SUBJECT AREAS General Cell Biology & Physiology

KEYWORDS Low-level-intensity ultrasound, Mechanical index, Spermatogonial stem cells, Colonization, Viability
Abstract

Background: Low-level-intensity ultrasound waves contribute to the proliferation, differentiation, and increasing the number of cells in vitro. However, the interaction of ultrasonic waves involving thermal effects, mechanical vibration, or cavitation as a cell proliferation factor has not been determined. Therefore, the aim of this study was to investigate the effect of cavitation (mechanical index) on spermatogonial stem cell proliferation and colonization by removing heat effects caused by ultrasound radiation. Isolated spermatogonial stem cells from neonatal mice were cultured in a DMEM culture medium with 10% FBS. Spermatogonial stem cells were stimulated by low-level ultrasound for five days and colonization and viability were evaluated on the 7th day.

Results: Regarding the low intensity of ultrasound, the Rayleigh integral model was used for acoustic pressure computation. According to the results of modeling, the intensities of 0.28, 0.45, 0.96, and 1.34 W/cm² were selected at 0.5 cm of distance with the mechanical indices of 0.40, 0.51, 0.75, and 0.89. The mechanical indices of 0.40 and 0.89 resulted in 93±4 and 32±4 colonies, respectively. An increase in colony diameter was observed for the mechanical index of 0.40 during all days of the culture. In the culture on the 7th day, it had the largest average colony diameter of 134.05±1.22 µm in comparison with other groups (p<0.05). Cell viability did not significantly differ across groups (p=0.08).

Conclusion: The results suggest that a low-intensity ultrasound of 40 kHz with a 0.40 mechanical index can be effective in increasing the proliferation and colonization of spermatogonial stem cells during culture. In other words, a mechanical index within the threshold of cavitation increases the proliferation and
Colonization of spermatogonial stem cells.

Background

Recently, biostimulation with low-intensity ultrasound (LIUS) has been studied in the proliferation and differentiation of stem cells in vitro [1]. Low-frequency ultrasound (LF) has a wide range of therapeutic and industrial applications, and novel emerging usages are being introduced in this range [2]. Researchers believe that biochemical and mechanical stimulation conditions are necessary for the proliferation and differentiation of stem cells [3, 4], and lack of elasticity and mechanical stress reduce the stem cell differentiation [5, 6]. Moreover, several studies on stem cells such as dental, blood, and spermatogonial stem cells (SSCs) have been conducted by low-intensity ultrasound waves [7]. SSCs are valuable stem cells in treatment and research [8]. Understanding the process of spermatogenesis is essential, and it can be a great help in treating infertile men [9]. Colonization of spermatogonial cells is an important part of the treatment of infertility, germ cell gene change, cell transfection, and differentiation of SSCs in vitro [10]. Cellular responses to low-intensity ultrasound are parameter-dependent [11]. In general, ultrasound biological effects consist of thermal and non-thermal (acoustic cavitation) effects [12]. To increase the effect of ultrasound waves in molecular and cellular dimensions, a process is required for transmitting ultrasonic wave energy to these small dimensions. The phenomenon of acoustic cavitation can induce this effect [13, 14]. Acoustic cavitation is classified into stable and inertial cavitation. Stable cavitation is the continuous oscillation of acoustic cavitation over a large number of cycles driven by the pressure fluctuations of the applied acoustic field. This type of
cavitation typically produces highly localized acoustic streaming which may cause shear stresses on a nearby cell. Inertial cavitation is a transient type of cavitation where the acoustic cavitation oscillates heavily over a single or multiple cycles, eventually leading to a violent collapse/implosion. The collapse is associated with localized high pressures and temperatures and high-velocity liquid jets [15]. Mechanical index (MI) was introduced by Apfel and Holland (1991) as a quantity expressing the biological effects of cavitation [14, 16].

There is growing evidence that integrins are promising candidates for sensing extracellular matrix-derived mechanical stimuli and converting them into biochemical signals. Mechanical stimuli can affect both the actin cytoskeleton and cell cycle progression. Direct mechanical stimulation such as the stretching of cells can activate the extracellular-signal-regulated kinase (ERK) pathway in different cell systems, leading to cell proliferation. Acoustic cavitation interaction of low-intensity ultrasound can be regarded as a form of nonphysiological mechanical energy indirectly applying mechanical stress to the cultured cells [17]. Nevertheless, in all studies, specific sonication conditions are determined by considering the availability of the radiation frequency without physical or mechanical reasons or the explanation of the mechanism type [18], and the interaction of low-intensity (low-frequency) ultrasound has not been studied. In our previous study [19], we calculated the acoustic pressure in the medium by ultrasonic propagation based on a tissue-inducing Rayleigh integral model in which wave equations were linearly calculated in a homogeneous environment. Then, it was used to extract the physical parameters of acoustic pressure and mechanical index. In the present study, the effect of these parameters on SSC viability and colonization was evaluated using a quantitative approach to investigate the effect of the MI of LF and LIUS on
spermatogonial stem cell colonization by removing heat effects caused by ultrasound radiation.

Methods

The pressure equation was solved at any point in cylindrical coordinates and extracted minimum acoustic pressure ($P_{\text{min}}$). To extract the MI plan, acoustic variables included the frequency of 40 kHz (Ultrasound Laboratory, Medical Physics Department, Tarbiat Modares University, Iran), acoustic intensity of 0 to 1.34 W/cm$^2$, and the continuous exposure mode. Modeling was performed in 32°C water (in vitro) with the density of 1000 kg/m$^3$, acoustic propagation speed of 1519 m/s, and attenuation coefficient of 0.002 N/MHz [20]. For validation, acoustic pressure was calculated at different distances and compared with the experimental results [19]. Based on the experimental study, the target radius was equal to the hydrophone piston radius (PA124, Precision Acoustics Ltd., Dorchester, UK, 1.3cm sensor radius). The MI according to the intended frequency ($f$) and the minimum acoustic pressure $P_{\text{min}}$ was defined as:

$$\text{MI} = \frac{P_{\text{min}}}{\sqrt{f}} \quad (1)$$

This was applied within the frequency range of 0.5-15 MHz, but Ahmadi [21] showed that it is an appropriate index for frequencies below about 500 kHz.

The present study was conducted under the protocol approved by the Animal Experimental Committee of the Medical Sciences Faculty of Tarbiat Modares University.

Isolation and culture of SSCs from neonatal mice (NMRI, National Medical Research Institute) was performed according to the specified protocol [19]. The animals were
euthanized quickly and humanely to avoid any pain by overdose of chemical anesthetics (2-3 times the anesthetic dose) and confirmed by heart tissue harvest [22]. The testicles were extracted for 10 min and collected after washing in Dulbecco's Minimum Essential Medium (DMEM), placed in a new medium. After the removal of the capsule, the testicles were cut into smaller pieces and placed in a culture medium containing 0.5 mg/ml of collagenase IV (Sigma) and incubated at 37° C for 20 min, then centrifuged for 5 min with 1500 rpm. Afterwards, the medium was plaque exchanged with PBS and centrifuged twice for 3 min at 1000 rpm. Next, 0.5 mg/ml of trypsin (Sigma) was added to this solution for 2 min and centrifuged for 5 min at 1500 rpm. The resulting mixture included two types of cells: Sertoli and spermatogonial cells. Cells in various groups were cultured in 10% FBS in DMEM medium and incubated for 24 h prior to treatment with LIUS (37 °C, 5.3% CO₂) (BINDER Co., German, Tuttlingen). Using immunocytochemistry, the Promyelocytic Leukemia Zinc Finger (PLZF) protein (Santa Cruz Biotechnology) (the marker for SSCs) was detected in spermatogonial cell-derived colonies. Secondary antibodies were FITC (fluorescein isothiocyanate) and RT (reverse transcriptase) (Santa Cruz Biotechnology), and DAPI (40.6-diaminofluorescein-2-phenylindole) (Santa Cruz Biotechnology) was used to stain cell nucleus [23].

The exposure time was selected under ±1 °C. The temperature of the plate containing the culture medium was controlled by a micro-thermometer during LIUS stimulation.

The effect of ultrasound waves was studied in a culture medium containing 10% FBS; 500,000 spermatogonial stem cells exposed to 40 kHz ultrasound waves; mechanical indices of 0.40, 0.51, 0.75 and 0.89; intensity of 0.28, 0.45, 0.96, and
1.34 W/cm²; the energy density of 20.16, 18.90, 32.64, and 32.16 J/cm²; exposure time of 72, 42, 34, and 24 s for five consecutive days; and compared with control and sham groups. The cells were maintained in Dulbecco's Minimum Essential Medium (Gibco) supplemented with 10% fetal bovine serum (Gibco). Ultrasound stimulation was applied to SSCs cultured in an enclosed 3.5cm tissue culture plate in another incubator (37 °C, 5.3% CO₂) (mini Galaxy E, Rs Biotech Co., UK, Irvine). It was sonicated through the bottom of the well through a coupling gel between the transducer and the plate. Each experiment was performed five times, for various sonication conditions.

After various stimulation intensities, SSCs were cultured for seven days. The colonies resulting from spermatogonial cells were assayed on the 7th day with an invert-phase microscope (Zeiss, Germany) equipped with an ocular grid. Cell viability in different groups was compared with Trypan blue. Before measuring the number and diameter of the colonies, the microscope was calibrated.

The data of the viability rate and colonization of stimulated cells are presented as mean ± standard deviation (SD). One-way ANOVA was run to analyze differences between groups at the significance level of 0.05. All the data in this study were analyzed using SPSS statistical software.

Results

Minimum acoustic pressure changes were obtained at different points along the axis in the range of induced cavitation threshold 0.7 (potential hazard) [24], less or more than the threshold at different intensities with a radius of 1.8 cm (Fig. 1).
The axial contours of a 40 kHz ultrasound transducer indicated that the near-field depth is 0.4 cm. As the increasing intensity of ultrasound waves from 0.28 to 1.34 \text{W/cm}^2 on the target surface with a radius of 1.8 cm, also showed an increase in acoustic pressure from 54.5 kPa at 1.5 cm to 192 kPa at 0.3 cm from the transducer surface.

The mechanical index changes in the near-field depth showed less volatility. The ultrasound mechanical index was related to the intensity of the waves. The increase in the mechanical index from 0.27 at 1.5 cm to 0.96 at 0.3 cm from the transducer area was estimated. In this study, the mean values of the mechanical index in minimum and maximum intensity were 0.27±0.05 and 0.96±0.35, respectively. Table 1 present the mean (SD) of mechanical indices in the 40 kHz ultrasonic transducer. After selecting the intended intensity, the distance was selected as another effective parameter (Table 1).

| Intensity (W/cm$^2$) | Distance (cm) | Pressure (kPa) | Mechanical Index | Mechanical limit |
|----------------------|--------------|---------------|------------------|------------------|
| 0.28                 | 0.50         | 81            | 0.14±0.40        | 0.19<MI<0.58     |
| 0.45                 | 0.50         | 103           | 0.17±0.51        | 0.25<MI<0.75     |
| 0.96                 | 0.50         | 151           | 0.26±0.75        | 0.36<MI<1.07     |
| 1.34                 | 0.50         | 178           | 0.30±0.89        | 0.43<MI<1.27     |

In Table 1, the desired mechanical indices were estimated at the frequency of 40 kHz with an intensity of 0.28, 0.45, 0.96 and 1.34 W/cm$^2$ at a distance of 0.50 cm from the transducer surface. At the 0.5 cm distance, the radial profile of the mechanical index for 0.28 W/cm$^2$ intensity was 0.4±0.12 (Fig. 2a). Figures 2b and 2c respectively illustrate the acoustic pressure changes and the mechanical index changes for the intensity of 0.28 W/cm$^2$ at the distance of 0.5 cm from the
transducer surface along the radial axis of the transducer.

In the center of the transducer, the mechanical index equaled 0.58. It gradually decreases when reaching 0.19 on the sides (Fig. 2a). The color change from blue to red showed an increase in acoustic pressure and mechanical index. In the validation results of a previous study [19], there was a significant correlation between the measured pressure and calculated pressure at 40 kHz (p<0.05).

Thermal control results are given in Fig. 3. The average time to increase 1 °C in 0.40, 0.51, 0.75, and 0.89 mechanical indices was about 72, 42, 34, and 24 s, respectively (Fig. 3).

The immunocytochemistry test for PLZF marker was clearly expressed in SSCs and colonies and thus the nature of these cells was confirmed. The colonies obtained after two steps of enzymatic digestion were spherical or elliptical with defined boundaries. To control the cultured cells, negative groups without added primary antibodies were brought to PLZF, and the expression of the genes was not observed due to the lack of antibodies, confirming the nature of cultured spermatogonial cells. DAPI was used to stain the nucleus. The qualitative study was performed by immunofluorescence to establish the nature of the resulting spermatogonial stem cells and for the qualitative evaluation of the specific protein markers of spermatogonial stem cells. The spermatogonial stem cell pluripotent activity is expressed in Fig. 4.

After the appearance of colonies in each group, the count and diameter of the colonies were extracted every day for seven days. According to the colony number data, the colony appearance time was equal in all groups (in the first 48 hours) (Fig. 5).

The number of colonies on the 7th day was the highest (93±4) in the group with the
mean mechanical index of 0.40 and the lowest (32±4) in the group with the mechanical index of 0.89 compared to the control group (65±4). There were significant differences among groups with 0.40 and 0.51 mechanical indices with all groups from the 5th to the 7th day (p<0.05).

An increase in the diameter of the colony was observed in the group of 0.40 mechanical index in all the days of culture. The average diameter of colonies in the 0.40 mechanical index was 174.50±1.22 μm (Fig. 6). From the 3rd to the 7th day before cell passages, there was a significant difference between the group with 0.40 mechanical index and the other groups (p<0.05). There was no significant difference between the groups (p=0.08). Cell viability was 100% in groups with 0.40, 0.75, and 0.89 mechanical indices and controls, and it was 98% and in the group with 0.51 mechanical index and the sham group. The percentage error was very low, approximately 0.0% to 1.4%, in various groups.

Discussion

LIUS is non-physiological mechanical energy which inserts direct mechanical stress into cultured cells and is a type of noninvasive mechanical stimulation. In physiological conditions of 37 °C and using low intensity, non-thermal effects can be dominant, and the main interaction, i.e. acoustic cavitation, is important. According to the studies, stable cavitation without collapse and the ability to apply stress without chemical activities produce beneficial effects in low intensities. The mechanical index parameter is the quantity that will define the phenomenon of acoustic cavitation [14, 15, 24]. Cavitation threshold for generating the bioeffects of low-frequency ultrasound have been reported, but these vary with the type of cell or
tissue being studied. Hill [24] reported that, in 0.25 to 3MHz frequencies, the intensity threshold for inertial cavitation in a liquid suspension of cells was 1 W/cm². At 20 kHz, the threshold to produce observable lesions in human skin was determined to be 2.5 W/cm² (MI=1.94) in vitro, which can be considered a hazard limit for contact to human skin [26].

On the other hand, the biological activity of low-frequency ultrasound waves is the result of the stimulation of cells by combining stable cavities and effective acoustic streams in vitro [28]. Ebrahiminia [27] investigated the exposure parameters in LIUS in near fields of 40 kHz and 1 MHz by an iodide chemical dosimeter. Results indicated that the dosimeter absorption is higher in the continuous mode of sonication than the pulse mode. Results have been shown to be most frequent in 40 kHz. These experimental results are similar to the modeling results of the mechanical index. Hideo (2009) [11] examined the frequencies of 41, 158, and 445 kHz, reporting a reduction in cavitation by increasing the frequency and its maximum at the intensity of 300 mW/cm² and 41 kHz. The results of these studies are consistent with the results of calculating the mechanical index that represents cavitation.

Furthermore, LIUS is an acoustic pressure wave that can produce localized mechanical stimulation for cells to conduct the activity of cellular membrane tensile receptors, ion channels, and integrin (extracellular messages). There is growing evidence that integrins are promising candidates for sensing extracellular matrix-derived mechanical stimuli and converting them into biochemical signals. Thus, there is growing evidence that integrins are promising candidates for sensing extracellular matrix-derived mechanical stimuli and converting them into
biochemistry signals [17]. Consequently, low-intensity ultrasound waves can stimulate transmembrane proteins such as integrin to divide and can enter these cells into a mitotic process in order for self-renewal or differentiation pathway.

A significant increase in proliferation of SSCs in the mechanical index of 0.40 was shown. An increase in proliferation was observed in the 0.51 mechanical index group, so that in comparison with 500,000 cells, it was respectively 2.89±0.07 and 2.17±0.10 in the two groups. The effects of secondary factors, i.e. LIUS, growth, and proliferation of SSCs, have been well observed in cell groups. Mohaqiq et al. [7] showed the continuous LIUS of 200 mW/cm\(^2\) causes a significant increase of 2.26±0.03 times in the proliferation of initial cells compared to controls (1.63±0.03 times) after seven days of cultivation.

The effect of low-intensity ultrasound stimulation on the proliferation and reproductivity of HepG2 and 3T3 cells in vitro was examined with a 1.06MHz generator by changing the parameters [29]. Cell viability and reproductivity at different time after sonication were measured by MTT and colony formation assay. The results illustrated that ultrasound irradiation at 0.4-0.8 W/cm\(^2\) and a high pulse repetition frequency (100 Hz) can facilitate cell proliferation, while above 0.8 W/cm\(^2\) would resist it. Therefore, cellular responses to low-intensity ultrasound are parameter-dependent. Jong (2009) [30] studied mesenchymal stem cells derived from the human umbilical cord and showed that 40 kHz LIUS, intensity less than 25 to 35 mW/cm\(^2\), periods of 100, 300, or 600 s, and a duty factor of 50% improve the proliferation of mesenchymal stem cells derived from the human umbilical cord.

Considering the effect of the LIUS mechanical index parameter, in this study, an increase was observed in the colony's diameter in the group with the mechanical
index of 0.40 with the average diameter of the colony being 174.50±1.22 μm. Moreover, a reduction in colony diameter was found in the group with a 0.89 mechanical index with the mean diameter of the colony being 137.45±1.03 μm in comparison with the control group (154.7±1.78 μm) and the sham group (139.52±0.62 μm). The number of colonies on the 7th day of culture compared to the control group were the highest in the group with 0.40 mechanical index (93±4) and the least (32±4) in the group with 0.89 mechanical index. The number of colonies on the 7th day of culture in control group, sham group, and groups with 0.51 and 0.75 mechanical indices equaled 65±4, 38±1, 73±2, and 35±2, respectively.

This study is similar to the study by Xu [18] reporting the effect of LIUS on hematopoietic stem cells in five days of radiation and an increase in cell proliferation, colonization, and viability.

Lim et al. [31] studied the effects of low-intensity ultrasound on the proliferation and osteogenic differentiation of human alveolar bone-derived mesenchymal stem cells (hABMScs). Gene expression indicated that LIPUS treatment had a positive influence on the expression of mRNA for ALP and Col-I. These results suggest that LIUS treatment may affect the cell viability and osteogenic differentiation of hABMScs.

Finally, according to other studies, the bio-stimulating effects of LIUS irradiation promote proliferation and maintain cell viability, and better results can be achieved by selecting the optimum parameters. Thus, the results of the present study indicate the effect of 0.40 mechanical index on proliferation and colonization of SSCs for the first time.
The mechanical index has been introduced to control the risks of diagnostic and clinical applications of ultrasound. Therefore, it is necessary to determine the limit of mechanical index affecting cultured cells. In the study by Kotopulis et al. [32], to avoid dangers and harm to babies' lung, a mechanical index less than 0.3 and, to prevent damage to the intestine, a mechanical index between 0.3 and 0.7 were proposed. Moreover, in the study by Hlinomazova [33], the mechanical index of 0.23 for eye applications was introduced in an FDA report. According to studies on the mechanical index range of cavitation threshold, the mechanical indices in culture media are less than 0.7 because the eye tissue and culture medium are made of water-equivalent material. Thus, considering the cavitation threshold of different materials, it is essential to find effective mechanical indices for proliferation and colonization.

Conclusions

According to the results, SSCs in the level of the mechanical index parameter show increases in cell proliferation and colonization. LIUS in the fine mechanical index can be an effective strategy for improving culture and the results of stem cell enrichment.
