We show that equilibrium monomer and centre-of-mass concentration profiles of lattice polymers in a gravitational field, computed by Monte-Carlo simulations, provide an accurate and efficient road to the osmotic equation-of-state of polymer solutions, via a straightforward application of the hydrostatic equilibrium condition. The method yields the full equation of state over a wide range of concentrations from a single simulation, and does not suffer from significant finite size effects. It has been applied to self-avoiding walk polymer chains with nearest neighbour monomer attractions, from the good solvent to the theta solvent regimes. The consistency of the method has been carefully checked by varying the strength of the gravitational field.

I. INTRODUCTION

While the osmotic equation of state (e.o.s.) of off-lattice models of polymer solutions or melts can be readily computed from the contact theorem, according to which the osmotic pressure is proportional to the monomer density at a hard wall, the task is significantly more arduous for polymers on a lattice. For short chains or low polymer concentrations the chemical potential may be calculated from the insertion probability of a test chain and the pressure then follows by standard thermodynamic integration. The insertion method can be extended to solutions of longer polymers provided configurational bias Monte-Carlo algorithms are used. An alternative method, the repulsive wall thermodynamic integration (RWTI) method, which remains efficient at high polymer concentrations, or in the melt, was proposed by Dickman. It extends the contact theorem approach, but requires several simulation runs for increasing wall-monomer repulsion and subsequent thermodynamic integration for each state point, rendering the method rather cumbersome. Moreover a recent analysis by Stukan et. al. revealed that the RWTI method is prone to large finite-size effects, particularly at high polymer concentrations, which can only be overcome by switching to grand-canonical ensemble simulations.

In this paper we show that the e.o.s. of dilute or semi-dilute polymer solutions is much more efficiently computed by subjecting the polymers to a strong gravitational field. The resulting sedimentation profile of the polymer solution then leads directly, via the hydrostatic equilibrium condition, to the osmotic e.o.s. over a wide range of concentrations from a single Monte-Carlo (MC) run. The method extends an idea which has been successfully applied to concentrated dispersions of rigid colloidal particles (e.g. spherical or plate like) to the case of flexible polymers; it applies to on- and off-lattice models alike.

II. MONOMER AND CENTRE-OF-MASS CONCENTRATION PROFILES

Sedimentation equilibrium of macromolecular solutions or colloidal dispersions arises from the balance between gravity, which pulls particles to lower altitudes $z$, and the entropic drive toward homogeneity, and is characterised by a concentration profile $\rho(z)$. If $m$ is the buoyant mass of the particles, the sedimentation length is defined by $\zeta = k_B T/m g$, where $g$ is the acceleration of gravity and $k_B T$ the thermal energy. For compact, micron-sized colloids, $\zeta$ is typically of the order of a few particle diameters, but for the much lighter fractal polymer chains, $\zeta$ is very large under normal gravity, so that the solution remains nearly homogeneous in practice. However, in simulations $g$ can be tuned to induce a measurable modulation of the concentration profile.

We consider systems of $N$ polymer chains, each of $L$ monomers (or segments) living on a cubic lattice of spacing $a$. Each site hosts at most one monomer, corresponding to the self-avoiding-walk (SAW) model, while non-connected nearest neighbour segments interact with energy $-\epsilon$. The dimensionless inverse temperature is $\beta' = \beta \epsilon = \epsilon/k_B T; \beta^* = 0$ corresponds to the athermal SAW limit, while the $\theta$-solvent regime is reached for $\beta^* \approx 0.265$ for $L=500$ chains. Each monomer experiences the gravitational energy $-m g z$, and the gravitational coupling constant is the dimensionless ratio $\lambda_m = a/\zeta_m = m g a/k_B T$. Sedimentation equilibrium is characterised by the monomer concentration profile $\rho_m(z)$, i.e. the mean number of monomers per unit volume at altitude $z$. A more coarse-grained representation focuses on the centre-of-mass (CM) of each polymer coil, of characteristic dimension equal to the radius of gyration $R_g$. The gravitational field acts on the CM, and the corresponding sedimentation length is $\zeta_{cm} = k_B T/M g = \zeta_m/L$ where $M = L m$ is the total mass of the polymer. The relevant gravitational coupling constant is

$$\lambda_{cm} = \frac{R_g}{\zeta_{cm}} = \frac{M g R_g}{k_B T} = \lambda_m L R_g/a \sim \lambda_m L^{1+\nu} \quad (1)$$

where $R_g \sim a L^\nu$ with $\nu$ the Flory exponent ($\nu \approx 0.59$ in
good solvent and $\nu = 0.5$ in $\theta$ solvent. At sedimentation equilibrium, the CM concentration profile is $\rho_{cm}(z)$, which satisfies the normalisation,

$$ \int_0^\infty \rho_{cm}(z)dz = n_s, \quad (2) $$

where $n_s = N/A$ is the number of polymers per unit area of an x-y cross-section of the sedimentation column.

Two limits of the concentration profile are known explicitly. First, the system of independent (free) monomers, i.e. $L = 1$ polymers, reduces in the SAW limit ($\beta^* = 0$) to a single occupancy lattice gas in a gravitational field. The corresponding concentration profile $\rho_m^{(i)}(z)$ is easily calculated to be:

$$ \rho_m^{(i)}(z) = \frac{e^{\beta\mu - z/\zeta_m}}{1 + e^{\beta\mu - z/\zeta_m}} \quad (3) $$

where $\mu$ is the monomer chemical potential. At sufficiently high altitudes ($z \to \infty$) the profile follows the barometric law for monomers: $\rho_m^{(i)}(z) \sim \exp(-\beta mgz) \sim \exp(-z/\zeta_m)$. Upon introducing connectivity constraints, however, the concentration profile contracts significantly. At high altitudes $z$, where the polymer-polymer interactions are negligible, the concentration profile takes the form

$$ \rho_m(z) \propto \rho_{cm}(z) \sim \exp(-\beta mLgz) \sim \exp(-z/\zeta_{cm}), \quad (4) $$

following the barometric law for polymers. In other words, it is contracted by a factor $L$ over a system of unconnected monomers. This follows from the well-known $1/L$ reduction of the ideal component of the osmotic pressure of polymer solutions $P^{id} = \rho_m/L$, where $\rho_m$ is the bulk monomer concentration. In fact, if the e.o.s. and hence the free energy density of a homogeneous ($g = 0$) polymer solution is known as a function of bulk polymer concentration $\rho$ and temperature, the full concentration profile in the weak modulation limit $\lambda \ll 1$ can be easily calculated within the local density approximation (LDA)\textsuperscript{4}. Here we adopt the opposite point of view. We solve the inverse problem, and as explained in the next section, we extract the unknown e.o.s. from concentration profiles computed by MC simulations.

The simulations were carried out for the cubic lattice model defined earlier, in a simulation box of dimensions $l_x \times l_y \times l_z$ in units of $a$. The square base of area $A = l_x \times l_y$ was periodically repeated in the x and y directions; most runs were for $l_x = l_y = 100$. The vertical dimension $l_z$ was chosen such that for reasonable values of the gravitational coupling constant $\lambda_{cm}$, the polymer concentration at the highest altitude was negligible compared to the density at the bottom. Most simulations were carried out for $N = 1600$ polymers of length $L = 500$, using pivot, translation, reptation and configurational bias Monte-Carlo moves. Starting from an initial homogeneous configuration, the system was equilibrated until the downward drift of the overall CM of the system stopped. The profiles $\rho_m(z)$ and $\rho_{cm}(z)$ were then calculated from altitude histograms averaged over several million configurations (the statistics are of course $L$ times better for the monomer than the CM profiles.) For given $N$, $L$ and $\beta^*$, simulations were carried out for several gravitational couplings $\lambda_{cm}$. Local polymer concentrations $\rho_{cm}(z)$ are expressed relative to the bulk overlap concentration $\rho^* = 3/4\pi R_g^3$ where $R_g$ is chosen to be the temperature dependent radius of gyration at zero concentration. For a given $N$, higher values of $\lambda_{cm}$ are required to achieve higher polymer concentrations near the bottom of the simulation cell.

![FIG. 1: Monomer and centre of mass profiles for $N = 1600$ SAW polymer chains of length $L = 500$, shown for two values of the gravitational coupling constant $\lambda_{cm}$. (a) Profiles plotted on a linear scale. (b) The same profiles, but now plotted on a logarithmic scale. The dashed lines denote the barometric law \textsuperscript{4}, valid at low densities.](image)

![FIG. 2: Concentration profiles for $N=1600$ polymers of length $L=500$, at $\lambda_{cm}=0.842$, and $\beta^*=0$. The dashed line is the convoluted profiles obtained from equation \textsuperscript{6}. Examples of concentration profiles $\rho_m(z)$ and $\rho_{cm}(z)$ for $\beta^*=0$, a model for polymers in a good solvent, are shown in Figure \textsuperscript{1}. As expected, the profiles steepen when gravity, i.e. $\lambda_{cm}$ increases. The CM profiles exhibit a marked first adsorption layer at the bottom, which is much smaller in $\rho_m(z)$ profiles\textsuperscript{11}, but beyond that layer](image)
the two profiles coincide within the statistical errors of \( \rho_{cm}(z) \). The CM layering and preceding “correlation hole” in \( \rho_{cm}(z) \) (which is more clearly apparent in Figure 2) may be traced back to the effective wall/CB repulsion of entropic origin. The logarithmic plots of the profiles reveal linear behaviour at high altitudes with slopes of \(-1/\zeta_{cm}\), in agreement with the asymptotic barometric behaviour, thus providing a direct check on the convergence of the MC simulations. The close agreement between \( \rho_m(z) \) and \( \rho_{cm}(z) \) beyond the CM adsorption layer is of course a consequence of the polymer connectivity. The agreement may be quantified by assuming that the monomer/CB form factor (which describes the distribution of monomers around the CM in a polymer coil) is independent of the local polymer density and taken to be that appropriate for an ideal (Gaussian coil) polymer, namely:

\[
\omega_{CM}(r) = \frac{L}{R_g^3} e^{(-3r^2/2R_g^2)}
\]  

(5)

where \( r^2 = x^2 + y^2 + z^2 \) is the monomer/CB distance. The approximate relation between \( \rho_m(z) \) and \( \rho_{cm}(z) \) is then simply given by the following convolution:

\[
\rho_m(z) = \int_0^\infty \omega_{CM}(|z - z'|) \rho_{cm}(z')dz'.
\]  

(6)

III. FROM CONCENTRATION PROFILE TO OSMOTIC PRESSURE

In order to extract the osmotic e.o.s. from the concentration profiles of section 2, we proceed as in ref. For sufficiently slowly varying profiles, i.e. for sufficiently weak external field, the LDA holds and the Euler-Lagrange equation associated with the minimisation of the free energy functional with respect to the concentration profile \( \rho_{cm}(z) \) leads back to the macroscopic equation of hydrostatic equilibrium:

\[
\frac{dP(z)}{dz} = -Mg\rho_{cm}(z)
\]  

(7)

where \( P(z) \) is the local osmotic pressure at altitude \( z \). Integration of Eq. 7 yields:

\[
\beta P(z) = \int_z^\infty \rho_{cm}(z')dz'.
\]  

(8)

Thus \( P(z) \) and \( \rho_{cm}(z) \) are known as functions of altitude, with elimination of \( z \) leading to the desired e.o.s. of the bulk polymer solution \( P = P(\rho_{cm}, T) \). Note that the LDA approximation is not expected to be accurate near the hard wall where \( \rho_{cm}(z) \) varies rapidly within the first adsorption layer, so that the lower integration limit in Eq. 8 should be taken at \( z \gtrsim R_g \), i.e. beyond the peak of \( \rho_{cm}(z) \), where \( \rho_{cm} \) and \( \rho_m \) become indistinguishable.

Eq. 8 has an obvious intuitive interpretation: the system relaxes to a density \( \rho(z) \) such that the local pressure \( P(\rho(z)) \) counteracts the weight of the polymers above. Conversely, when the e.o.s. is known, Eq. 7 can be directly integrated to calculate the concentration profile. For example, in the semi-dilute regime, where the osmotic equation of state obeys the well known scaling law \( \beta P(\rho)/\rho \sim \gamma(\rho/\rho^*)^{1/(3\nu - 1)} \), with \( \gamma \) a dimensionless constant that depends on polymer details, the resulting concentration profile is given by:

\[
\rho^{sd}(z) = \rho_0\left(1 - \left(\frac{\rho_0}{\rho^*}\right)^{1/\nu}\frac{\lambda_{cm} g}{3\gamma \nu R_g}\frac{z}{3\gamma \nu R_g}\right)^{3\nu - 1}
\]  

(9)

where \( \rho_0 \) is the maximum polymer density, reached at \( z = 0 \), and follows from inverting the equation:

\[
P(\rho_0) = Mg n_s,
\]  

(10)

if the wall-induced layering at the bottom of the container is ignored. Eq. 9 provides an accurate fit to the density profile in the semi-dilute regime, but at higher altitude the analytic profile \( \rho(z) \) fails to cross over to the barometric law as illustrated in Figure 4.

We have carried out the above inversion procedure for \( \beta^* = 0, 0.1, 0.2, \) and 0.265 (\( \theta \) solvent). The resulting e.o.s. \( P(\rho, T) \) should be independent of the gravitational coupling used in the MC simulations provided \( \lambda_{cm} \) is not too large, i.e. the gravitational field is not too strong. This
was checked explicitly by carrying out the inversion procedure for two different values of $\lambda_{cm}$; the resulting e.o.s. always turned out to be practically identical, with very small differences (typically less than 1% over the whole concentration range) providing an estimate for the sum of systematic and statistical errors. However, if the applied gravitational field is too strong ($\lambda_{cm} \gtrsim 1$) the resulting profiles vary too rapidly with $z$ for LDA to remain accurate. This reflects itself in the failure of the resulting compressibility factor $Z=\beta P/\rho$ to go over to its ideal gas limit as $\rho \to 0$, as illustrated in the inset of Figure 4. Our results for $Z(\rho,T)$ are plotted in Figure 4 along four isotherms, and compared to the predictions of MC simulations of bulk polymer solutions based on the RWTI procedure. The agreement is seen to be excellent throughout. In fact some apparent discrepancies between our earlier data, based on the RWTI method and those obtained with the present method were resolved when contentious RWTI high concentration points were re-run with considerably improved statistics.

In an effort to detect possible finite size effects, we repeated some of the simulations with a four times larger base area. Any observed differences in the resulting data were within statistical noise.

A related consistency test of the LDA-based inversion procedure is provided by the scale invariance property of the LDA concentration profile, according to which, along any isotherm, the re-scaled profiles $\rho_{cm}(z/\zeta_{cm})$ or $\rho_{cm}(z/\zeta_{cm})$ depend only on the dimensionless product $n_{a}\lambda_{cm}a^{2}$. This means that as long as LDA applies, the re-scaled profiles should be identical if the number of polymers is divided by a given factor, provided the gravitational coupling $\lambda_{c}$ is multiplied by the same factor. An illustration of this scale invariance is shown in Figure 5. The equation-of-state extracted from the density profiles are in perfect agreement. Deviations from scale invariance would signal the breakdown of the LDA assumption, providing a diagnostic for the consistency of the procedure.

FIG. 4: Concentration profiles, compared to the analytic form from equation (8). Note the excellent agreement in the semi-dilute regime and the expected disagreement in the dilute regime where the barometric law takes over.

FIG. 5: Equation of state isotherms calculated by inversion of concentration profiles (lines) compared to earlier simulations using the RWTI method (symbols). Whereas the former need about 50 independent simulations per isotherm, the present method requires only one simulation per isotherm. The solid lines are for runs $\lambda_{cm} < 1$, the dotted $\beta^{*} = 0$ line is at $\lambda_{cm} = 4.21$ and the dashed $\beta^{*} = 0.1$ line is at $\lambda_{cm} = 1.97$.

FIG. 6: (a) Three different concentration profiles from simulations with different numbers of polymers and gravitational strengths, but with the product $n_{a}\lambda_{cm}a^{2}$ held constant. Note that the equations of state (b) generated from the concentration profiles are practically identical, as are the concentration profiles (c) when scaled by the gravitational length.

IV. EFFICIENCY OF INVERSION METHOD

By inverting the concentration profile in an imposed external field, we measure the full equation of state in a single simulation. This contrasts with the RWTI method, where for each value of $\rho$ a number of separate simulations are needed to perform thermodynamic integration. For example, when we calculated the e.o.s. of $L = 500$ polymers as a function of solvent quality in 12.
using the RWTI method, we needed about 5 simulations for each of the 10 statepoints along each isotherm. In the current work, we used only 1 simulation of similar size to each of the 50 simulations per isotherm carried out in13. As demonstrated in Fig. 5, the results are of comparable accuracy, but achieved with considerably less CPU time.

For a given \( \lambda _{cm} \) and number of polymers \( N \), the maximum density achieved under an external field can be estimated from Eq. (10). If the e.o.s. scales as \( \beta P(\rho) R_g^3 \sim (\rho/\rho^*)^\alpha \), then the maximum density \( \rho_0 \) scales as

\[
\rho_0 / \rho^* \propto \left( N \lambda _{cm} A/(R_g)^2 \right)^{1/2}
\]

Larger \( \rho_0 \) can be achieved by increasing \( \lambda _{cm} \), although this is constrained by the LDA criterion, or by increasing \( N \). For semi-dilute polymers \( \alpha \approx 2.3 \) in good solvent and \( \alpha \approx 3 \) in a theta solvent12,13. To double \( \rho_0 \), the number of polymers \( N \) must be increased by a factor five for the former and eight for the latter solvent quality. On the other hand, for the RWTI method, doubling \( \rho_0 \) simply means doubling \( N \), irrespective of \( \alpha \). Of course to calculate an isotherm, this may also imply doubling the number of different \( \rho \) at which independent simulations must be performed. Furthermore, as pointed out by Stukan et al., finite size effects become more severe for larger polymer concentrations. As an example, they calculated the pressure of bond-fluctuation model polymers of length \( L = 20 \), using a box with a width \( l_z = l_y = 20 \) and varying the distance \( l_z \) between the two hard walls used for thermodynamic integration. At the rather high monomer packing fraction \( \phi = NL/V = 0.5 \) they used, the influence of the two hard walls was noticeable even up to distances of \( l_z = 160 \), where the RWTI method overestimated the pressure by about 3%. We performed comparable simulations for \( L = 20 \) SAW polymers at the same melt-like density. In a gravitational field we were able to reproduce the \( l_z \rightarrow \infty \) results of the RWTI method, but with the number of polymers \( N \) which the latter method would need for a size \( l_z = 20 \) box only. Thus the less favourable scaling of our external field method with \( N \) is partially offset by less severe finite size effects, allowing significantly fewer particles to be used.

V. CONCLUSIONS

We have shown that the hydrostatic equilibrium method, which allows the e.o.s. of polymer solutions to be computed along an isotherm in a single simulation, which determines the polymer concentration profiles in a gravitational field, is both accurate and efficient. It provides the osmotic pressure as a function of concentration with a computational effort which is a small fraction (typically under 5%) of that required using the RWTI method, since the latter requires a series of MC simulations at different densities, and several independent simulations at each density are needed for thermodynamic integration. Moreover the finite size problems which can affect the RWTI method are insignificant in the present method, mainly because the simulated system is “open” at high altitudes, i.e. essentially extends to infinity in the \( z \)-direction. The hydrostatic equilibrium method applies equally well to on and off-lattice models of interacting polymers. The only apparent limitation of the method is that a large gravitational field, i.e. large values of \( \lambda _{cm} \) are required to achieve large densities. For too large \( \lambda _{cm} \) the underlying LDA becomes inaccurate, and the inversion procedure can lead to erroneous results. Hence the method is expected to be well adapted to dilute and semi-dilute solutions, while to reach polymer densities typical of polymers melts, several runs with increasing values of \( \lambda _{cm} \) are needed to cover successive and partially overlapping ranges of \( \rho/\rho^* \).

We plan to extend the present method to determine the osmotic e.o.s. of more complex polymeric systems, including block copolymer solutions and melts.
