Key words: holography, thermomagnetic recording, amorphous magnetic materials, tiling optical addressing, three-dimensional (3D) display

A holographic display is a realistic three-dimensional (3D) display because it produces an exact copy of the wave front of scattered light from 3D objects. It demands a wide viewing angle for 3D visualization. However, the viewing angle of holographic displays based on conventional spatial light modulators (SLMs) is less than 3°. The pixel pitch of conventional SLMs is in the range of 10–100 μm. Recently, we have fabricated a two-dimensional pixel array with sub-micrometer-scale pixels for a wide-viewing-angle holographic display. The pixels were driven by a thermomagnetic recording system using a metal mask that formed fringe patterns. However, the reconstructions of 3D images were fixed. In this paper, we describe the results of the reconstruction of any 3D images using a tilling optical addressing method. The tilling optical method reproduced any magnetic fringe pattern with $5 \times 10^7$ pixels for the reconstruction of 3D images.

1. Introduction

A holographic display is expected to produce a realistic three-dimensional (3D) display without special glasses because it produces an exact copy of the wave front of scattered light from an object.(1–8) In general, a 3D holographic display demands wide viewing angles for 3D visualization.

However, the viewing angle $\theta$ of holographic displays based on conventional spatial light modulators (SLMs) is less than 3° in accordance with eq. (1)\(^{(9)}\):

$$\theta = \sin^{-1}(\lambda/2p),$$

(1)

†Corresponding author: e-mail: takagi@ee.tut.ac.jp
where \( \lambda \) is the wavelength of the reference light, and \( p \) is the pixel pitch of the SLMs. The \( p \) of conventional SLMs [liquid crystal devices (LCDs)\(^{10}\) and digital micromirror devices (DMDs)\(^{11}\)] is in the range of 10–100 \( \mu \)m. Downsizing the pixel sizes of SLMs for a wide viewing angle is limited by the driving current lines and other limitations of the fabrication process. Therefore, we developed a holographic display with a wide viewing angle using magnetic pixels (3D-MOSLM).\(^{12}\) To form magnetic pixels, we used a thermomagnetic recording system\(^{13-16}\) to control the direction of magnetization by the optical addressing method. This method has the advantage that it is possible to fabricate sub-micrometer-scale pixel arrays without a driving line and a pixel structure on the magnetic medium.

We have reported that the 3D image can be reconstructed with a wide viewing angle from sub-micrometer-scale magnetic pixels. To write many magnetic submicron-size pixels on the array, a frame-written laser system was used; the beam from a pulsed laser passed a two-dimensional (2D) hologram metal pattern positioned by a three-axis positioning stage. The magnetic pixel was formed with dimensions of 800 \( \times \) 900 nm\(^2\), and the viewing angle of the reconstructed image was more than 30°. However, for demonstrating the principle, the reconstructed 3D images were fixed, because this system used a metal mask with a fixed 2D hologram pattern. Therefore, the display could not change the 3D images because the metal mask was used to write the hologram pattern.

In this paper, we describe the results of forming magnetic pixel patterns using the tiling optical addressing method. In this method, a part of the fringe images is shown on DMDs and transfers the fringe pattern to a magnetic film. This method can enlarge the area of a 2D hologram pattern when the writing position is adjusted by an \( x \)-\( y \)-\( z \) stage.

2. Experiments

First, the magnetic film was an amorphous \( \text{Tb}_78\text{Fe}_{22} \) (\( a \)-TbFe) film (100 nm thick) with perpendicular magnetization\(^{17-19}\) fabricated on a glass substrate by ion beam sputtering. The magnetization intensity became approximately zero at the Curie temperature of 120 °C. As anti-oxidizing films, 20-nm-thick SiN films were fabricated on a glass substrate and those 50 nm thick were fabricated on the \( \text{Tb}_{22}\text{Fe}_{78} \) film. These SiN films produced a localized mode in \( a \)-TbFe to provide a large rotation angle.\(^{20}\) The magnetic media structure was designed by the matrix approach method\(^{21}\) for localized light in magnetic media. The Kerr rotation angle was 0.7°, the Faraday rotation angle was 1.3°, the reflectivity was 8.8%, and the transmissivity was 0.18% at 532 nm.

Second, to control the hologram pattern, we fabricated an optical system using the tiling optical addressing method, which consists of a pulsed laser, a DMD, objective lenses, an \( x \)-\( y \)-\( z \) stage, and magnetic media. The optical system for the tiling optical addressing method is shown in Fig. 1. A DMD (Discovery 1100, 1024 \( \times \) 768 pixels, maximum driving speed of 22 kHz/frame) was used for the tiling optical addressing method. The DMD showed part of the 2D hologram pattern. To write the hologram, a pulsed laser (Nd:YAG laser) operating at 355 nm with a pulse width of approximately 10 ns and a frequency of 10 Hz was used. The optical parametric oscillator was a MOPO-SL-1P (Spectra-Physics) to control wavelength. The laser was used to illuminate the
DMD. The DMD displayed the image of a 2D hologram pattern. The laser power ranged from 10 to 40 mW in 10 mW steps to fabricate the magnetic pixels. To expand the hologram area, the writing area was moved with an x-y-z stage (the maximum moving distance was 20 mm with 1 μm resolution).

The 2D hologram pattern on the DMD was transferred to the magnetic film by two object lenses whose focal lengths are 100 and 10 mm. The pixel size was decreased to one-tenth of the original size of the DMD. Therefore, the pixel size of the DMD was 13.6 μm, and the magnetic pixel size was 1.36 μm. The viewing angle of the 3D images was about 23° in accordance with eq. (1).

To demonstrate the 3D-MOSLM, we calculated a 2D hologram pattern of a 3D object by the computer-generated hologram method. The 2D hologram pattern was calculated by the half-zone plate method. This method has an advantages, that is, the calculation time is half that of the full-zone plate method and the reconstructed image can be cut from a conjugate image. The 3D object was a 3D framed-cube image, the length of a side of which was 3.74 mm, the length of a side of the hologram area on the magnetic medium was 14 mm, and the distance from the magnetic medium was 20 mm (Fig. 2). There were approximately 10000 × 10000 pixels in the hologram area.

![Fig. 1. (Color online) Optical system for the tilling optical addressing method.](image1)

![Fig. 2. (Color online) An original 3D image for the computer-generated hologram.](image2)
We measured the characteristics of the holographic display of the 3D-MOSLM with a submicron magnetic pixel array. The optical system for object visualization consisted of a CW laser (λ = 532 nm, 8.6 mW/cm²) as the reference beam, a polarizer, the 3D-MOSLM with a magnetic hologram pattern, an analyzer, and a charge-coupled device (CCD) for the detection of 3D images. The polarization direction of the reconstructed image from the magnetic medium was rotated 90° from the incident light. Therefore, this 3D-MOSLM had an adequate ratio of intensity of 1st diffracted light to intensity of 0th transmitted light. The transmissivity of the polarizer and analyzer was about 35% and the extinction ratio was from 10⁻⁴ to 10⁻⁵. The diffraction ratio was 18% at 90°. This optical system operated in transmission mode. Therefore, the reconstructed image was represented as transmitted light from the 3D-MOSLM.

3. Results

Figure 3 shows the mesh pattern on the DMD and the mesh pattern of the magnetic pixels produced on the magnetic medium by the tiling optical addressing method. A square width was 136 μm on the DMD, and a square was 10 × 10 pixels in Fig. 3(a). Figure 3(b) shows the magnetic pixel array when the laser power was 30 mW. The hologram pattern of light on the DMD could be reduced to one-tenth its size and transferred to the magnetic film. In this result, a pixel 13.6 μm in size on the DMD was reduced to 1.36 μm on the magnetic pixels by objective lenses.

We wrote the magnetic pixel array of a 2D hologram pattern obtained by the computer-generated hologram. Figure 4(a) is a part of the computer-generated hologram pattern that was displayed on the DMD. This image size was reduced to one-tenth of the original by the tiling optical addressing system and was transferred to the magnetic film. Figure 4(b) shows the transferred 2D hologram pattern. The 2D hologram pattern on the DMD was accurately transferred by reducing its size on the magnetic film.

![Fig. 3. Mesh pattern of magnetic pixels: (a) hologram pattern on the DMD and (b) magnetic pixel pattern on magnetic media.](image-url)
Fig. 4. Fringe pattern of 3D object: (a) part of the hologram image on the DMD and (b) magnetic pixel image of the same area.

Fig. 5. (Color online) Reconstructed image of a 3D object: (a) viewing angle was 5° from the left side and (b) viewing angle was 0°.

Figure 5 shows the reconstructed holographic 3D image. The 3D image could be reconstructed by transferring a 2D hologram pattern when a reference light illuminated the magnetic pixel array. The reconstructed images showed the same pattern that was designed by the computer. These results show that the 3D-MOSLM can represent a flexible 3D image.

4. Conclusions

A holographic display represents the image of a real 3D object. We have developed a wide-viewing-angle 3D-MOSLM. In this paper, we described the results of forming magnetic pixel patterns using the tilling optical addressing method. This optical system has a DMD to display any 2D hologram pattern, objective lenses to reduce the pixel size, and a pulsed laser for thermomagnetic recording. The magnetic pixel size was about 1.36 μm. This optical method could represent any 3D image.
