Physics Department, Tsinghua University, Beijing 100084, China

(Dated: May 2, 2014)

We investigated the chiral symmetry and $U_A(1)$ anomaly at finite temperature by applying the functional renormalization group to the $SU(3)$ linear sigma model. Expanding the local potential around the classical fields, we derived the flow equations for the renormalization parameters. In chiral limit, the flow equation for the chiral condensate is decoupled from the others and can be analytically solved. The Goldstone theorem is guaranteed in vacuum and at finite temperature, and the two phase transitions for the chiral and $U_A(1)$ symmetry restoration happen at the same critical temperature. In general case with explicit chiral symmetry breaking, the two symmetries are partially and slowly restored, and the scalar and pseudoscalar meson masses are controlled by the restoration in the limit of high temperature.

1. INTRODUCTION

The chiral symmetry is one of the fundamental properties of quantum chromodynamics (QCD). In chiral limit with zero current quark mass, the QCD Lagrangian density respects the symmetry of $U_L(3) \times U_R(3) = U_V(1) \times U_A(1) \times SU_V(3) \times SU_A(3)$ at classical level. In vacuum, the condensate of right-hand quark and left-hand anti-quark $\langle \bar{q}_L q_R \rangle$ breaks the $SU_A(3)$ symmetry, and the $U_A(1)$ is broken by the anomaly due to the nontrivial topology of principal bundle of gauge field. The chiral symmetry breaking leads to a rich meson and baryon spectrum, and as a supplement the $U_A(1)$ anomaly explains the non-degeneracy of $\eta$ and $\eta'$ mesons. As a strong interacting system should approach its classical limit at high temperature, the chiral symmetry is believed to be restored in hot medium. The relation between the two symmetries in vacuum and at finite temperature has been studied for a long time. While the two symmetries are expected to be restored at high temperature, it still is an open question whether the two phase transitions happen under the same condition.

The lattice simulation is a powerful tool to study the QCD symmetries in vacuum and at finite temperature. The chiral condensate is observed to decrease with increasing temperature and the chiral susceptibility shows a peak at a critical temperature $T_c$. By a proper definition, the topological charge and its susceptibility are used to describe the $U_A(1)$ anomaly in the pure gauge field theory and the unquenched theory. In both cases, the susceptibility drops down above the critical temperature $T_c$ of the chiral restoration and the charge keeps an obvious deviation from zero at high temperature $T > T_c$. The simulation for the instanton model shows such a partial restoration too. On the other hand, the observation of the hadron spectra provides an experimental way to test the restoration of the two symmetries in hot medium created in relativistic heavy ion collisions. The mass shift due to the chiral restoration enhances or reduces the hadron thermal production, for instance for the kaon yields and ratios. The partial restoration of the $U_A(1)$ symmetry is closely related to the production of $\eta$ meson and spin-excited hadrons in hot medium.

The effective models are often used to describe the QCD phase structure, especially at finite baryon density where the lattice simulation meets the fermion sign problem and can not yet present precise result. For the study of chiral symmetry at low energy, the effective models at hadron level can include only scalar and pseudoscalar mesons. In this work we choose the linear sigma model which has been widely discussed in vacuum. The simplest version of this model is with the symmetry of $SU_L(2) \times SU_R(2)$ or $O(4)$, including only the Goldstone modes $\pi$ and their partner, the $\sigma$ meson. The linear sigma model is considered as a good laboratory for various approximation methods like mean field and the Cornwall-Jackiw-Tomboulis (CJT) approximation. In the frame of this model, the $\sigma$ and $\pi$ properties have been deeply investigated in vacuum and hot medium. The model is also extended to include fundamental represented quarks coupled to the mesons in Yukawa form. However, in the $SU(2)$ version the $U_A(1)$ anomaly can not be properly studied, since there are no enough flavors for $\eta$ and $\eta'$ mesons which are related to the anomaly. In order to study the chiral symmetry and $U_A(1)$ symmetry at the same time, the flavor symmetry group is chosen as $SU_L(3) \times SU_R(3)$ in this work.

The pion, kaon and eta mesons are the Goldstone modes corresponding to the spontaneous $SU_A(3)$ symmetry breaking. These zero mass mesons are guaranteed by the Nambu-Goldstone theorem in vacuum as well as at low temperature $T < T_c$. However, in the mean filed approximation and the CJT approximation, the Nambu-Goldstone theorem is destroyed at low temperature. In this work we use the functional renormalization group (FRG) method to study the chiral symmetry and $U_A(1)$ symmetry in the $SU(3)$ linear sigma model at finite temperature. As a non-perturbative method, the FRG has been used to study phase transitions in various systems like cold atom gas, nucleon gas and hadron gas. By solving the flow equation which connects physics at different momentum scales, the FRG shows a great power to describe the phase transitions and the corresponding critical phenomena, which are normally difficult to be controlled in the mean field approximation because of the absence of the quantum fluctuations. Instead of adding hot loops to the thermo-
dynamic potential in usual ways of going beyond mean field, the FRG effective potential at tree level of mean field approximation includes already quantum fluctuations through the mass and coupling constant renormalization and can guarantee the Nambu-Goldstone theorem in the chiral symmetry breaking phase. We proceed as follows. In Section 2, we briefly review the SU(3) linear sigma model, following the notation in [17], and apply the functional renormalization to the model. The flow equations are derived in general case with explicit chiral breaking terms, and the one for the chiral condensate can be solved analytically in chiral limit. In Section 3 we present the numerical results for the light and strange quark condensates and the topological susceptibility at finite temperature. Finally in Section 4 we summarize our results.

2. APPLICATION OF FUNCTIONAL RENORMALIZATION TO THE SU(3) LINEAR SIGMA MODEL

The SU_L(3) × SU_R(3) linear sigma model has been widely studied in mean field and CJT approximation in vacuum and at finite temperature [14, 29, 30]. Following the notations in [17], the Lagrangian density of the model is expressed as

\[ \mathcal{L} = \text{Tr} \left( \partial_\mu \phi^\dagger \partial^\mu \phi - m^2 \phi^\dagger \phi + c \left[ \text{Det}(\phi) + \text{Det}(\phi^\dagger) \right] \right) - \lambda_1 \left[ \text{Tr}(\phi^\dagger \phi) \right]^2 - \lambda_2 \text{Tr}(\phi^\dagger \phi^\dagger \phi^\dagger \phi) + \text{Tr} \left[ H(\phi + \phi^\dagger) \right], \]

(1)

where the meson matrix \( \phi = T_a \phi_a \) and the trace Tr are defined in the flavor space, the meson field \( \phi_a = \sigma_a + i \pi_a \) contains the scalar part \( \sigma_a \) and the pseudoscalar part \( \pi_a \), the \( 3 \times 3 \) Gell-Mann matrices \( T_a = \lambda_a / 2 \) for \( a = 1, \ldots, 8 \) and \( T_0 = \sqrt{2/3} I \) for \( a = 0 \) obey the relations \( \text{Tr}(T_a T_b) = \delta_{ab} / 2 \), \( [T_a, T_b] = i f_{abc} T_c \) and \( \{ T_a, T_b \} = d_{abc} T_c \) with the structure constants \( f_{abc} \) and \( d_{abc} \), \( m^2 \) is the mass parameter, and \( c, \lambda_1, \lambda_2 \) are the coupling constants.

The Lagrangian density (1) is invariant under the SU_L(3) × SU_R(3) transformation, except the last term which explicitly breaks the chiral symmetry,

\[ \text{Tr} \left[ H(\phi + \phi^\dagger) \right] = h_a \sigma_a, \]

(2)

where the matrix \( H \) is defined as \( H = h_a T_a \) with 9 parameters \( h_a \).

The determinant term in (1) explicitly breaks the \( U_A(1) \) symmetry which in QCD is violated by the anomaly. If the coefficient \( c \) of the \( U_A(1) \) anomaly term vanishes, the symmetry group of the system is enlarged to \( U_L(3) \times U_R(3) \).

In vacuum and at finite temperature but zero density, there are only scalar condensates

\[ \langle \phi \rangle = T_a \langle \sigma_a \rangle, \]

(3)

where \( \langle X \rangle \) means the ensemble average of the operator \( X \). To simplify the notation, we use \( \bar{\sigma} \) to replace \( \langle \sigma \rangle \) in the following. Making a shift for the meson field \( \phi \rightarrow \langle \phi \rangle + \delta \phi \) and substituting it into the Lagrangian density (1), the effective potential of the system at classical level can be written as

\[ U(\bar{\sigma}) = \frac{m^2}{4} \bar{\sigma}^2 - G_{abc} \bar{\sigma}_a \bar{\sigma}_b \bar{\sigma}_c + \frac{1}{3} F_{abcd} \bar{\sigma}_a \bar{\sigma}_b \bar{\sigma}_c \bar{\sigma}_d \]

\[ - h_a \bar{\sigma}_a, \]

(4)

and the dynamical masses generated by the condensates can be extracted from the coefficients of the term \( (\delta \phi)^2 \) and form two \( 9 \times 9 \) matrices \( M_S \) and \( M_P \) for the scalar and pseudoscalar mesons,

\[ (M_S^2)_{ab} = m^2 \delta_{ab} - 6 G_{abc} \bar{\sigma}_c + 4 F_{abcd} \bar{\sigma}_c \bar{\sigma}_d, \]

\[ (M_P^2)_{ab} = m^2 \delta_{ab} + 6 G_{abc} \bar{\sigma}_c + 4 H_{abcd} \bar{\sigma}_c \bar{\sigma}_d, \]

(5)

with the coefficients defined as

\[ G_{abc} = \frac{c}{6} \left[ d_{abc} + \frac{9}{2} d_{000} \delta_{a0} \delta_{b0} \delta_{c0} \right] - \frac{3}{2} \left[ \delta_{a0} d_{0bc} + \delta_{b0} d_{0ac} + \delta_{c0} d_{0ab} \right], \]

\[ F_{abcd} = \frac{\lambda_1}{4} \left( \delta_{ab} \delta_{cd} + \delta_{ad} \delta_{bc} + \delta_{ac} \delta_{bd} \right) + \frac{\lambda_2}{8} \left( d_{abe} d_{cde} + d_{ade} d_{bce} + d_{ace} d_{bde} \right), \]

\[ H_{abcd} = \frac{\lambda_1}{4} \delta_{ad} \delta_{bc}, \]

\[ + \frac{\lambda_2}{8} \left( d_{abe} d_{cde} + f_{ade} d_{bce} + f_{ace} d_{bde} \right). \]

(6)

The physical condensates are determined by minimizing the potential,

\[ \frac{\partial U(\bar{\sigma})}{\partial \bar{\sigma}_a} = 0 \]

(7)

which leads to the gap equations

\[ m^2 \bar{\sigma}_a - 3 G_{abc} \bar{\sigma}_b \bar{\sigma}_c + \frac{4}{3} F_{abcd} \bar{\sigma}_b \bar{\sigma}_c \bar{\sigma}_d - h_a = 0. \]

(8)

In different thermodynamic environments, the condensate \( \langle \phi \rangle \) can be further simplified. Since the isospin zero mesons \( \sigma_0 \) and \( \sigma_8 \) or \( \sigma_8 \) can couple to the vacuum without violating Lorentz invariance and parity, the classical field matrix \( \langle \phi \rangle \) and the coefficient matrix \( H \) in the chiral breaking term contain only two components, \( \langle \phi \rangle = T_0 \bar{\sigma}_0 + T_8 \bar{\sigma}_8 \) and \( H = T_0 h_0 + T_8 h_8 \). In order to simplify the expressions, we make a rotation for the condensates \( \bar{\sigma}_0 \) and \( \bar{\sigma}_8 \) and the chiral breaking parameters \( h_0 \) and \( h_8 \),

\[ \bar{\sigma}_u = \sqrt{\frac{2}{3}} \bar{\sigma}_0 + \sqrt{\frac{1}{3}} \bar{\sigma}_8, \]

\[ \bar{\sigma}_s = \sqrt{\frac{1}{3}} \bar{\sigma}_0 - \sqrt{\frac{2}{3}} \bar{\sigma}_8, \]

\[ h_u = \sqrt{\frac{2}{3}} h_0 + \sqrt{\frac{1}{3}} h_8, \]

\[ h_s = \sqrt{\frac{1}{3}} h_0 - \sqrt{\frac{2}{3}} h_8. \]

(9)
In terms of the rotated condensates $\bar{\sigma}_u$ and $\bar{\sigma}_s$ and the rotated breaking parameters $h_u$ and $h_s$, the classical potential and the gap equations can be explicitly expressed as
\[
U(\bar{\sigma}_u, \bar{\sigma}_s) = \frac{m^2}{2} \left( \bar{\sigma}_u^2 + \bar{\sigma}_s^2 \right) - \frac{c}{2\sqrt{2}} \bar{\sigma}_s^2 \bar{\sigma}_u + \frac{\lambda_1}{4} \left( \bar{\sigma}_u^2 + \bar{\sigma}_s^2 \right)^2 + \frac{\lambda_2}{8} \left( \bar{\sigma}_u^2 + 2\bar{\sigma}_s^4 \right),
\]
and
\[
m^2 \bar{\sigma}_u - \sqrt{2} c \bar{\sigma}_u \bar{\sigma}_s + \lambda_1 \left( \bar{\sigma}_u^2 + \bar{\sigma}_s^2 \right) \bar{\sigma}_u + \frac{1}{2} \lambda_2 \bar{\sigma}_u^3 = h_u,
\]
\[
m^2 \bar{\sigma}_s - \sqrt{2} c \bar{\sigma}_u \bar{\sigma}_s + \lambda_1 \left( \bar{\sigma}_u^2 + \bar{\sigma}_s^2 \right) \bar{\sigma}_s + \lambda_2 \bar{\sigma}_s^3 = h_s.
\]
For the meson mass matrices $M_S$ and $M_P$, each has only one independent off-diagonal element $M_{S\bar{S}} = M_{S\bar{p}}$ and four independent diagonal elements $M_{S\bar{S}}, M_{S\bar{p}}$ and
\[
m_{a0}^2 = (M_S^2)_{11} = (M_S^2)_{22} = (M_S^2)_{33},
\]
\[
m_n^2 = (M_S^2)_{44} = (M_S^2)_{55} = (M_S^2)_{66} = (M_S^2)_{77},
\]
\[
m_p^2 = (M_P^2)_{11} = (M_P^2)_{22} = (M_P^2)_{33},
\]
\[
m_K^2 = (M_P^2)_{44} = (M_P^2)_{55} = (M_P^2)_{66} = (M_P^2)_{77},
\]
and diagonalizing the meson subspace at $a = 0, 8$ generates the pseudoscalar mesons $\eta$ and $\eta'$ and the corresponding scalar mesons. There are six parameters in the model, the mass $m$, the three coupling constants $c, \lambda_1$ and $\lambda_2$ and the two chiral breaking parameters $h_u$ and $h_s$. They should be determined by the experimental data in vacuum. First, the partial conservation of axial-vector currents at low momentum $\vec{p} < k$ determines the couplings $\lambda_2$ and $c$.

The combination of the isospin zero pseudoscalar mesons $\eta$ and $\eta'$ determines the couplings $\lambda_2$ and $c$.

\[
\lambda_2 = 2\sqrt{6} \bar{\sigma}_u m_K^2 \sqrt{2} \sigma_0 m_\pi^2 + \bar{\sigma}_s (m_n^2 + m_p^2),
\]
\[
c = \frac{2}{f_K - f_\pi} (2f_K - f_\pi).
\]

Substituting the above obtained parameters into any of the two gap equations, one can get the relation between the mass $m$ and the coupling $\lambda_1$. By fitting a scalar meson mass, for instance $m_\pi$, one can then separately fix the two parameters. In summary, the six parameters $m, c, \lambda_1, \lambda_2, h_u$ and $h_s$ are fitted by the experimental values of $m_\pi, m_K, f_\pi, f_K$, and $m_n^2 + m_p^2$, and one of the scalar meson masses. It is necessary to note that, in this way one can fix a group of parameters, but the obtained condensates may not correspond to the minimum of the potential. One should check the secondary derivative of the potential, $\partial^2 U/\partial \bar{\sigma}_i \partial \bar{\sigma}_j > 0$.

We now apply the functional renormalization group to the SU(3) linear sigma model. The core quantity in the frame of FRG is the averaged effective action $\Gamma_k$ at a momentum scale $k$ in Euclidean space,

\[
\Gamma_k[\langle \phi \rangle] = \int d^4 x \left[ \text{Tr} \left( Z_k \partial_k \langle \phi \rangle \partial^k \langle \phi \rangle \right) + U_k(\langle \phi \rangle) + \cdots \right],
\]
where $Z_k$ is the wave function renormalization constant, $U_k(\langle \phi \rangle)$ is the classical potential \[10\] but with renormalized mass and coupling parameters $m_k, c_k, \lambda_{1k}$ and $\lambda_{2k}$ and scale dependent condensates $\bar{\sigma}_{uk}$ and $\bar{\sigma}_{sk}$, and the symbol $\cdots$ stands for the high order terms of the field $\langle \phi \rangle$. The scale dependence of the averaged action is characterized by the flow equation \[18, 20\] in momentum representation,

\[
\frac{\partial \Gamma_k[\langle \phi \rangle]}{\partial k} = \frac{1}{2} \int \frac{d^4 p}{(2\pi)^4} \text{Tr} \left[ \left( \Gamma_k^{(2)}[\langle \phi \rangle] + R_k \right)^{-1} \frac{\partial R_k}{\partial k} \right],
\]
where $\Gamma_k^{(2)}$ is the second order functional derivative of the averaged action $\Gamma_k^{(2)}[\langle \phi \rangle] = \delta^2 \Gamma_k/\delta \langle \phi \rangle^2$, and the infrared cutoff function $R_k$ which is used to suppress the quantum fluctuations at low momentum $p < k$ is chosen as the optimized regulator function $R_k = (k^2 - p^2)^\theta(k^2 - p^2)^\theta$ \[31\]. From our numerical calculation shown in the next section, the symmetry restoration and meson mass spectra at finite temperature are not sensitive to the choice of the cutoff function \[32\].

Following the effective action flow starting from the ultraviolet momentum $k = \Lambda$, the physics we are interested in could be obtained at $k = 0$.

By assuming the space-time independence of the classical field $\langle \phi \rangle$, the effective action to the lowest order is determined by the classical potential only,

\[
\Gamma_k = \int d^4 x U_k \left( \langle \phi \rangle \right).
\]

With the known infrared cutoff function $R_k$, after doing the three-momentum cutoff integration for the mesons at finite temperature, the FRG flow equation can be simplified as

\[
\partial_k U_k = Z_{Sk}^{-1} k^4 4 \left( 1 - \eta_{Sk} \right) T \sum_n \text{Tr} D_{Sk} \]
\[
+ Z_{P_k}^{-1} k^4 4 \left( 1 - \eta_{P_k} \right) T \sum_n \text{Tr} D_{P_k}
\]
with the meson propagators $D_{Sk}^{-1} = Z_{Sk}^{-1} (\omega_n^2 + k^2) + M_S^2$ and $D_{P_k}^{-1} = Z_{P_k}^{-1} (\omega_n^2 + k^2) + M_P^2$ and the definition $\eta_k = -k \partial_k Z_k^{-1} / Z_k^{-1}$, where $\omega_n = 2n\pi T$ with $n = 0, 1, 2 \cdots$ is the meson Matsubara frequency in the imaginary time.
The formalism of finite temperature field theory, and we have considered different renormalization constants $Z_{Sk}$ and $Z_{P k}$ for the scalar and pseudoscalar fields. In order to complete the set of flow equations, we need equations for the evolution of $Z_{Sk}$ and $Z_{P k}$ [20]. To the one-loop level they read

$$- \partial_k Z_{Sk}^{-1} = \frac{Z_{Sk}^{-1} Z_{P k}^{-1} k^4}{3 \pi^2 T} \sum_n \text{Tr} (D_{Sk}^2 \Gamma_{SSS} D_{Sk}^2 \Gamma_{SSS}) + \frac{Z_{Sk}^{-2} k^4}{6 \pi^2 T} \sum_n \text{Tr} (D_{P k}^2 \Gamma_{SP} D_{P k}^2 \Gamma_{SP})$$

$$- \partial_k Z_{P k}^{-1} = \frac{Z_{P k}^{-1} Z_{Sk}^{-1} k^4}{3 \pi^2 T} \sum_n \text{Tr} (D_{P k}^2 \Gamma_{P SP} D_{P k}^2 \Gamma_{P SP})$$

where $(\Gamma_{SSS})_{bc} = \partial^3 U_k / \partial \sigma_b \partial \sigma_c$, $(\Gamma_{SP})_{bc} = \partial^3 U_k / \partial \bar{\sigma}_b \partial \sigma_c$, and $(\Gamma_{P SP})_{bc} = \partial^3 U_k / \partial \bar{\sigma}_b \partial \bar{\sigma}_c$ are 9×9 matrices for the three-line vertexes with a fixed external meson $a$. In the above discussion we have assumed that the wave function renormalization constant depends only on the Lorentz transformation property of the mesons, but is independent of the detailed meson types. In the following numerical calculations related to the three-line vertexes, we take the Goldstone mode $a = 4$.

As we will see from the numerical calculation in the next section, the contribution from the wave function renormalization to the thermodynamics of the system is very small and can be safely neglected as a first order approximation. In this case, by taking $Z_{Sk} = Z_{P k} = 1$, the flow equation (21) is further simplified as

$$\partial_k U_k = \frac{k^4}{6 \pi^2 T} \sum_n \text{Tr} (D_{Sk} + D_{P k})$$

Note that the parameters $h_u$ and $h_s$ (or $h_0$ and $h_8$) which explicitly break the chiral symmetry are scale independent, and only the condensates $\bar{\sigma}_u$ and $\bar{\sigma}_s$ (or $\bar{\sigma}_0$ and $\bar{\sigma}_8$) which spontaneously break the chiral symmetry depend on the scale $k$. In the treatment of the flow equation with classical potential, the mass and coupling constant renormalization leads to four $k$-dependent parameters $m_k, c_k, \lambda_k, \lambda_{2k}$ controlled by the flow equation (21), and the condensates $\bar{\sigma}_{uk}$ and $\bar{\sigma}_{sk}$ are determined by the gap equations (11).

Considering the partially degenerated diagonal elements and the simple off-diagonal structure of the mass matrices $M_S$ and $M_P$, the trace in (21) can be easily done, and the flow equation becomes

$$\partial_k U_k = \frac{k^4}{6 \pi^2 T} \left[ \text{Tr} (D_{Sk} + D_{P k}) + 3 D_{ak} + 4 D_{sk} + 3 D_{zk} + 4 D_{KK} \right]$$

with two 2×2 mixed matrices

$$M_S = \left( \begin{array}{cc} (M_S^2)_{00} & (M_S^2)_{08} \\ (M_S^2)_{80} & (M_S^2)_{88} \end{array} \right),$$

$$M_P = \left( \begin{array}{cc} (M_P^2)_{00} & (M_P^2)_{08} \\ (M_P^2)_{80} & (M_P^2)_{88} \end{array} \right)$$

and the corresponding propagators $D_{Sk}^{-1} = \omega_n^2 + k^2 + \lambda_{2k}^2$ and $D_{P k}^{-1} = \omega_n^2 + k^2 + \lambda_{2k}^2$. Different from the O(4) model [24] while $\text{Tr}(\phi \phi)$, $\text{Tr}(\phi \phi)^2$ and $\text{Det}(\phi \phi)$ are invariant under the $SU_L(3) \times SU_R(3)$ transformation, not all the meson masses can be expressed with the eigenvalues of these operator composites.

We now expand the potential around the minimum $\sigma_{uk}$ and $\sigma_{sk}$. Shifting the field $\sigma_u = \sigma_{uk} + \delta \sigma_{uk}$ and $\sigma_s = \sigma_{sk} + \delta \sigma_{sk}$, the derivative of the potential on the left hand side of the flow equation could be expressed as powers of $\delta \sigma_{uk}$ and $\delta \sigma_{sk}$,

$$\dot{U}_k(\sigma_{uk} + \delta \sigma_{uk}, \sigma_{sk} + \delta \sigma_{sk}) = \dot{U}_k + \frac{\partial^2 U_k}{\partial \delta \sigma_{uk} \partial \delta \sigma_{sk}} \delta \sigma_{uk} \delta \sigma_{sk} + \frac{1}{2} \frac{\partial^2 U_k}{\partial \delta \sigma_{uk}^2} \delta \sigma_{uk}^2$$

$$+ \frac{1}{2} \frac{\partial^2 U_k}{\partial \delta \sigma_{sk}^2} \delta \sigma_{sk}^2$$

with the definition $\dot{U}_k = \partial_k U_k$. By comparing the coefficients of $\delta \sigma_{uk}, \delta \sigma_{sk}, \delta \sigma_{uk}^2, \delta \sigma_{sk}^2$ and $\delta \sigma_{uk} \delta \sigma_{sk}$ on the left and right hand sides of the flow equation (22), one obtains four independent differential equations for the six parameters $m_k^2, c_k, \lambda_k, \lambda_{2k}, \sigma_{uk}$ and $\sigma_{sk}$. Together with the two gap equations, their $k$-dependence are fully determined. Note that in deriving the four flow equations we have used the relations $\partial_k \delta \sigma_{uk} = - \partial_k \sigma_{uk}$ and $\partial_k \delta \sigma_{sk} = - \partial_k \sigma_{sk}$.

Before numerically solving the flow equations which will be done in the next section, we firstly discuss their chiral limit analytically. From the relation between $h_8$ and $\bar{\sigma}_8$,

$$h_8 = m_8^2 \bar{\sigma}_8,$$

since there is no reason for the $\kappa$ meson to be massless in chiral limit, the condensate $\bar{\sigma}_8$ should vanish in the case of $h_0 = h_8 = 0$. In this limit, there remains only one gap equation for the condensate $\bar{\sigma}_0$,

$$m^2 - \frac{c}{\sqrt{6}} \bar{\sigma}_0 + \left( \lambda_1 + \frac{\lambda_2}{3} \right) \bar{\sigma}_0^2 = 0,$$

and the off-diagonal elements in the mass matrices $M_{S, P}$ disappear. In the phase of spontaneous chiral symmetry breaking, there are eight pseudoscalar Goldstone modes $\pi, K$ and $\eta$ which dominate the thermodynamics of the system. From the flow equation (22), the heavy modes do not contribute much to the flow, we can keep only the terms with the Goldstone modes. In this approximation the flow equation for the chiral condensate $\bar{\sigma}_{0k}$ is decoupled from the others,

$$\partial_k \bar{\sigma}_{0k}^2 = \frac{8 k^4}{3 \pi^2 T} \sum_n \frac{1}{(\omega_n^2 + k^2)^2}$$

$$= \frac{2 k}{3 \pi^2} (1 + 2 n_k + 2 \frac{k}{T} n_k + 2 \frac{k}{T} n_k^2 / T)$$

with the Fermi-Dirac distribution $n_k = 1 / (e^{k/T} - 1)$. 
It is easy to see that the right hand side of the flow equation [27] is always positive, which leads to a monotonically increasing $\bar{\sigma}_k$ with the momentum scale $k$ at any temperature. Therefore, when we start at an ultraviolet momentum $\Lambda$, the physical condensate at $k = 0$ is guaranteed to be finite from the evolution of the flow equation. On the other hand, from the meson frequencies $\omega_n = 2n\pi T$, the condensate drops down with increasing temperature at any momentum scale $k$, which may lead to a phase transition of chiral symmetry restoration at a critical temperature $T_c$. In fact, the flow equation can be analytically integrated out with the solution

$$\bar{\sigma}_{0\Lambda}(T) = \bar{\sigma}_{0\Lambda}^2(T) + f(\Lambda, T) - f(k, T)$$

with the definition

$$f(k, T) = \frac{T^2}{3\pi^2} \left[ 5 \left( \frac{k}{T} \right)^2 + 4 \left( \frac{k}{T} \right)^2 n_k + 12 \frac{k}{T} \ln(-n_k) - 12 \ln2 \left( \frac{k}{T} \right) \right],$$

where $\ln2(x) = \sum_{i=1}^{\infty} x^i / i^2$ is the polylogarithm function. At very high momentum, the temperature effect on the system becomes weak, and we can reasonably take the boundary condition of the flow equation $\bar{\sigma}_{0\Lambda}(T)$ at finite temperature as the one $\bar{\sigma}_{0\Lambda}(0)$ at zero temperature. The condensate $\bar{\sigma}_{0\Lambda}(0)$ is determined by reproducing the vacuum value $\bar{\sigma}_{00}(0)$,

$$\bar{\sigma}_{0\Lambda}^2(0) = \bar{\sigma}_{0\Lambda}^2(0) + f(0, 0) - f(\Lambda, 0).$$

The critical temperature $T_c$ for the chiral phase transition is then determined by

$$\bar{\sigma}_{0\Lambda}^2(0) + f(\Lambda, T_c) - f(0, T_c) = 0.$$  

In the symmetry restoration phase with $T > T_c$, the potential expansion should be around the zero condensate $\bar{\sigma}_0 = 0$. In this case, all the mesons become degenerate with mass $m^2$ and their contributions to the flow equation are the same. The procedure for the SU(2) model is discussed in [27, 28].

3. NUMERICAL RESULTS

In this section we show our numerical results for chiral symmetry and $U_A(1)$ symmetry restoration at finite temperature. In the case with explicit chiral symmetry breaking, one has to solve the coupled four flow equations, if the wave function renormalization is neglected, together with the two gap equations. The initial condition for the four differential equations at a fixed temperature is the values of the six parameters at the ultraviolet momentum $\Lambda$, namely $m_\lambda(T), \lambda_\Lambda(T), \lambda_{1\Lambda}(T), \lambda_{2\Lambda}(T), \bar{\sigma}_{u\Lambda}(T)$ and $\bar{\sigma}_{s\Lambda}(T)$. Considering the fact that the system at high enough momentum is dominated by the dynamics and not affected remarkably by the temperature, the temperature dependence of the parameters at the ultraviolet momentum can be safely neglected. Therefore, we take the temperature independent initial values $m_\lambda(T) = m_\lambda(0), \lambda_\Lambda(T) = \lambda_\Lambda(0), \lambda_{1\Lambda}(T) = \lambda_{1\Lambda}(0), \lambda_{2\Lambda}(T) = \lambda_{2\Lambda}(0), \bar{\sigma}_{u\Lambda}(T) = \bar{\sigma}_{u\Lambda}(0)$ and $\bar{\sigma}_{s\Lambda}(T) = \bar{\sigma}_{s\Lambda}(0)$, and they are so chosen to reproduce their vacuum values at $k = 0$ discussed in Section 2, by solving the flow equations and gap equations at zero temperature.

Fig. 1 shows the evolution of the condensates $\bar{\sigma}_{u\Lambda}, \bar{\sigma}_{s\Lambda}$ and $\bar{\sigma}_{s\Lambda}$ at zero temperature. With increasing momentum scale $k$, the condensates $\bar{\sigma}_{u\Lambda}$, $\bar{\sigma}_{s\Lambda}$ drop down continuously and approaches to zero at $k \sim 1$ GeV. From the relation $h_{s\Lambda} = m_{s\Lambda}^2 \bar{\sigma}_{s\Lambda}$, the $k$-independence of the chiral breaking parameter $h_{s\Lambda}$ leads to a divergent meson mass $m_{s\Lambda}$ at $k \sim 1$ GeV. Therefore, we take 1 GeV as the ultraviolet momentum $\Lambda$ for the evolution of the renormalization parameters. We have checked that the numerical results are insensitive to the value of the momentum cut $\Lambda$. Both the light and strange quark condensates $\bar{\sigma}_{u\Lambda}$ and $\bar{\sigma}_{s\Lambda}$ go up with increasing scale $k$, as we analyzed in the end of Section 2 in chiral limit.

The temperature dependence of the light and strange quark condensates at $k = 0$ is shown in Fig. 2. While the both condensates are almost constants at low temperature $T < 50$ MeV, they monotonically decrease at high enough temperature, as we expected from the analysis in chiral limit. Since strange quarks are much heavier than light quarks, which is reflected in the values of the explicit symmetry breaking parameters $h_{\Lambda}$ and $h_{s\Lambda}$, the SU(2) symmetry restoration should be much faster than the SU(3) symmetry restoration. This is the reason why the light quark condensate drops more rapidly than the strange quark condensate. The qualitative behavior of the condensates shown here is similar to what obtained in the frame of CJT approximation [17].

What is the effect of the wave function renormalization on the condensates? Solving the flow equations
The topological susceptibility can be related to the anomaly, the ninth Goldstone mode $\eta$ where

\[ \langle \eta \rangle \propto k \]

for the renormalized mass and coupling constants $m^2$, $c_k$, $\lambda_{1k}$ and $\lambda_{2k}$ and \[ 24 \] for the renormalized wave functions $Z_{Sk}$ and $Z_{Pk}$ and the gap equations \[ 11 \] for the condensates $\bar{\sigma}_{ak}$ and $\bar{\sigma}_{sk}$, and taking the vacuum values $Z_{S0} = Z_{P0} = 1$ at $T = k = 0$, the momentum scale dependence of $Z_{Sk}^{-1}$ and $Z_{Pk}^{-1}$ at zero temperature are shown in Fig. 3. While the scalar part varies strongly with the scale $k$, the renormalization for the pseudoscalar mesons, among which the Goldstone modes dominate the thermodynamics of the system, is a very smooth function in the whole region $0 < k < \Lambda$. Considering the fact of \[ \eta_k \propto \partial_k Z_{P}^{-1} \] in the flow equation \[ 13 \], the contribution from the wave function renormalization to the averaged action is expected to be slight. From Fig. 3, the temperature dependence of the light and strange quark condensates, including the contribution from the wave function renormalization, is almost the same as the one shown in Fig. 2. Therefore, for the following numerical calculations we will omit the wave function renormalization as a first order approximation.

The $U_A(1)$ anomaly is described by the topological susceptibility [4]

\[ \chi = \int d^4 x \langle 0 \mid T(Q(x)Q(0)) \rangle \langle 0 \mid \]

with $Q(x)$ being the topological charge determined by the QCD coupling constant $g$ and the gauge field tensor $F^a_{\mu \nu}$,

\[ Q(x) = \frac{g^2}{64\pi^2} \epsilon_{\mu \nu \rho \sigma} F^a_{\mu \nu}(x) F^a_{\rho \sigma}(x), \] (33)

where $\epsilon_{\mu \nu \rho \sigma}$ is the antisymmetric tensor. By introducing the anomaly, the ninth Goldstone mode $\eta'$ is no longer massless. The topological susceptibility can be related to

the pseudoscalar meson masses in the linear sigma model,

\[ \chi = \frac{f^2}{6} \left( m_{\eta'}^2 + m_{\eta''}^2 - 2m_k^2 \right) \]

\[ = \frac{g^2}{12} \left( \sqrt{6} \sigma_0 - 3\lambda_2 \sigma_s^2 \right). \] (34)

It is determined not only by the three-line coupling $c$ but also by the four-line coupling $\lambda_2$, although the $U_A(1)$ symmetry is broken only by the determinant term which is irrelevant to $\lambda_2$.

The temperature dependence of the topological susceptibility is shown in Fig. 4. It decreases with temperature in the region of $T \geq 100$ MeV, indicating a continuous restoration of $U_A(1)$ symmetry. Different from the lattice simulation for the $SU(3)$ Yang-Mills theory [4] where the susceptibility drops down rapidly, the susceptibility remains still 30% of its vacuum value at high temperature $T = 250$ MeV. Unlike the condensates which never in-

crease with temperature, the susceptibility shows a slight increase in the low temperature region of \( T < 100 \text{ MeV} \), which is observed also in simulations in the interacting instanton liquid model\(^6\).

The chiral symmetry and \( U_A(1) \) symmetry restoration shown above control the meson masses in hot medium. The temperature dependence of the meson masses is shown in Figs. 6 and 7. There are four different mesons for each species, the triplet \( a_0 \), quartet \( \kappa \), and the mixed \( \sigma \) and \( f_0 \) for the scalar mesons, and the triplet \( \pi \), quartet \( K \), and the mixed \( \eta \) and \( \eta' \) for the pseudoscalar mesons. As temperature increases, the scalar meson masses \( m_{f_0}, m_\kappa \) and \( m_{a_0} \) drop down monotonically, but \( f_0 \) and \( \kappa \) are heavier than \( a_0 \) at \( T < 200 \text{ MeV} \) and become lighter than \( a_0 \) at \( T > 200 \text{ MeV} \). The Goldstone modes \( \pi \) and their chiral partner \( \sigma \) become degenerate at high temperature, due to the chiral symmetry restoration. The similar behave is for the mesons \( a_0 \) and \( \eta' \). At \( T = 250 \text{ MeV} \) there are \( m_\pi \approx m_\sigma \approx 200 \text{ MeV} \) and \( m_{a_0} \approx m_{\eta'} \approx 900 \text{ MeV} \). The mixed mode \( \eta' \) behaves similarly to the other seven Goldstone modes \( \pi \) and \( K \). While the mass of the other mixed meson \( \eta' \) slightly goes up at low temperature and drops down at high temperature, the difference between \( \eta \) and \( \eta' \) decreases with increasing temperature, due to the partial restoration of the \( U_A(1) \) symmetry.

In chiral limit, the condensate \( \bar{\sigma}_0 \) disappears and the flow equation for the condensate \( \bar{\sigma}_0 \) is decoupled from the others and can be analytically solved as \(^{28}\). The evolutions of \( \bar{\sigma}_{0k} \) at different temperature is shown in Fig. 8. While the temperature dependence at low momentum scale \( k \) is remarkable, the condensate is almost \( T \)-independent when the scale is large enough. This supports our choice of \( T \)-independent initial condition at \( k = \Lambda \). With increasing temperature, the solution at \( k = 0 \) approaches to zero continuously, indicating the phase transition of chiral symmetry restoration. The temperature dependence of the physical condensate and topological susceptibility at \( k = 0 \) is shown in Fig. 9.

The condensate drops down much faster than that in the general case with explicit chiral symmetry breaking, see Fig. 2. The critical temperature for the chiral phase transition determined by \( \bar{\sigma}_{00}(T_c) = 0 \) is \( T_c = 130 \text{ MeV} \).

The topological susceptibility \(^4\) for the \( U_A(1) \) anomaly is simplified as

\[
\chi = \frac{1}{3\sqrt{6}} c_0^3 \tag{35}
\]

in chiral limit. After a rapid decrease in the vicinity of vacuum, it becomes very smooth and finally vanishes at the same critical temperature for the \( SU_A(3) \) symmetry restoration.

4. CONCLUSION

We investigated in this paper the chiral symmetry and \( U_A(1) \) symmetry restoration at finite temperature, by applying the functional renormalization group to the \( SU(3) \)
FIG. 8: The evolutions of the condensate $\bar{\sigma}_0(k)$ at different temperature in chiral limit.

FIG. 9: The temperature dependence of the chiral condensate $\bar{\sigma}_0$ and topological susceptibility $\chi$ in chiral limit, scaled by their vacuum values.

In general case with explicit chiral symmetry breaking, we numerically solved the coupled flow and gap equations at finite temperature, starting from the classical potential at the ultraviolet momentum $k = \Lambda \sim 1$ GeV and extracting physics including quantum fluctuations at $k = 0$. In this case a partial restoration of the $SU_A(3)$ and $U_A(1)$ symmetries is observed. Different from the results obtained in other approximations like CJT method, the light and strange quark condensates drop down with temperature slowly. As a result of the partial restoration of the two symmetries, the pseudoscalar triplet $\pi$ and its chiral partner $\sigma$ (the scalar triplet $a_0$ and $\eta'$) become degenerate at high temperature, and the difference between the mixed modes $\eta$ and $\eta'$ gradually disappears in the limit of high temperature.
