The Cooper pair shuttle is a simple model system that combines features of coherent and incoherent transport. We evaluate the full counting statistics (FCS) of charge transfer via the shuttle in the incoherent regime. We describe two limiting cases when the FCS allows for classical interpretation. Generally, the classical interpretation fails yielding negative and imaginary "probabilities". This signals that superconducting coherence survives even in incoherent regime. We evaluate the current noise in some detail.

PACS numbers:

The Josephson effect\(^{1}\) consists in coherent Cooper pair transfer through a tunnel junction between two bulk superconductors. It results in a dissipationless current present as a ground state property of the system. This is in contrast to dissipative electron transfer in normal conductors. In latter case, it is possible to evaluate the full counting statistics (FCS) of charge transfers\(^{2}\) in terms of classical probabilities. Thereby, the transport properties are fully understood and characterized: one can predict not only the average current, but also the current noise and all higher moments of the current distribution function.

One can also access the FCS of a superconducting Josephson junction\(^{3}\). Due to gauge symmetry breaking in the superconducting state, this FCS can not be interpreted in classical terms yielding negative "probabilities". The use and the interpretation of the FCS in this case is that it determines the quantum evolution of the detector that measures the current.

A recent proposal puts forward an interesting way to transfer Cooper pairs: to shuttle them (controllably) between the superconducting electrodes\(^{4}\). Although the original proposal puts emphasis on mechanical degrees of freedom, a Cooper pair shuttle is essentially a superconducting single electron transistor (SSET) with variable time-dependent Josephson coupling to the superconducting leads\(^{5}\). The Coulomb island of this SSET is brought in contact with one electrode at a time, the electrode contacted being periodically altered.

It is interesting that the supercurrent between the leads is achieved as a result of a non-equilibrium driven process, generally accompanied by dissipation. The coherence of Cooper pairs transferred is determined by the coherence of different charge states in the island, this being mostly affected by fluctuations of the gate voltage\(^{6}\). The transport results from the interplay between the coherent Josephson coupling and decoherence effects. This is why the Cooper pair shuttle presents a model to bridge between the limits of coherent and incoherent transport. The model is simple indeed, one can restrict the consideration to just two quantum states.

Thus motivated, we have analyzed the FCS of the Cooper pair shuttle in the most interesting incoherent regime, where no net supercurrent is shuttled. The regime is achieved in the limit when the voltage fluctuations are classical. If the fluctuations come from an environment, this implies that the temperature of the environment exceeds the relevant energy scales of the shuttle. Naively, from the absence of the net current one would conclude that no charge transfer occurs in the system. However, transfers do occur, the current is zero only in average, and the FCS presents a convenient way to reveal this circumstance. This stipulates the understanding of transport properties of the shuttle and, generally, the interplay between the coherent and incoherent transport.

The results are as follows. If the period of the shuttling is sufficiently long for decoherence to be accomplished, the FCS can be interpreted in terms of classical elementary events: Cooper pair transfers. During the shuttling cycle, either no transfer takes place or a pair is transferred in either direction. There is an apparent similarity with the FCS of the pumping in normal systems studied in\(^{7,8}\). The FCS in the opposite limit of short cycles allows for alternative classical interpretation in terms of a superconducting current randomly switching between two opposite values.

In the general intermediate situation, the FCS can not be interpreted in classical terms. An attempt to evaluate the probabilities per cycle yields negative and even imaginary values. This is a clear signature of the fact that the superconducting coherence survives strong dephasing although this coherence does not manifest itself in net superconducting current. It was recently explained\(^{9,10}\) that any FCS can be characterized directly so one would not have to measure higher cumulants of the current noise one by one. However, the immediate physical value measured would also depend on the properties of the concrete detector. This is also a way to experimentally observe the FCS of the Cooper pair shuttle.

The system of interest is presented schematically in Fig.\(^{1}\). It consists of a Cooper pair box, or Coulomb island, connected with Josephson junctions to the super-
conducting leads $L$ and $R$. Conventionally, we assume the separation of energy scales, $\Delta \gg E_C \gg E_J$, $\Delta$ being the superconducting energy gap, $E_C$ being the charging energy of the box, and $E_J$ being a typical Josephson junction energy. Under these conditions quasiparticles degrees of freedom are not involved in the system’s dynamics. In addition, the gate voltage is chosen to bring two charge states of the box, say, $|0\rangle$ and $|1\rangle$, to the degeneracy point. Under these assumption, we can restrict the consideration to these two states only and the shuttle is described by the Hamiltonian

$$\hat{H}(t) = 2\varepsilon V(t)\sigma_z - \sum_{b=L,R} \frac{E_J^{(b)}(t)}{2} (e^{i\phi_b} \sigma_+ + \sigma_- e^{-i\phi_b}),$$

(1)

which we write in terms of $2 \times 2$ Pauli matrices $\sigma_z$, $\sigma_\pm \equiv (\sigma_x \pm i\sigma_y)/2$ in the space spanned by $|0\rangle, |1\rangle$. $V(t)$ is proportional to the deviation of the gate voltage from the value corresponding to the degeneracy point and $\phi_b$, $\phi_L$ are the phases of the macroscopic superconductors. Only $\phi = \phi_R - \phi_L$ is a physical quantity which we will assume to be fixed; this can be obtained by closing the circuit endpoints in a loop pierced by a constant magnetic flux. $E_J^{(L,R)}(t)$ are time-dependent Josephson energies of left and right junction. For the sake of concreteness, we assume stepwise periodic variation of both Josephson energies with time as shown in the lower panel of Fig. 1. Each lead is contacted during time interval $t_j$ and the box contacts no lead during time interval $t_C$ for each period $T = 2(t_j + t_C)$. We call $t_j$ and $t_C$ the “Josephson contact” and the “free evolution” time respectively. An idea to realize the required time dependence in Josephson coupling by means of an experimentally realizable SQUIDs based device has been proposed in Ref.\textsuperscript{7}.

We assume $V(t)$ to be a classical stochastic variable with white noise statistics, \langle V(t) \rangle_{\text{stoc.}} = V_0$ and $\langle V(t)V(t') \rangle_{\text{stoc.}} = \gamma \hbar^2/(2\varepsilon^2)\delta(t-t')$, where $\langle \cdot \rangle_{\text{stoc.}}$ defines the average over the fluctuations. Thus defined, $\gamma$ is just the inverse decoherence time of the two charge states. If we neglected the fluctuations, the time evolution of the system would be fully coherent governed by the coherent part of the Hamiltonian $\hat{H}_c \equiv \langle \hat{H} \rangle_{\text{stoc.}}$. In this case the quantum state of the central grain would acquire dynamical phases $2\theta = E_J t_j/h$ during the Josephson contact times and $2\chi = 2\varepsilon V_0 t_C/h$ during the free evolution times (we assume that $V_0$ is only present during both intervals of the free evolution time).

With fluctuations, the shuttle will be described by a $2 \times 2$ density matrix that obeys the following Bloch equation:

$$\frac{\partial \hat{\rho}}{\partial t} = -\frac{i}{\hbar} \left(\hat{H}_c(t)\hat{\rho} - \hat{\rho}\hat{H}_c(t)\right) - 2\gamma (\hat{\rho} - \sigma_z \hat{\rho} \sigma_z).$$

(2)

The only stationary solution of this equation is quite trivial: $\hat{\rho} \propto 1$, this corresponds to the absence of the averaged superconducting current. Therefore, the shuttle operates in incoherent regime. This is a combined effect of the decoherence term and Josephson coupling. In the absence of Josephson coupling, voltage fluctuations cannot cause transitions between the charge states so no relaxation takes place. With Josephson coupling, the voltage fluctuations cause transitions between the stationary states separated by energy $2E_J$ at $V_0 = 0$. Classical voltage fluctuations result in equal transition rates with increasing and decreasing energy. In fact, the ratio of these rates is given by Boltzman factor $\exp(2E_J/T_b)$, $T_b$ being the temperature of the environment producing the fluctuations. As shown in Ref.\textsuperscript{7}, proper account of this factor leads to anisotropic $\hat{\rho} \neq 1$ and to the net supercurrent vanishing at $T_b \gg E_J$. This defines the incoherent regime under consideration.

Let us evaluate the FCS. One starts with the assumption that a transport process can be characterized by the probabilities $P_\tau(N)$ of $N$ electrons transferred through the contact in a time interval $\tau$ and attempts to compute the characteristic function of this probability distribution defined as:

$$e^{-\Phi(\lambda,\tau)} = \sum_{N} P_\tau(N) e^{i\lambda N}.$$  

(3)

The general quantum expression for this function can be obtained by coupling the system to a detector for a measuring time $\tau$ and interpreting the detector readout in terms of charge transfer.\textsuperscript{5} The FCS in this case is defined as integral kernel that relates the initial and final density matrices of the detector, and reads

$$e^{-\Phi(\lambda,\tau)} = \text{Tr} \left[ \hat{U}_{\lambda}(\tau,0) \hat{\rho}(0) \hat{U}_{\lambda}^\dagger(\tau,0) \right],$$  

(4)

Figure 1: Upper panel. Cooper pair shuttle consists of a Cooper pair box coupled to superconducting leads through Josephson junctions. Two charge states are tuned to degeneracy point by the gate voltage. Lower panel. The specific time dependence of $E_J^{(R,L)}$ within a single period $T$ provides the shuttling.
where \( \mathcal{U}_\lambda(\tau, 0) = \overline{T} e^{-\int_0^\tau \hat{H}_\lambda(s) \, ds} \) is the unitary evolution operator corresponding to the modified Hamiltonian \( \hat{H}_\lambda = \hat{H} + \lambda I / e \), \( \overline{T} \) being the operator of the electric current. Two such operators provide non-unitary evolution of the initial density matrix of the system \( \hat{\rho}(0) \) into \( \hat{\rho}'(\tau) \).

For our shuttle model, the implementation of this general scheme is especially simple since the density matrix is just \( 2 \times 2 \) matrix. Following Ref. [4], we also gauge the counting field \( \lambda \) to the left electrode, this yields \( \hat{H}_\lambda = \hat{H}_c(\phi_L \rightarrow \phi_L + \lambda) \). We derive an equation for \( \hat{\rho}' \) that looks very similar to the Bloch equation \( (\lambda) \)

\[
\frac{\partial \hat{\rho}'}{\partial t} = -\frac{i}{\hbar} \left( \hat{H}_\lambda \hat{\rho}' - \hat{\rho}' \hat{H}_\lambda \right) - 2 \gamma (\hat{\rho}' - \sigma_z \hat{\rho}' \sigma_z). \tag{5}
\]

The difference is that the Hamiltonians governing evolution of “bra”’s and “ket”’s differ by opposite shifts.

This system of 4 linear equations can be solved with initial conditions \( \hat{\rho}'(t_0) \) to obtain a linear map \( M \) that gives \( \hat{\rho}' \) after a cycle, \( \hat{\rho}'(t_0 + T) = M \hat{\rho}'(t_0) \). All four eigenvalues \( \mu_i \) of \( M \) satisfy the condition \( |\mu_i| \in [0, 1] \). Since we study statistics of low-frequency fluctuations, \( T \gg T \) by definition. Therefore, the FCS is determined by the eigenvalue with the greatest magnitude,

\[
e^{-\xi(\lambda, \tau)} = \bar{\mu}(\lambda)^T / T, \quad \text{where} \quad 1 - \bar{\mu} = \min_{i=1, \ldots, 4} \left( 1 - \mu_i \right). \tag{6}
\]

This is in accordance with the method and the result[2] for FCS of charge transport described by a master equation.

The most transparent way to present the FCS is to define the probabilities \( p_N \) to transfer \( N \) electrons per cycle, as it has been done in Ref. [3] to characterize the pumping of normal electrons, \( p_N = \frac{1}{2\pi} \int_{-\pi}^{\pi} d\lambda \rho e^{-iN\lambda} \bar{\mu}(\lambda) \).

The FCS in the limit considered is always an even function of \( \lambda \), so that the pairs are shuttled in either direction with equal probability, \( p_N = p_{-N} \).

We analyze the FCS in several limiting cases. First we consider the limit of long periods \( 1/t_C, 1/t_J \ll \gamma \ll E_I / \hbar \). This is in fact an adiabatic limit since the relaxation and decoherence are fully developed within each time interval \( t_C, t_J \). In this case, \( \bar{\mu}(\lambda) = \cos^2 \lambda \rightarrow p_0 = \frac{1}{2}; p_{\pm 2} = \frac{1}{4} \),

so that, each shuttling between the superconductors transfers either one Cooper pair or none, this occurs with equal probabilities. The pair is transferred with equal probabilities in either direction. It is interesting to note that this simple result is quite general and relays on neither the periodicity of shuttling nor the concrete time dependence of \( E_I(t) \) provided the adiabaticity is preserved. The shuttle may even return (several times) to the same superconducting terminal before contacting the opposite one: the charge transfer is in this case associated with two trips between the opposite terminals.

Leading corrections to adiabatic FCS are exponentially small, \( \approx \exp(-2\gamma T) \).

Another interesting limit is that of small Josephson couplings \( E_J \ll \hbar \gamma \) and sufficiently long cycles \( 1/t_C, 1/t_J \ll E_I \). In this case, the charge relaxation time \( \gamma \ll \hbar^2 / E_I^2 \) may be long, exceeding both decoherence time and cycle duration. The relevant parameter \( \exp(-t_J E_I^2 / (\hbar \gamma^2)) \equiv f \) determines the efficiency of the charge relaxation during a cycle. The FCS becomes more complicated, for \( f \approx 1 \) it is given by

\[
\bar{\mu}(\lambda) = \frac{1}{2} \left( 1 + f^2 \right) \cos^2 \lambda + f \sin^2 \lambda (1 - f^2) \times \\
\times \frac{1}{2} \left( \cos^2 \lambda - \left( \frac{1 - f}{1 + f} \right)^2 \sin^2 \lambda \right). \tag{9}
\]

and, generally speaking, all \( p_N \neq 0 \). This is because the charge cannot completely relax during a cycle providing “memory effect” so that charge transfers in different cycles are not independent and elementary event of charge transfer can encompass several cycles. Still, probabilities remain positively defined owing to the fact that in the limit of long cycles the FCS depends neither on the superconducting phase \( \phi \) nor on dynamical phases \( \theta, \chi \).

Beyond this limit, the FCS does depend on \( \phi \). As mentioned in Ref. [3], the classical interpretation in this case may fail and one can not assure that \( p_\phi \) positive or even real. Indeed, we have found this in numerical calculations at \( \gamma T \approx 1 \) (Fig. 2). This clearly signals that the superconducting coherence remains in the system although the decoherence completely destroys the average supercurrent.

This becomes evident when analyzing the opposite limiting case of very short cycles \( \gamma T \ll 1 \). In this case, the cumulants of the current are contributed by FCS at \( \lambda \approx \gamma T \ll 1 \). In this region, the FCS reads

\[
\bar{\mu} - 1 \approx \gamma_0 + \sqrt{\left( \frac{\gamma_0}{2} \right)^2 - \left( \frac{\lambda I}{e} \right)^2}, \tag{10}
\]

where \( I_s \) is the superconducting current in the absence of decoherence \( \gamma = 0 \) and \( \gamma_0 \) is the relaxation time in the limit \( \gamma \rightarrow 0 \):

\[
I_s = \frac{2e}{T} \frac{d\phi}{d\phi}, \quad \gamma_0 = \frac{\gamma}{\sin^2 \alpha} \left( \frac{t_J}{T} P_J + \frac{t_C}{T} P_C \right)
\]

where \( \alpha \equiv \arccos(\cos^2 \theta \cos 2\chi - \sin^2 \theta \cos \phi) \) and \( P_J, P_C \) are always positive polynomial functions in \( \sin(\cdot) \) and \( \cos(\cdot) \) of the phases \( \phi, \chi, \theta \): \( P_C(\phi, \chi, \theta) = 2 \sin^2(2\theta) (1 + \cos \phi \cos(2\chi)) \) and \( P_J(\phi, \chi, \theta) = 2 (1 + \sin^2 \theta \cos \phi \cos(2\chi)) + \cos(2\theta) (\cos^2 \theta \cos^2(2\chi) - \sin^2 \theta \cos^2 \phi) \)

FCS of this type corresponds to a supercurrent randomly switching at time scale \( 1/\gamma_0 \gg T \) between the opposite values \( \pm I_s \), so that the coherence is preserved at
Figure 2: Fourier components, $p_N$, with $N = 0, 2, 4$ of $\mu(\lambda)$ plotted versus $E_J/\gamma$. Each line is labeled by the corresponding value of $N$. Adiabatic regime (a): $\gamma t_J = 5$; positive probabilities. General situation (b-c): $\gamma t_J = 0.9$; $p_N$ can be negative and even imaginary. Other parameters are fixed to $t_J = t_C$, $\chi = \pi/5$, $\phi = \pi/4$ for all plots.

Low-frequency noise $S(\omega = 0)$ is obtained directly from the definition of the FCS, $S(0) = -e^2/T \lim_{\lambda \to 0} \partial^2(\bar{\mu}/\partial \lambda^2)$. From the Eq. [9] we obtain $S(0) = 2e^2/T \times (1-f)/(1+f)$ in the adiabatic limit. The noise is enhanced in the opposite limit of short cycles, $S(0) = 2I_s^2/\gamma \gg e^2/T$ and is sensitive to all dynamical phases. The numerical results in the intermediate regime (Fig. 3) show in addition a quasi-oscillatory dependence on the dynamical phase $\theta$.
