features found in a single spectrum, or for mapping observations, then GoF alone is used.
and computationally efficient. To maintain consistency with sparse observation, detected feature lists from the SLW and SSW bands are combined in spatially overlapping regions. Since the SLW and SSW cubes express different on-sky footprints with spaxels of different spatial dimensions, feature lists are combined in the following way. An SSW equivalent grid is generated with each element populated by a feature list of the detected SSW features from the corresponding SSW spaxel spectrum. For each grid element, the SLW feature list is taken from the detected features of the spectrum in the nearest SLW spaxel. If the nearest SLW spaxel is more than \( \sqrt{2} \) times the width of an SLW spaxel away from the grid element, then no SLW features are projected into the grid element. The resulting feature list for each grid element is input to method 1 with the end product being a velocity map. The peripheries of these maps tend to contain only SLW features due to the different cube footprints.

### 2.5 Neutral carbon check

Although the checks for wing fitting are geared towards preserving the detection of \([\text{CI}]^3P_2 - ^3P_1\) in the SLW spectra, it is not always positively identified within the primary FF algorithm. As mentioned above, the \([\text{CI}]^3P_2 - ^3P_1\) fine structure transition is in close spectral proximity to the \(^{12}\text{CO}(7-6)\) rotational transition and these features show significant line blending. As this is a prevalent feature in far-infrared spectra of certain source types, a dedicated search for missed \([\text{CI}]\) is performed after the source radial velocity \(v\) is estimated. The method assumes that both \([\text{CI}]^3P_2 - ^3P_1\) and \(^{12}\text{CO}(7-6)\) are coupled in approximately the same reference velocity frame, giving a separation between the two features of 2.69 GHz (rest frame). For a non-zero radial velocity, \(v\), this difference can be expressed as

\[
\Delta = \left(1 + \frac{v}{c}\right)^{-1} \times 2.69 \text{ (GHz)},
\]

where \(c\) is the speed of light.

The \(^{12}\text{CO}(7-6)\) emission feature, although typically dominant in terms of intensity compared to the \([\text{CI}]^3P_2 - ^3P_1\) emission, is not necessarily stronger than \([\text{CI}]^3P_2 - ^3P_1\), therefore a search is performed that looks for features within ±0.8 GHz of the velocity corrected positions of the \(^{12}\text{CO}(7-6)\) and \([\text{CI}]^3P_2 - ^3P_1\) features. If only one emission feature is found by the nominal FF line identification tool, a section of the input spectrum of width 40 GHz is extracted. The partial spectrum is then fitted for three test cases, using one and two sinc functions and the polynomial continuum model. The centre of the spectral section and the initial estimate for the emission frequency of the model feature is derived from the detected frequency of the \([\text{CI}]^3P_2 - ^3P_1\) feature. A successful detection occurs if the fitted feature returns an SNR \(\geq 5\), and the emission frequency is within 0.8 GHz of the predicted frequency based on the \([\text{CI}]^3P_2 - ^3P_1\) line. Further details about the neutral carbon check routine, and examples of each of the three test cases, are presented in Paper IV.

### 2.6 Visual inspection of the FF results

In total, 868 HR sparse observations were processed by the FF. The spectra for 384 of these exhibit characteristics associated with sources that have some spatial extent (see the Semi-Extended and Extended source entries in Table 1). For these 384 observations, there can be a poor shape to the continuum and high levels of fringing in the point-source calibrated data, and thus the point-source FF results may not be optimal. The FF results for all 868 observations were visually inspected, with an additional inspection of the extended-source calibrated FF results for the 384 partially or fully extended sources that were observed in sparse mode. The results were graded as ‘good’, ‘acceptable’, or ‘poor’, depending on the number of features found or missed and the polynomial fit to the continuum. Overall, and considering both the point and extended-source calibrated data, 99 per cent of the FF results fall into the ‘good’ or ‘acceptable’ categories. 8 per cent of these show an improved catalogue for the extended-source results, in one or both of the centre detectors. All partially or fully extended sources are flagged in the FF catalogue(s) meta data. If the alternate calibration results for one or more of the centre detectors improves beyond the point-source results, this is also indicated in the metadata.

### 3 THE FEATURE FINDER PRODUCTS

The FF produces products for all publicly available SPIRE FTS observations, although some targets known to be featureless are skipped, this includes observations of Uranus, asteroids, Callisto, and the SPIRE dark sky field (Swinyard et al. 2014; Benielli et al. 2014; Müller et al. 2014; Spencer et al. 2016). The type of FF product does vary depending on the resolution and observing mode, for instance, there are few features for LR observations, so there are no feature catalogues provided for these, but the postcards and continuum parameters are provided in the FF data products. The results for Neptune, Mars, and Saturn are also not included, as some of these lines are partially resolved and the FF, tuned specifically for unresolved spectral features, does not produce results as good as their existing models.

The FF products provided (per observation) are:

(i) a significant spectral feature catalogue (for HR),

(ii) continuum fit parameters, and

(iii) a postcard per observation.

In addition, the SPIRE Automated Feature Extraction CATalogue (SAFECAT) provides a combined catalogue of both sparse and mapping results. All products are provided as multi-extension FITS tables. In this section, we describe each of these products in detail.

#### 3.1 Significant feature catalogues per observation

Significant feature catalogues per observation contain: the measured frequency of features with \(|\text{SNR}| \geq 5\), the error on the measured frequency; the SNR measured using the fitted peak and the local noise in the residual spectrum after the total fitted model has been
For each observation the best fit to the continuum, \( P(\nu) \), is provided in the form of third-order polynomial parameters \((p_i)\) of the form

\[
P(\nu) = p_0 + (p_1 \times \nu) + (p_2 \times \nu^2) + (p_3 \times \nu^3),
\]

where \( \nu \) is the frequency. A second-order polynomial is used for LR observations.

Each fitted continuum parameters file contains a table of the parameters obtained from fitting the continuum of the spectrum, and the associated error, from the centre detectors (for sparse observations) or each spaxel of the SLW and SSW cubes (for mapping observations). For sparse observations the metadata reports the observation identifier and the nominal pointing coordinates. For mapping observations there are additional columns in the table for spaxel coordinates both in terms of spaxel row and column indices, and RA and Dec.

### Table 3. The number of features detected by the FF

| FF Group  | Data Cal. | Source Class. | Obs. Count | SLW Lines | SSW Lines |
|-----------|-----------|---------------|------------|-----------|-----------|
| HR sparse | Pt. source | All 643 | 6299 | 5606 |
|           | Pt.        | 285 | 3547 | 3874 |
|           | Semi.      | 243 | 2010 | 1355 |
|           | Ext.       | 115 | 742  | 377  |
| Ext. source | All 348 | 2564 | 1538 |
|           | Semi.      | 232 | 1844 | 1175 |
|           | Ext.       | 116 | 720  | 363  |
|           | Off-axis   | 509 | 17868 | 12852 |
| HR Mapping | Ext. source | All 205 | 99784 | 141368 |

The FF postcards are provided for quick inspection and qualitative analysis of FF results. An example postcard for sparse mode is shown in Fig. 4, upper panel: it presents the input spectra, the best fit to the continuum, and vertical bars representing the features found with their height scaled proportionate to the SNR. Only the spectra from the central detectors of the two bolometer arrays (SLWC3 and SSWD4) are included, since these are the only spectra processed for these observations. Only two science and a few calibration sparse observations had the central detectors pointed directly off-source.
4 FEATURE FINDER VALIDATION AND RESULTS

This section presents the methods used to validate the core FF routines and output products, including presentation of the validation methods, and the presentation of some of the key FF product results. Validation for the radial velocity estimating routines (Section 2.4) and neutral carbon check (Section 2.5) is provided in the companion papers Paper II and Paper IV, respectively.

4.1 Completeness

The completeness of the FF catalogues represents the fraction of real features detected, in the context of our testing framework, as a function of SNR. The completeness was estimated using Monte Carlo simulations. Repeated observations of the SPIRE dark sky field (RA: 17h40m12s and Dec.: +69d00m00s (J2000)) provide realistic noise levels, so these were used as a base population for simulating test spectra. There is an asymmetry present in the SPIRE FTS ILS that leads to a shortfall in measured line flux of 2.72 per cent, when calculated from fitted sinc parameters (see Hop15). To better replicate the fitting performed by the FF it is important to introduce this asymmetry into the simulated spectra. Therefore spectral lines were added using an empirical line profile.

Several completeness test iterations were run. For each test a dark sky observation was selected at random, from a parent pool of all deep (> 15 repetitions) high-resolution dark sky observations. Both the spectra from the SLW and SSW centre detectors were used. For the first two test sequences, random lines were added to the base spectrum, with ten lines added for the first test and four for the second. As the majority of SPIRE FTS observations are of targets that exhibit some level of 12CO emission, a template was created to include a 12CO ladder for the third test sequence.

The template was based on co-added observations of NGC 7027 (see Hop15 for details on how the data were co-added and cleaned of faint lines). To derive the template, a sinc profile per 12CO line and a third-order polynomial were simultaneously fitted to the co-added data. The best-fitting sinc-parameters were used to add copies of the SPIRE FTS empirical line profile at the position of the 12CO lines. The 12CO lines of NGC 7027 are unusually strong and suffer from less blending than spectral lines in most other SPIRE FTS observations. Therefore, to represent more typical spectra, the 12CO template was scaled to 30 per cent, with the continuum scaled to 60 per cent. To ensure the simulated spectra covered a range of line strengths and source velocities, two additional modifications are imposed. First, the 12CO ladder was scaled by a flux factor that varied from a few Jy to around 90 Jy. Secondly, to introduce a range of source velocities in the simulated population, a random redshift was generated from a Gaussian distribution with a mean of zero and σ of 0.025. The 12CO ladder was redshifted and normalized using the associated luminosity distance. Finally, for each band of each simulated spectrum, four lines were added at random frequencies, with randomly generated SNRs. For all three tests, the random lines were added using an empirical line profile.

To better evaluate the results, a completeness test was run. For each test a dark sky observation was selected at random, from a parent pool of all deep (> 15 repetitions) high-resolution dark sky observations. Both the spectra from the SLW and SSW centre detectors were used. For the first two test sequences, random lines were added to the base spectrum, with ten lines added for the first test and four for the second. As the majority of SPIRE FTS observations are of targets that exhibit some level of 12CO emission, a template was created to include a 12CO ladder for the third test sequence.

The template was based on co-added observations of NGC 7027 (see Hop15 for details on how the data were co-added and cleaned of faint lines). To derive the template, a sinc profile per 12CO line and a third-order polynomial were simultaneously fitted to the co-added data. The best-fitting sinc-parameters were used to add copies of the SPIRE FTS empirical line profile at the position of the 12CO lines. The 12CO lines of NGC 7027 are unusually strong and suffer from less blending than spectral lines in most other SPIRE FTS observations. Therefore, to represent more typical spectra, the 12CO template was scaled to 30 per cent, with the continuum scaled to 60 per cent. To ensure the simulated spectra covered a range of line strengths and source velocities, two additional modifications are imposed. First, the 12CO ladder was scaled by a flux factor that varied from a few Jy to around 90 Jy. Secondly, to introduce a range of source velocities in the simulated population, a random redshift was generated from a Gaussian distribution with a mean of zero and σ of 0.025. The 12CO ladder was redshifted and normalized using the associated luminosity distance. Finally, for each band of each simulated spectrum, four lines were added at random frequencies, with randomly generated SNRs. The 12CO ladder was redshifted and normalized using the associated luminosity distance. Finally, for each band of each simulated spectrum, four lines were added at random frequencies, with randomly generated SNRs. For all three tests, the random lines were added using an empirical line profile.
The completeness is calculated as the fraction of lines recovered per SNR bin, with associated errors of

$$\sigma_C = \sqrt{\frac{C(1 - C)}{N_{\text{Total}}}},$$

where $C$ is the completeness, $N_{\text{Total}}$ is the total number of added lines, and $\sigma_C$ is the associated error.

Due to the large statistical sample number for each test, the associated errors are small. Fig. 6 shows the completeness results for the SLW and SSW detectors for all three tests. The completeness for $3\sigma$, $5\sigma$, and $10\sigma$ are given in Table 4. From Fig. 6 and Table 4, the FF catalogues are essentially complete for spectral features with SNRs greater than 10. Below this threshold the completeness is affected by how rich in features a particular spectrum is and how strong those features are. If there are many strong features, such as for test 3 that includes a $^{12}$CO ladder, the completeness at $5\sigma$ is approximately 20 per cent lower than for spectra containing only four random lines. The change in completeness reflects the different noise properties of SPIRE FTS data depending on the source configuration. When there are only a few weak spectral lines present, the noise is predominantly random. When there are many spectral lines present, the noise may be dominated by the systematic noise introduced by the wings of the lines themselves. If the blending of sinc wings is significant, then faint features are more easily lost and spurious faint features are more easily detected. Validation of the FF routine with respect to false positives and the low SNR cutoffs was conducted using the lineless calibration sources as presented in Section 2.3.3 and Fig. 3.

### 4.2 Comparison with ‘python peaks’

The FF method relies solely on the standard data processing of SPIRE FTS data. Occasionally, there are unique conditions in the observation data causing failure of the FF algorithm. To help overcome this challenge, and to validate the standard FF results, a search for spectral features has been developed outside of HIPE, using PYTHON SCIPY methods in the SCIPY SIGNAL package (Jones et al. 2001). The continuum is subtracted from the SPIRE FTS apodized data (Fulton et al. 2014), using the best-fitting parameters already determined by the FF. A wavelet function, as implemented in SCIPY SIGNAL FIND PEAKS CWT, is used to search for peaks with SNR > 8. The noise can then be estimated with these strong peaks omitted. A second search for peaks is then carried out with the SCIPY method SCIPY SIGNAL ARGRELEXTREMA, using the noise estimate in order to find local maxima with SNR > 3 (increased to SNR > 5 in the overlap region of the two FTS bands). We call this two-step alternative method to find peaks in apodized SPIRE FTS data ‘python peaks’ (PP). It should be noted that an SNR of 3 calculated by PP approximately corresponds to an SNR of 5 for the final FF SNR estimates due to the different noise properties in the apodized and raw unapodized spectra. The PP results are compared to the nominal FF features and a spectroscopic
Figure 6. FF completeness as a function of input SNR. The left-hand and middle panels show results for random line injection only, whereas the results in the right-hand panel includes the addition of a $^{12}$CO ladder. For all three tests, the completeness is approximately 100 per cent for features with SNR greater than 10$\sigma$. However, for weaker features, the completeness depends on how rich in spectral features the spectrum is and the range of strengths of these features. For instance, at 5$\sigma$ the completeness drops from an average of 93 per cent when there are only four features added to each simulated spectra (the left case) to an average of 68 per cent if there is a significant $^{12}$CO ladder. The drop in completeness reflects the change in noise properties of SPIRE FTS spectra, which are dominated by the systematic noise of the sinc wings for sources that exhibit a spectrum rich in lines.

Table 4. Completeness results for the three Monte Carlo simulations. For test 1, four random lines were added to each simulated spectrum. For test 2, 10 random lines were added. For test 3, four random lines and a $^{12}$CO ladder were added. The 3$\sigma$, 5$\sigma$, and 10$\sigma$ completeness (C) is given for each test as $C_{\text{SLWC3}}/C_{\text{SSWD4}}$.

| Test | 3$\sigma$ | 5$\sigma$ | 10$\sigma$ |
|------|----------|----------|-----------|
| 1    | 0.51/0.53| 0.92/0.93| 1.00/1.00 |

Table 5. Information on the SPIRE FTS calibration sources used for the FF comparison. The column ‘N$_{\text{obs}}$’ gives the number of observations recorded for the respective source.

| Name      | Type                  | RA         | Dec        | N$_{\text{obs}}$ |
|-----------|-----------------------|------------|------------|-----------------|
| AFGL 2688 | Proto planetary nebulae | 21:02:18.78| +36:41:41.2 | 23              |
| AFGL 4106 | Post red supergiant    | 10:23:19.47| −59:32:04.9 | 30              |
| CRL 618   | Proto planetary nebulae | 04:45:53.64| +36:06:53.4 | 23              |
| NGC 7027  | Planetary nebulae      | 21:07:01.59| +42:14:10.2 | 31              |

Figure 7. Example spectra for the four main SPIRE FTS line source calibrators (Hop15). The inset plot shows the AFGL 4106 spectrum at a more suitable vertical plot range.

Table 6. For each of the four spectral calibration sources, the total number of FF features matched to a line (from Hop15) is given in the ‘Hit’ column. The ‘Miss: with SNR cutoff’ and ‘Miss: no SNR cutoff’ columns present the total number of lines without a match when considering only those features above the SNR threshold applied by the FF (with SNR cutoff) or all features found prior to application of the SNR threshold (no SNR cutoff). The ‘Extra’ column reports the total number of extra features found (i.e. no corresponding line in Hop15). Results are given separately for the SLWC3 and SSWD4 detectors. For the numerical entries, the count is followed by a percentage, separated by a ‘/’. Each entry contains two sets of results, the upper entry reports data including the full detector band while the lower entry labelled ‘clean’ presents the results within the lower noise region of the band only (unshaded regions in Fig. 8).

| Source | Band | Hit | Miss: with SNR cutoff | Miss: no SNR cutoff | Extra |
|--------|------|-----|-----------------------|---------------------|-------|
| AFGL   | Clean| 583 | 528.7%                | 15/2.5%             | 84    |
| 2688   | SSWD4| 593 | 70/11.3%              | 28/4.5%             | 168   |
|        | Clean| 444 | 38/8.2%               | 16/3.5%             | 159   |
| 4106   | SSWD4| 238 | 109/16.3%             | 62/20.7%            | 2     |
|        | Clean| 220 | 82/30.4%              | 50/18.5%            | 1     |
| CRL    | Clean| 502 | 499.7%                | 40/8.0%             | 77    |
| 618    | SSWD4| 586 | 74/11.9%              | 35/5.6%             | 160   |
|        | Clean| 481 | 448/7.1%              | 25/9.4%             | 120   |
| NGC    | Clean| 563 | 269/39.4%             | 119/17.4%           | 43    |
| 7027   | SSWD4| 332 | 79/21.2%              | 40/10.8%            | 83    |
|        | Clean| 279 | 53/17.1%              | 31/10.0%            | 82    |

As a consequence of using apodized data, PP suffers less from wing-fitting and false detections in areas of high noise, such as the fringing for spectra of partially extended sources. Additionally, due to the necessary checks during the FF, there are some cases of significant infrared line template list. This comparison is used to improve the FF results by adding missed features and removing spurious ones.
features being wrongly discarded. These lost features can be restored using the PP/FF/line-list comparison. As all SPIRE FTS spectra of partially extended sources have been flagged as such, the PP/FF comparison can also be used to identify if there is a fringe-fitting issue, as in these cases there is a large discrepancy in features to peaks found. If there are many more features in the initial FF results beyond 900 GHz (in SLW), this indicates a problem and all features at frequencies greater than the rest-frame frequency of $^{12}\text{CO}(8-7)$...
Table 7. The mean SNR and percentage of times [CI] $^3P_2 - ^3P_1$ and CH + (1−0) (rest frequency 835.08 GHz) were missed for 31 observations of the line calibration sources.

| Species         | $N_{\text{obs}}$ | $\nu$ (GHz) | SNR | Per cent miss |
|-----------------|------------------|--------------|-----|---------------|
| [CI] $^3P_2 - ^3P_1$ | 31               | 809.13       | 24.8| 3             |
| CH + (1−0)      | 31               | 835.06       | 50.0| 0             |

(i.e. 921.80 GHz) are removed from the catalogue. Further details of this method, and the corresponding spectral line identification are available in Paper III.

4.3 Comparison with the SPIRE FTS calibration sources

The four sources AFGL 2688, AFGL 4106, CRL 618, and NGC 7027 are spectral-line rich, and were monitored throughout Hershel’s mission as part of the SPIRE Instrument Control Centre’s systematic
A thorough analysis of the SPIRE FTS calibration source data is presented in *Hop15*, which includes detailed line fitting. Example spectra for each of these sources are provided in Fig. 7, and show that these data cover a range in brightness, with SSW continuum levels between tens of Jy, for AFGL 4106, to hundreds of Jy, for AFGL 2688. There is also a difference between the sources in line strength and line density, which results in different levels of blending.

In this section, the line catalogues and SNRs from *Hop15* are used as a comparison to the FF results for the observations of these four sources. All the observations included in the comparison were taken in HR sparse mode. The spectra used are corrected for pointing offset, and observations of AFGL 4106 have a high level of background subtraction. The corrected data are available as HPDPs (Section 2.1.6) via the Spectrometer calibrators legacy data page.

Three cases were considered when assessing the FF results against the line catalogues: a line has been successfully found; a line has been missed; an extra feature has been found. If the assumption that all significant lines have been included in the line lists is employed, then in the latter case, the extra feature is likely to be spurious. However, where there are repeated extra features found at a similar frequency, it may be that a real line was not included in the line catalogues or that the line was measured with an SNR of less than 5. To compare the FF results with the known lines for each source, the following steps were taken per observation, while treating the results for SLWC3 and SSWD4 separately.

(i) The line lists were adjusted for each observation, so only lines with a measured SNR ≥ 5 were considered.

(ii) Each remaining line position was compared to the features in the final FF catalogues and to all features found before final SNR estimate was taken and the SNR cut was applied.

(iii) A feature detected using the FF within 0.5 GHz of a feature in the reference catalogue was considered a match. If multiple features matched this criteria, the closest feature to the line position was taken. (Note: a 2 GHz match window was used for the simulated feature validation in Section 4.1.)

(iv) If no feature was found to match, this was recorded as a missed line.

(v) After all line positions were checked, features in the FF catalogues without a match were recorded as extras.

For the four line source calibrators, Table 6 collates the total number of lines matched (a hit), as well as the missed and extra features for each of the line sources. The overall success rate of the FF was assessed by considering the number of lines without a FF match (a miss) for all observations per source; false positives are assumed to be negligible for SNR ≥ 10 as discussed in Section 4.1. Fig. 8, presenting the same results as in Table 6, shows the total number of misses for each line, compared to lines identified in *Hop15*, while the symbols are coloured by the average SNR for that line, with a red outline if the average SNR < 7. Also plotted (as cyan symbols) are the total number of misses when considering all features found (i.e. before the final SNR threshold cut is applied). Misses are observed mainly for lines near the band edges and within the noisy regions near the edges (see Fig. 3), and features subject to high levels of blending. For all but NGC 7027, a few lines at the ends of the SLW frequency band are missed for a higher proportion of the observations, although these all have low SNR, generally close to the lower limit of 5. The 12CO spectral features are rarely missed for these sources, with exceptions being 1 of 23 12CO(12–11) lines (rest frequency 1382.00 GHz) in AFGL 2688, 12 of 23 12CO(5–4) lines (rest frequency 576.27 GHz) in AFGL 2688, 14 of 30 12CO(4–3) lines (rest frequency 461.04 GHz) in AFGL 4106, and 2 of 23 12CO(4–3) lines in CRL 618. All but one of these missed 12CO lines are within the noisy spectral regions. The majority of the missed features in the good spectral regions are associated with low-SNR lines from less abundant isotopes/isotopologues (further details are provided in Fig. 10).

In addition, AFGL 4106 is embedded in high Galactic Cirrus, which leads to extra systematic noise, on both narrow and wide frequency scales, particularly towards the band edges. The inset within Fig. 8 shows an example where 12CO(4–5) is missed (in the AFGL 4106 observation 1342214814), because the line intensity is at an amplitude similar to the local noise. One of the AFGL 4106 observations (ID 1342208380) is excluded from our analysis due to an exceptionally large pointing error of ~24 arcsec. This results in the source being missed by SSWD4 and only partial source coverage with SLWC3.

Two lines of low significance, but not at the edge of the bands, are missed for NGC 7027. However, these are in the wings of strong lines and likely rejected by the FF as potential ‘wing fitting’. Thus, these are missed less often before the final FF checks. [CI] P3 − P1 is missed only once for all of the 31 NGC 7027 observations, and is recovered using the neutral carbon check (see Section 2.5). Fig. 9 illustrates the close proximity of the 12CO(7–6) and [CI] feature for NGC 7027.

Fig. 10, and Tables 7 and 8 present the matched lines grouped by species and rotational transition. As explained above, only one 12CO line is missed in some AFGL 4106 observations, and this.
Figure 11. Details of the features found and models fitted for NGC 7027, around the most blended frequency range (∼800 GHz). The spectrum, all features found, and the features remaining after the final SNR cut are plotted in the left-hand and middle panels, for two observations of NGC 7027 (i.e. observations 1342189121 and 1342188197). The filled circles show which SNR threshold iteration the features were initially found at, while the red triangles show features in the final catalogue (with a final SNR > 5). On the left, the two lines at ‘786.0’ and ‘793.2’ GHz (green circles) are just below the final SNR cut, while they are above the SNR cut for the 1342188197 FF catalogue (centre). The right-hand panel shows the residual spectrum for the left case (in blue) after the continuum model and all the sinc models fitted, but the ones for these two lines, are subtracted. Whereas for the input spectrum (black line) it is hard to see features, there are two clear peaks in the residual at the positions expected.

Figure 12. Example FF features found in observations of AFGL 4106, which have no match in the Hop15 line lists. Thicker lines are caused by the overlaying of a feature at similar frequency in multiple observations of AFGL 4106. The spectrum plotted is taken from all observations of AFGL 4106 that have been co-added and continuum subtracted.

does not change if all the features found are considered (plotted as cyan symbols, where different to the result when matching to the final FF catalogues). All but the lowest significance 13CO lines are matched for every observation, with the rate of missed features below 10 percent. There are 12 HCN transitions within the SPIRE FTS bands that are detected with SNR > 5, with no recorded misses. HCO + (7−6) has no misses when considering all the features found. It is, however, discarded as too faint or unreliable for 16 percent of line source FF catalogue candidate features. HCO + (9−8) has several close (and more significant) neighbouring lines, including 12CO(7−6) and [CI] 3P2 − 3P1, so it is more often than not lost in the wings of these prominent features. However, the other lines in Tables 7 and 8 are matched for most observations, regardless of their SNR, with few discarded by the FF SNR cut or reliability checks.

Fig. 11 gives an example of two faint lines (centred at 786.0 and 793.2 GHz) that the FF catalogues are missing for some observations of NGC 7027. Although both features are usually found at the 10 or 5 SNR threshold iterations, their final SNRs can fall under the cut of 5 in the final global model fit. The frequency region around these lines (∼780–850 GHz) also provides a good example of the difficulty of extracting faint features from a spectrum where there are also strong features and significant line blending. Although it should be noted that, relatively speaking, NGC 7027 does not suffer from high levels of blending. The continuum subtracted SLWC3 spectra from two observations of NGC 7027 (1342189121 and 1342188197) are plotted in the left-hand and middle panels of Fig. 11, to show the region of interest. In both cases, the faint lines are found at the lower positive SNR thresholds, but for 1342189121, these lines have final SNRs < 5. Also in this region is the difficult to detect the [CI] 3P2 − 3P1 feature, due to its close proximity to 12CO(7−6). Both of these features are found for both observations. Looking directly at the spectra, it is hard to see any peaks corresponding to ‘786.0’ and ‘793.2’ GHz, while the marker position for [CI] 3P2 − 3P1 appears to be horizontally offset from the nearest peak. In the NGC 7027 panel of Fig. 8 there is an insert that shows the spectrum, total model, and sinc profiles from the total fitted model that correspond to [CI] 3P2 − 3P1 and 12CO(7−6). The first positive side lobe is not well fitted by the sinc for 12CO(7−6), but after adding the [CI] 3P2 − 3P1 sinc, the fit only suffers from the known line asymmetry, leading to the minor bumps seen in the residual. If all the sincs from the total model are subtracted from the input spectrum, bar the two corresponding to ‘786.0’ and ‘793.2’ GHz, then the partial residual is that seen in the right-hand panel of Fig. 11, where there are two clear peaks at the expected positions.

One last aspect of this comparison are the extra features found. Not all low significance lines were included by Hop15, if these did not improve the overall fit to the data. Therefore, some of the extra features can be excluded from the ‘likely spurious’ category, as illustrated by Fig. 12.

4.4 Accessing the products and further information

Full details on the FF workings and the associated products are available via the main FF ESA web page. Through the FF pages, one can access documentation, a list of SPIRE FTS literature, and what papers should be referenced when publishing work based on SPIRE FTS data. Tables are provided including all the observations that have an associated FF result. These tables allow access to the FF products and provide a quick way to check the postcards. The combined catalogues and all collections of the postcards can also be accessed. The tables link to FF products stored in the ESA Herschel

11The Herschel SPIRE Spectral Feature Catalogue ESA DOI: doi.org/10.5270/esa-lysf2yi.
5 SUMMARY

This paper has presented details of the SPIRE FTS FD process and the associated products. All results are available through the Herschel Science Archive as Highly Processed Data Products. The iterative FF was run on all standard observations of the SPIRE FTS, both in sparse or mapping modes. Line features in each of the two spectral bands were extracted from observations in HR mode, while for the low-resolution mode we only provide the corresponding parameters of the best-fitting polynomial continuum. In sparse mode, the two central detectors of each band were considered separately from the off-axis detectors (see Paper III), while all spatial pixels were included together for mapping mode. The features are provided with their SNR; deriving line fluxes is beyond the scope of the automated FF process.

The final combined catalogue of all sparse and mapping observations lists 267,159 features at $\text{SNR} \geq 5$, from 874 (i.e. 669 sparse mode and 205 mapping mode) unique HR observations. The off-axis line search reports an additional 33,840 spectral features (see Paper III for details). Continuum spectra parameters are provided for an additional 199 HR sparse mode observations, and 257 LR sparse mode (only for the central detectors) and 70 LR mapping mode (all spatial pixels) observations.

The FF catalogue is complete for features at SNR above 10, decreasing to 50–70 per cent completeness down to SNR of 5. The detections were validated with a set of methods and each feature has associated flags that can be used to assess the feature fidelity. There are 7,691 (or 4.6 per cent) features flagged as a poor fit.

A customized check for the presence of the faint $[^{3}\Pi_2 - ^{3}\Pi_1]$ line, sometimes buried in the side lobes of the much stronger $^{12}\text{CO}(7–6)$ line, leads to an additional 4,781 features included in the catalogue from 162 unique observations.

Herschel has provided our highest resolution and most sensitive view of the far-infrared universe to date. The legacy value of the SPIRE FTS observations will be further enhanced by the spectral FF algorithm presented in this paper.

ACKNOWLEDGEMENTS

Herschel was a European Space Agency (ESA) space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from the United States government National Aeronautics and Space Administration (NASA). SPIRE has been developed by a consortium of institutes led by Cardiff Univ. (UK) and including: Univ. Lethbridge (Canada); NAOC (China); CEA, LAM (France); IFSI, Univ. Padua (Italy); IAC (Spain); Stockholm Observatory (Sweden); Imperial College London, RAL, UCL-MSSL, UKATC, Univ. Sussex (UK); and Caltech, JPL, NHSC, Univ. Colorado (USA). This development has been supported by national funding agencies: the Canadian Space Agency (CSA); the Chinese Academy of National Astronomical Observatories (NAOC); the French Atomic Energy Commission (CEA), the French National Centre for Space Studies (CNES), the French National Centre for Scientific Research (CNRS); the Italian Space Agency (ASI); the Spanish Ministry of Economy and Competitiveness (MCIINN/MINECO); the Swedish National Space Agency (SNSB); the United Kingdom Science and Technology Facilities Council (STFC), the United Kingdom Space Agency (UKSA); and NASA (USA). This research is supported in part by the Canadian Space Agency (CSA), the Natural Sciences and Engineering Research Council of Canada (NSERC), Canada Research Chairs (CRC), and CMC Microsystems. This research has made use of the NASA/Infrared Processing and Analysis Center (IPAC) Infrared Science Archive, which is operated by the NASA Jet Propulsion Laboratory (JPL), and California Institute of Technology (CalTech), under contract with NASA. This work used the SciPy (www.scipy.org) and Astropy (www.astropy.org). Astropy Collaboration et al. 2013; Price-Whelan et al. 2018) Python packages. Table formatting followed the Planck Style Guide (Lawrence et al. 2013).
