ABSTRACT

In this paper, we study the “standardized candle method” using a sample of 37 nearby (redshift \( z < 0.06 \)) Type II plateau supernovae having \( BVRI \) photometry and optical spectroscopy. An analytic procedure is implemented to fit light curves, color curves, and velocity curves. We find that the \( \overline{V}−I \) color toward the end of the plateau can be used to estimate the host-galaxy reddening with a precision of \( σ(A_V) = 0.2 \) mag. The correlation between plateau luminosity and expansion velocity previously reported in the literature is recovered. Using this relation and assuming a standard reddening law \( (R_V = 3.1) \), we obtain Hubble diagrams (HDs) in the \( BVI \) bands with dispersions of \( ∼0.4 \) mag. Allowing \( R_V \) to vary and minimizing the spread in the HDs, we obtain a dispersion range of \( 0.25−0.30 \) mag, which implies that these objects can deliver relative distances with precisions of \( 12%−14% \). The resulting best-fit value of \( R_V \) is \( 1.4 ± 0.1 \).

Key words: distance scale – galaxies: distances and redshifts – supernovae: general

1. INTRODUCTION

Core-collapse supernovae (CCSNe) are in general closely associated with star-forming regions in late-type galaxies (e.g., Anderson & James 2008). Therefore, they have been attributed to stars born with initial mass \( > 8 \) \( M_⊙ \) that undergo the collapse of their iron cores after a few million years of evolution and the subsequent ejection of their envelopes (e.g., Burrows 2000). According to theoretical studies, these SNe leave a compact object as a remnant, either a neutron star or a black hole (Baade & Zwicky 1934; Arnett 1996; Janka et al. 2007).

Among CCSNe, we can observationally distinguish those with prominent hydrogen lines in their spectra (dubbed Type II; Minkowski 1941), those with no H but strong He lines (Type Ib), and those lacking H or He lines (Type Ic); see Filippenko (1997), and references therein. Although all of these objects are thought to share largely the same explosion mechanism, their different observational properties are explained in terms of how much of their H-rich and He-rich envelopes were retained prior to explosion. When the star explodes with a significant fraction of its hydrogen envelope intact, it should display an H-rich spectrum and a light curve characterized by an optically thick phase of \( ∼100 \) days of nearly constant luminosity called a “plateau,” which comes to an end at the point when all of the hydrogen in the envelope has recombined. This phase is followed by a sudden drop of 2–3 mag and thereafter by an exponential decay in luminosity caused by the radioactive decay of \(^{56}\)Co into \(^{56}\)Fe (e.g., Nadyozhin 2003; Utrobin 2007). Nearly 50% of all CCSNe belong to this class of “Type II plateau” SNe (SNe IIP; Cappellaro et al. 1999; Botticella et al. 2008).

A decade ago, the standardized luminosities of Type Ia SNe (e.g., Phillips 1993; Hamuy et al. 1996; Riess et al. 1996; Phillips et al. 1999) led to the construction of Hubble diagrams (HDs) at redshifts \( z = 0−0.1 \) with dispersions of only \( ∼0.15 \) mag, which opened up the opportunity of measuring the expected deceleration of the universe. At the end of the millennium, Riess et al. (1998) and Perlmutter et al. (1999) reported independent observations of high-redshift SNe (\( z = 0.1−0.5 \)) which permitted the measurement of the expansion history of the universe over \( ∼5 \) Gyr of look-back time. Contrary to expectations, these observations revealed that the universe is currently described by an accelerated expansion. The discovery of cosmic acceleration, which was subsequently confirmed by additional studies of SNe Ia (e.g., Astier et al. 2006; Wood-Vasey et al. 2007; Hicken et al. 2009; Freedman et al. 2009), implies the possible existence of a cosmological constant, a concept initially introduced by Albert Einstein at the beginning of the 20th century. Its origin is still a mystery, and there are many other possible candidates for the repulsive “dark energy” that permeates the universe (see Frieman et al. 2008 for a review).

The acceleration of the universe has now been indirectly confirmed by other independent experiments such as the Wilkinson Microwave Anisotropy Probe (Spergel et al. 2007; Bennett et al. 2003) and baryon acoustic oscillations (Blake & Glazebrook 2003; Seo & Eisenstein 2003), as well as more directly with the integrated Sachs–Wolfe effect (e.g., Boughn & Crittenden 2004; Fosalba et al. 2003) and X-ray observations of clusters of galaxies (Allen et al. 2008), but it is nevertheless important to obtain additional independent confirmation of the SN Ia results. Although SNe IIP are not as luminous and uniform as SNe Ia, Hamuy & Pinto (2002) showed that the luminosities of the former can be standardized to levels of 0.4 and 0.3 mag in the \( V \) and \( I \) bands, respectively. This finding converted these objects into precise distance indicators and potentially into useful tools to measure cosmological parameters. Moreover, SNe IIP would be more abundant at high redshift than SNe Ia, since the star
formation rate increases with redshift until \( z \approx 2.5 \) (see Hopkins & Beacom 2006, and references therein).

Type IIP SNe provide two routes to distance determinations. First, the “expanding photosphere method” (EPM; Kirshner & Kwan 1974) is a technique based on theoretical models that is independent of the extragalactic distance scale (Eastman et al. 1996; Dessart & Hillier 2005). In EPM the spectral energy distribution of the SN is approximated as a black body, and atmosphere models permit one to correct the dilution of the photospheric flux relative to a Planck function due to electron scattering. From a detailed analysis of the properties of the SN atmospheres, Eastman et al. (1996) showed that the most important variable in determining the dilution factors is the effective temperature. This result permits one to determine the photospheric angular radius of the SN from a measurement of the color temperature and infer the distance from the expansion velocity measured from spectral lines, without the need to craft specific models for each SN. This method can achieve dispersions of 0.3 mag in the HD, which translates into a 14% precision in relative distances (Schmidt et al. 1994; Hamuy 2001; Jones et al. 2009). Another approach, more accurate than the latter, consists of adopting corrections and color temperatures from tailored models for each observation, revealing an accuracy of \( \sim 10\% \) in distance determination of individual SNe (Dessart & Hillier 2006; Dessart et al. 2008, and the SEAM implementation of Baron et al. 2004).

Second, the “standardized candle method” (SCM) is an empirical technique initially proposed by Hamuy & Pinto (2002) based on an observational correlation between the absolute magnitude of the SN and the expansion velocity of the photosphere, the luminosity/expansion-velocity (LEV) relation. This correlation shows that SNe IIP with greater luminosities have higher expansion velocities, which permits one to correct for the large (\( \sim 4 \) mag) luminosity differences displayed by these objects to levels of only \( \sim 0.3 \) mag. So far, the SCM has been applied to 24 low-redshift \( (z < 0.05) \) SNe (Hamuy 2003b, 2005) and more recently by Poznanski et al. (2009) to 17 low-redshift \( (z < 0.03) \) SNe and by D’Andrea et al. (2010) to 15 intermediate-redshift \( (z < 0.144) \), as well as by Nugent et al. (2006) to 5 high-redshift \( (z < 0.29) \) SNe. The latter work was the first attempt to derive cosmological parameters from SNe IIP and demonstrated the enormous potential of this class of objects as cosmological probes. A similar attempt to standardize the luminosities of SNe IIP was done by Elmhamdi et al. (2003) based on the steepness of the \( V \)-light-curve slope at the inflection time.

Several major sky-survey programs now in progress or to be deployed in the upcoming years, such as the Palomar Transient time. Kwan1974) is a technique based on theoretical models that is independent of the extragalactic distance scale (Eastman et al. 1996; Dessart & Hillier 2005). In EPM the spectral energy distribution of the SN is approximated as a black body, and atmosphere models permit one to correct the dilution of the photospheric flux relative to a Planck function due to electron scattering. From a detailed analysis of the properties of the SN atmospheres, Eastman et al. (1996) showed that the most important variable in determining the dilution factors is the effective temperature. This result permits one to determine the photospheric angular radius of the SN from a measurement of the color temperature and infer the distance from the expansion velocity measured from spectral lines, without the need to craft specific models for each SN. This method can achieve dispersions of 0.3 mag in the HD, which translates into a 14% precision in relative distances (Schmidt et al. 1994; Hamuy 2001; Jones et al. 2009). Another approach, more accurate than the latter, consists of adopting corrections and color temperatures from tailored models for each observation, revealing an accuracy of \( \sim 10\% \) in distance determination of individual SNe (Dessart & Hillier 2006; Dessart et al. 2008, and the SEAM implementation of Baron et al. 2004).

Second, the “standardized candle method” (SCM) is an empirical technique initially proposed by Hamuy & Pinto (2002) based on an observational correlation between the absolute magnitude of the SN and the expansion velocity of the photosphere, the luminosity/expansion-velocity (LEV) relation. This correlation shows that SNe IIP with greater luminosities have higher expansion velocities, which permits one to correct for the large (\( \sim 4 \) mag) luminosity differences displayed by these objects to levels of only \( \sim 0.3 \) mag. So far, the SCM has been applied to 24 low-redshift \( (z < 0.05) \) SNe (Hamuy 2003b, 2005) and more recently by Poznanski et al. (2009) to 17 low-redshift \( (z < 0.03) \) SNe and by D’Andrea et al. (2010) to 15 intermediate-redshift \( (z < 0.144) \), as well as by Nugent et al. (2006) to 5 high-redshift \( (z < 0.29) \) SNe. The latter work was the first attempt to derive cosmological parameters from SNe IIP and demonstrated the enormous potential of this class of objects as cosmological probes. A similar attempt to standardize the luminosities of SNe IIP was done by Elmhamdi et al. (2003) based on the steepness of the \( V \)-light-curve slope at the inflection time.

Several major sky-survey programs now in progress or to be deployed in the upcoming years, such as the Palomar Transient Factory (Rau et al. 2009; Law et al. 2009), the Panoramic Survey Telescope and Rapid Response System (Hodapp et al. 2004), the Large Synoptic Survey Telescope (Tyson et al. 2003), the Visible and Infrared Survey Telescope (Emerson et al. 2004), the VLT Survey Telescope (Capaccioli et al. 2003), the Dark Energy Survey (Castander 2007), and the SkyMapper (Granlund et al. 2006), offer the promise of discovering SNe by the thousands. Thus, we will be inevitably confronted by enormous amounts of data on SNe IIP which will contain potentially valuable cosmological information. The challenge is to find an implementation of SCM that does not require spectroscopic data since these surveys will be purely photometric.

In spite of the great potential shown by the SCM, it still suffers from a variety of problems which need to be addressed: (1) the lack of a well-defined maximum in the light curves has prevented us from defining the phase of each event; (2) each SN shows a different color evolution, which has compromised the use of the photometric data for the determination of host-galaxy extinction; (3) the assumption for dereddening employed by Hamuy & Pinto (2002), namely, that all SNe reach the same asymptotic color toward the end of the plateau phase, has often led to negative extinction corrections, so it still needs to be further tested; and (4) the small sample size used so far, especially the scarcity of SNe in the Hubble flow, has prevented a proper determination of the intrinsic precision of the method.

With these obstacles in mind, we have developed a robust mathematical procedure to fit the light curves, color curves, and velocity curves, in order to obtain a more accurate determination of the relevant parameters required by the SCM (magnitudes, colors, and ejecta velocities), as described in detail in the thesis work of Olivares (2008). Here, we apply this technique to 37 SNe IIP in order to construct an HD, evaluate the accuracy of the SCM, and obtain an independent determination of the Hubble constant. Since our sample has several objects in common with the recent EPM analysis of Jones et al. (2009), we perform a comparison between SCM and EPM.

We organize this paper as follows. In Section 2, we describe all of our observational material including telescopes, instruments, and surveys involved. The analysis, methodology, and procedures, such as the \( A_G \), \( K \), and \( A_{host} \), corrections, are explained in detail in Section 3. The dereddening analysis, the HD, the value of the Hubble constant, and the comparison between SCM and EPM distances are addressed in Section 4. The final remarks in Section 5 provide a discussion about variations of the reddening law for SNe IIP and the possibility of a non-standard extinction law in the SN host galaxies. We present our conclusions in Section 6.

2. OBSERVATIONAL MATERIAL

This work makes use of data obtained in the course of four systematic SN follow-up programs carried out during the years 1986–2003: (1) the Cerro Tololo SN program (1986–1996); (2) the Calán/Tololo SN program (CT, 1990–1993); (3) the Optical and Infrared Supernova Survey (SOIRS, 1999–2000); and (4) the Carnegie Type II Supernova Program (CATS, 2002–2003). As a result of these efforts, photometry and spectroscopy (some infrared but mostly optical) was obtained for nearly 100 SNe of all types, 51 of which belong to the Type II class. Of these 51 SNe II, a subset of 33 objects meets the requirements for this study. Next, we describe in general terms the data acquisition and reduction procedures. For more details the reader can refer to M. Hamuy et al. (2010, in preparation).

2.1. Photometric Data

The photometry was acquired with telescopes from Cerro Tololo Inter-American Observatory (CTIO), Las Campanas Observatory, the European Southern Observatory (ESO) in La Silla, and Steward Observatory. Many different telescopes and instruments were used to generate this data set as shown in Table 1. In all cases, we employed CCD detectors and standard Johnson–Kron–Cousins–Hamuy \( UBVRIz \) filters (Johnson et al. 1966; Cousins 1971; Hamuy et al. 2001).

The images were processed with IRAF9 through bias subtraction and flat-fielding. All of them were further processed through the step of galaxy subtraction using template images of the host
The photometry of SN based on observations of Landolt and Hamuy standards (Landolt 1992; Hamuy et al. 1992, 1994). Owing to the nonstellar nature of the SN spectrum (e.g., Hamuy et al. 1990), significant systematic discrepancies can still remain due to the variety of instruments and telescopes, as shown in Table 1. Although this procedure partially removes the instrument-to-instrument differences in the SN magnitudes, it should be kept in mind that significant systematic discrepancies can still remain owing to the nonstellar nature of the SN spectrum (e.g., Hamuy et al. 1990).

Complementary photometry for SN 2003gd obtained by Van Dyk et al. (2003) and Hendry et al. (2005) was also incorporated in our analysis.

### 2.2. Spectroscopic Data

The spectroscopic data were also obtained with a great variety of instruments and telescopes, as shown in Table 1. The observations consisted of the SN observation immediately followed by an emission-line comparison lamp taken at the same position in the sky, and 2–3 flux standards per night from the list of Hamuy et al. (1992, 1994). We always used CCD detectors, in combination with different gratings/grisms and blocking filters. The reductions were performed with IRAF and consisted of bias subtraction, flat-fielding, one-dimensional spectrum extraction and sky subtraction, wavelength calibration, and flux calibration. No attempts were made to remove the telluric lines.

Our spectroscopic database was complemented with spectra obtained by the CfA SN program with the FAST CCD spectrograph (Fabricant et al. 1998) at the 1.5 m telescope of the Whipple Observatory (see Matheson et al. 2008 for details on the data reduction), and by the University of California, Berkeley SN program with the Kast double CCD spectrograph (Miller & Stone 1993) on the Shane 3 m telescope at Lick Observatory. The above standard procedures, including removal of telluric absorption lines, were employed to reduce the Lick spectra (e.g., Foley et al. 2003).

### 2.3. Subsample Used for this Work

Of the 51 SNe II observed in the course of these four surveys, a subset of 33 objects comply with the requirements of (1) being a member of the plateau subclass; (2) having sufficient spectroscopic temporal coverage; and (3) having light curves with good temporal coverage. To this sample we added four SNe from the literature: SN 1999gi, SN 2004dj, SN 2004et, and SN 2005cs. Table 2 lists our final sample of 37 SNe IIP. For each SN this table includes the name of the host galaxy, the equatorial coordinates of the SN, the heliocentric redshift and its source, the reddening due to our own Galaxy (Schlegel et al. 1998), and the survey during which the SN was observed.

### 3. METHODOLOGY AND PROCEDURES

In the thesis work of Olivares (2008), we describe in detail the techniques for correcting the photometry for Galactic absorption ($A_G$), $K$-correction terms, and host-galaxy dust absorption ($A_{\text{host}}$)—the so-called “$AK$ corrections.” In brief, we employ a library of 196 spectra of SNe II (including other SN types than just SNe IIP) to synthesize $K$-terms and absorption coefficients given the specific redshift and $A_V$ value of each SN. Synthetic $B$–$V$ and $V$–$I$ colors are used as proxies for the spectral energy distribution in order to account for the evolution of each SN.

#### 3.1. Fits to Light, Color, and Velocity Curves

In the first incarnation of the SCM, Hamuy & Pinto (2002) measured all of the relevant quantities (magnitudes, colors, and velocities) at fixed epochs with respect to the time of explosion. In most cases, however, it proves hard to constrain this time, thus hampering the task to compare data obtained for different SNe. It would be ideal to have a conspicuous feature in the light curves; unfortunately, unlike other SN types, SNe IIP generally do not show a well-defined maximum during the plateau phase.

One way around this is to use the end of the plateau as an estimate of the time origin for each event. In practice, it is not easy to measure this time owing to the generally coarser sampling of the light curves at this phase. Thus, our first aim is to implement a robust light-curve fitting procedure in order to obtain a reliable time origin to be used as a uniform reference epoch to measure magnitudes, colors, and expansion velocities. In the remainder of this section, we proceed to implement fitting methods to measure reliable colors and expansion velocities.

#### 3.1.1. BVRI Light-curve Fits

Figure 1 shows the BVRI light curves of SN 1999em. As can be seen, there are three distinguishable phases in the light curves.

1. **The plateau phase**, in which the SN shows an almost constant luminosity during the first ~100 days of its evolution. This phase corresponds to the optically thick period in which a hydrogen recombination wave recedes in mass coordinate, gradually releasing the internal energy of the star (see Kirshner & Kwan 1974; Nadyozhin 2003; Utrobin 2007; Bersten & Hamuy 2009, and references therein).
2. **The linear or radioactive tail**, a linear decay in magnitude (exponential in flux) starting about 130 days after the...
explosion. This phase corresponds to the optically thin period powered by the $^{56}\text{Co} \rightarrow ^{56}\text{Fe}$ radioactive decay (e.g., Weaver & Woosley 1980).

3. A transition phase of $\sim 30$ days between the plateau and linear phases.

Both the plateau and linear phases are trivial to model if taken separately, but the abrupt transition makes the fitting task much more challenging, especially with coarsely sampled light curves. After considering several options we ended up using the arithmetic sum of the three functions shown in Figure 1, as follows.

1. A Fermi–Dirac function (dotted line in Figure 1), which provides a very good description of the transition between the plateau and radioactive phases:

$$f_{FD}(t) = \frac{-a_0}{1 + e^{-(t-t_{PT})/w_0}},$$

where $a_0$ represents the height of the step in units of magnitude, $t_{PT}$ corresponds to the middle of the transition phase and is a natural candidate to define the origin of the time axis, and $w_0$ quantifies the width of the transition phase. At $t = t_{PT}$ the height of the step has been reduced by 4.7%, and it decreases down to 95.3% at $t = t_{PT} + 3w_0$.

2. A straight line (long-dashed line in Figure 1) which accounts for the slope due to the radioactive decay:

$$l(t) = p_0(t - t_{PT}) + m_0,$$

where $p_0$ corresponds to the slope of radioactive tail and an approximate slope for the plateau in units of mag per day, and $m_0$ corresponds to the zero point in magnitude at $t = t_{PT}$.

3. A Gaussian function (short-dashed line in Figure 1), which serves mainly for fitting the $B$ light-curve bump and the $I$
Figure 1. BVRI light curves of SN 1999em. BVRI magnitudes are respectively shown in top left, top right, bottom left, and bottom right panels. The solid line corresponds to the analytic fit. The segmented lines represent the decomposition of the main function into its three components: the Fermi–Dirac function (dotted line), a straight line (long-dashed line), and a Gaussian function (short-dashed line). The origin of the time axis corresponds to \( t_{\text{PT}} \) in Julian days for SN 1999em. Since the instrumental error bars are smaller than the symbols, they are not shown.

(A color version of this figure is available in the online journal.)

Light-curve curvature during the plateau phase:

\[
g(t) = -P e^{-(t - Q)^2/R^2},
\]

where \( P \) is the height of the Gaussian peak in units of magnitudes, \( Q \) is the center of the Gaussian function in days, and \( R \) is the width of the Gaussian function. The Gaussian function is also useful for reproducing the small-scale features that can appear in the \( V \)-band plateau.

The resulting analytic function we use to model the light curves is the sum of the three functions detailed above,

\[
F(t) = f_{\text{FD}}(t) + l(t) + g(t)
\]

\[
= \frac{-a_0}{1 + e^{(t - t_{\text{PT}})/w_0}} + p_0 (t - t_{\text{PT}}) + m_0 - P e^{-(t - Q)^2/R^2},
\]

which has eight free parameters. This function is fitted to the individual light curves in unison (not by parts) using a \( \chi^2 \) minimizing procedure. In order to find the minimum \( \chi^2 \), we use the Downhill Simplex Method (Nelder & Mead 1965). Despite being not very efficient in terms of the number of iterations required, it provides robust solutions. Examples of the analytic fits are shown as solid lines in Figure 1. Although we cannot model most of the small-scale features in the plateau, the fitting does a very good job in modeling the transition. Furthermore, the analytic function gives us important parameters that characterize the light-curve shape, particularly \( t_{\text{PT}} \) which provides a time origin. In the plots in Figure 1, the time axis is chosen to coincide with the value of this parameter obtained from the \( V \) light curve. In Table 3, we gather the eight parameters and the corresponding reduced \( \chi^2 \) (\( \chi^2 / \nu \)) of the \( V \) light curve fitting for the whole SN sample.

A critical quantity in the analysis that follows is \( t_{\text{PT}} \) and its uncertainty, both of which determine the uncertainties in all of the relevant SCM quantities. For most cases, when the tail phase has been observed, the \( \chi^2 \) minimizing routine has no difficulties finding \( t_{\text{PT}} \) and delivers a credible error. On the other hand, when the light curve does not have any late-time data points, the routine underestimates \( \sigma(t_{\text{PT}}) \), in which case we need to provide a more realistic estimate of this uncertainty. Only for a few cases did we have to arbitrarily set \( t_{\text{PT}} \) and its error based on the light-curve sampling (see Column 3 in Table 3).

Regardless of the sampling of the light curves, we assign a minimum of \( \sigma(t_{\text{PT}}) = 2 \) days. Although these uncertainties in \( t_{\text{PT}} \) are very conservative and arbitrary, they do not translate into high or unrealistic errors in quantities such as magnitudes, colors, or expansion velocities, as we will see later.

Note that Elmhamdi et al. (2003) used a similar approach as the one described here, except that their model function only has five independent parameters and is somewhat simpler than ours.

3.1.2. Color-curve Fits

Figure 2 shows the \( B-V \), \( V-R \), and \( V-I \) colors of three prototypical SNe IIP corrected for \( A_G \) and \( K \)-terms as described by Olivares (2008, chapter 3.1). The time origin in the abscissa corresponds to \( t_{\text{PT}} \), the middle of the transition phase. In each case we employ all the data points between days \(-100 \) and \(-10 \)
reddening in the SN host galaxy and be exploited to measure color excesses measured at this phase could be attributed to dust at the end of the plateau phase; hence, they proposed that the temperature of hydrogen recombination around 5000 K. Based on this physical argument, Hamuy & Pinto (2002) argued the photospheric temperature should approach and never get below the wavelength due to line blanketing. According to the theory, the SN expands and to a redistribution of flux from blue to red time owing to the decrease of the surface temperature as the photosphere gets redder with that, during the plateau phase, the photosphere expands.

The degree of the polynomial was chosen on a case-by-case to fit a Legendre polynomial shown with solid lines in Figure 2. The degree of the polynomial was chosen on a case-by-case basis and varied between third and sixth order. It is evident that, during the plateau phase, the photosphere gets redder with time owing to the decrease of the surface temperature as the SN expands and to a redistribution of flux from blue to red wavelengths due to line blanketing. According to the theory, the photospheric temperature should approach and never get below the temperature of hydrogen recombination around 5000 K. Based on this physical argument, Hamuy & Pinto (2002) argued that all SNe IIP should reach the same intrinsic colors toward the end of the plateau phase; hence, they proposed that the color excesses measured at this phase could be attributed to dust reddening in the SN host galaxy and be exploited to measure $A_{\text{host}}$. Hamuy & Pinto (2002) performed their analysis with a simple naked-eye estimate of the asymptotic colors. Here, we improve significantly this situation through the formal color-curve fitting procedure described above.

Armed with the polynomial fits, we proceeded to interpolate colors on a continuous grid with one-day spacing between days −80 and −10 for analyzing colors at multiple epochs (see Section 3.2). In a handful of cases, the data did not encompass the whole grid and we had to extrapolate colors, but never by more than 3 days from the nearest data point.

### 3.1.3. Fe II Based Expansion-velocity Curves

The third ingredient for SCM is the velocity of the SN ejecta. Different spectral lines yield different expansion velocities depending on the region from which the photon is emitted. The Fe II $\lambda$5169 line is thought to be a good proxy for SN IIP photospheric velocity (Dessart & Hillier 2005) and has been previously employed for SCM. Here, we use the Fe II expansion velocities measured by Jones et al. (2009) from the minimum of the P Cygni line profile after correcting the spectra for the heliocentric redshifts of the host galaxies. The uncertainties of these measurements were estimated to be $\sim$85 km s$^{-1}$ from the quality of the wavelength calibration and the signal-to-noise ratio (S/N) of the absorption feature of the P Cygni line profile. Although these measurements do not consider relativistic corrections, the latter prove negligible ($\lesssim$40 km s$^{-1}$) in the range considered here (2000–5000 km s$^{-1}$).

Table 3 shows Fe II velocities as a function of SN phase, for four different SNe selected for their wide range of sampling.
characteristics. As shown by Hamuy & Pinto (2002), the Fe II λ5169 expansion velocity curve during the plateau phase can be properly modeled with a power law, which we choose to be of the form

$$v_{\text{eff}}(t) = A (t - t_0)^\alpha,$$

where $A$, $t_0$, and $\alpha$ are free fitting parameters without obvious physical meaning.

In general, we fit for all three parameters, but when only two velocity measurements are available (e.g., SN 1992af in the top left panel of Figure 3) we fix the $\alpha$ exponent to $-0.5$, which corresponds to a typical value for our sample. As shown with solid lines in Figure 3, the fits are quite satisfactory. Here, we choose to restrict the power-law fits to the plateau phase, since the power-law behavior is not observed for expansion velocities beyond the transition phase. We use the same one-day continuous grid as for the color curves in order to interpolate velocities at different epochs between $-80$ and $-10$ days. Given the good quality of the fits and the shallow slope at late epochs, we allow extrapolations of up to 15 days past the nearest data point (see SN 1999cr in Figure 3). At the early-time boundary, we reduce the extrapolations to 10 days prior to the first point, because the power law becomes steeper at early times (e.g., see SN 2003gd in Figure 3). When only two velocity measurements are available, we reduce the extrapolations by 5 days. Since at the end of the plateau phase the SN atmosphere starts to become nebular, we discarded data points beyond the transition in the velocity fits. We do not impose any constraints on the first data point.

### 3.2. Host-galaxy Extinction Determination

To determine the host-galaxy extinction, we assume that all SNe IIP should evolve from a hot initial stage to one of uniform photospheric temperature, owing to the hydrogen-recombination nature of their photospheres.

Although simple in theory, there are a few practical difficulties when comparing the color evolution. First, it is not always possible to constrain the time of explosion and accurately compare color curves of different objects. One way around this is to use the transition time, $t_{\text{PT}}$, defined in Section 3.1.1. The second problem is illustrated in Figure 2: the color-curve shapes can vary significantly from one SN to another, preventing one from measuring a single color offset between two SNe. To circumvent this, we pick a single fiducial epoch in the color evolution and assess the performance of the color as a reddening estimator. Our polynomial fits to the color curves are very convenient for this purpose, since they allow us to interpolate reliable colors on a day-to-day basis over a wide range of epochs and explore which epoch gives the best results.

If all SNe share the same intrinsic temperature at some epoch, we expect the subset of dereddened SNe to have nearly identical colors ($C_0$); the remaining objects should show color excesses, $E(C) = C - C_0$, in direct proportion to their extinctions. A useful diagnostic to check our underlying assumption is the color–color plot: unreddened SNe should occupy a small region in this plane. If we further assume the same extinction law in the SN host galaxies, the subset of unreddened objects should describe a straight line originating from such a region. The figures of merit in this test are (1) the color dispersion displayed by the unreddened SNe, (2) the slope described by the reddened SNe (which is determined by the extinction law), and (3) the dispersion relative to the straight line (the smaller the better).

We have identified four objects in our sample (SN 2003B, SN 2003bl, SN 2003bn, SN 2003em) consistent with zero reddening. These objects were selected for having (1) no significant Na I D interstellar lines in their spectra at the redshifts of their host galaxies and (2) early-time spectra that show no signs of host-galaxy extinction. To judge the latter, we used extinction values determined from fits of SN IIP atmosphere models to our early-time spectra as done by Dessart & Hillier (2006) and Dessart et al. (2008). Such models use the SN spectral lines to constrain the photospheric temperature and the continuum to restrict the amount of extinction. Examples of fits are shown in Figure 4.

We investigated two color–color plots ($V - I$ versus $V - R$, and $V - I$ versus $B - V$) over a wide range of epochs (from day $-50$ to $-15$) after correcting the photometry for Galactic extinction and $K$-terms as described by Oliveira (2008). The best results were found for the $V - I$ versus $V - R$ diagram constructed from day $-30$, shown in Figure 5. Fortunately, all SNe in our sample have enough data to interpolate color curves at day 30. At this epoch, approximately the end of the plateau, we obtain the linear behavior expected for a sample with the same intrinsic color but different degrees of extinction. Shown with a triangle is the single SN consistent with zero extinction which is, remarkably, one of the bluest objects in this diagram; the other three unextinguished SNe do not have $R$-band photometry. A least-squares fit to the data yields a slope of $1.59 \pm 0.09$, which is lower than the $E(V - I)/E(V - R) = 2.12$ ratio expected for a Galactic extinction law ($R_V = 3.1$) shown as a vector
an uncertainty of \( A_V = 0.059 \) mag in the SN hosts compared to the Galaxy. The dispersion of \( \beta_V \) in Figure 5. This suggests a somewhat different extinction law for SN 1999cr. The bottom left panel shows a 10 day extrapolation for SN 2003gd prior to the first data point. SN 1999em velocities are shown in the bottom right panel as an example of good sampling.

We conclude from our exploration that, while the \( B-V \) color is problematic, both the \( V-R \) and \( V-I \) colors offer a promising route for dereddening purposes. In what follows, we will employ solely the \( V-I \) color since only a small subset of our objects possess \( R \)-band photometry. Although the evidence points to a non-Galactic reddening law, for now we will assume a standard reddening law (later we will relax this assumption; see Section 4.3.2).

Using our library of SN \( \eta \) spectra, we computed synthetically the appropriate conversion factor between \( E(V-I) \) and \( A_V \) for SNe \( \eta \) and a standard reddening law \( (R_V = 3.1) \), yielding

\[
\beta_V = \frac{A_V}{E(V-I)} = 2.518. \tag{6}
\]

The host-galaxy extinction can be computed from \( A_V(V-I) = \beta_V [(V-I) - (V-I)_0] \) and, assuming an intrinsic color of \( (V-I)_0 = 0.656 \pm 0.053 \) mag, its numerical expression with the corresponding uncertainty is

\[
A_V(V-I) = 2.518 [(V-I) - 0.656], \tag{7}
\]

\[
\sigma(A_V) = 2.518 \sqrt{\sigma_{(V-I)}^2 + 0.053^2 + 0.059^2},
\]

where \( V-I \) corresponds to the color of a given SN at day \(-30\) (corrected for \( K \)-terms and foreground extinction) and \( \sigma_{(V-I)} \) combines the instrumental errors in the \( V \) and \( I \) magnitudes, the uncertainty in \( A_G \) and the \( K \)-terms (see Olivas 2008, chapters 3.1.1 and 3.1.2, respectively), and the uncertainty in \( f_{PT} \).
Figure 4. Type IIP SN atmosphere models (wide gray line) fitted to our spectra (black line) in the rest frame. The top panel shows an example of an unsatisfactory fit to one of our late-time spectra. The middle panel shows a better fit to an early-time spectrum of SN 1991al. A much better fit is achieved for an early-time spectrum of SN 2003bl as shown in the bottom panel. Strong telluric lines are marked. (A color version of this figure is available in the online journal.)

The uncertainty in the intrinsic \((V-I)_0\) color was also included in the error of \(A_V\) along with the \(V-I\) standard deviation in the \(V-I\) versus \(V-R\) diagram.

The host-galaxy reddening values obtained from this technique are listed in Column 5 of Table 4 (with the uncertainties given in parentheses for the whole sample of 37 SNe). There are eight SNe with \(V-I\) colors bluer than \((V-I)_0\) which stand out in this table for their inferred negative reddenings. Although not physically meaningful, these negative values are statistically consistent with zero or moderate reddenings. In fact, seven of these eight objects differ by \(< 1.1\sigma\) from zero reddening. Only SN 1992af differs by \(1.8\sigma\) from \(A_{\text{host}} = 0\) mag.

As a comparison, Krisciunas et al. (2009) employed a similar procedure to determine the extinction to SN 2003hn. While we get \(A_V = 0.46 \pm 0.21\), they obtained \(A_V = 0.54 \pm 0.14\), values that are consistent within the uncertainties. In the following section, we compare this method with other dereddening techniques.

4. ANALYSIS

4.1. Comparing Dereddening Techniques

SN IIP atmosphere models were fitted to our library of spectra as done by Dessart & Hillier (2006) and Dessart et al. (2008). In these fits the spectral lines are used to constrain the photospheric temperature, and the corresponding continuum is employed to estimate the extinction. Thus, the quality of the fit depends on (1) the determination of the photospheric temperature by means of the spectral lines and (2) how well the continuum is represented by the extinguished blackbody emission. A
used the observed photometry to change the slope of a spectrum. Basically, this “mangling” correction was performed along the parallactic angle (Filippenko 1982) and the crucial condition for this technique to work is the spectrophotometric quality of the spectra used in the reddening determination: (a) gold: early-time spectra, without mangling correction; (b) silver: early-time spectra, with mangling correction; (c) bronze: late-time spectra, without mangling correction; and (d) coal: late-time spectra, with mangling correction. Note that the main criterion is whether the spectrum was obtained at early or late times, and the second criterion corresponds to the flux-calibration quality. We consider the unmangled spectra to be of higher quality than the mangled ones, because the former do not require any corrections and suggest that the observations were better performed.

The above subclassification is given for each SN in Column 3 of Table 4. Note that the uncertainty is directly related to this subclassification. Dessart et al. (2008) estimate an error of $\sigma_{E(V-I)} = 0.05$ mag when using early-time spectra, and $\sigma_{E(B-V)} = 0.10$ mag when using late-time spectra. We refine this argument, ramping up from 0.05 to 0.10 mag, depending on the number of spectra employed for each extinction determination. These values are given in Table 4 in units of $A_V = 3.1 \ E(B-V)$.

Figure 7 shows a comparison between the spectroscopic reddening $A_V$(spec) and our color reddening $A_V(V-I)$ derived in Section 3.2, for the 17 SNe belonging to the top three subclasses (gold + silver + bronze). Good agreement is found between both techniques, with a dispersion of 0.38 mag. The resulting $\chi^2 = 1.4$ suggests that this dispersion is consistent with the combined errors of both techniques. The exceptions are two objects, SN 1999br and SN 2003ho. SN 1999br has only plateau-phase photometry, making it hard to determine $t_{PT}$. Although the uncertainty in $t_{PT}$ is quite large (20 days), this does not have a great impact on the error of the $V-I$ color due to the flatness of the color curve at these epochs ($+0.0024$ mag day$^{-1}$). Another possible reason for the disagreement could be an intrinsically redder $V-I$ color than that of the bulk of the SNe, caused by the extreme properties (low luminosity and expansion velocity) of SN 1999br. The second discrepant object (SN 2003ho) belongs to the bronze group, so it is possible that the difference could be due to the use of a late-time spectrum in the determination of the spectroscopic reddening.

Another way to estimate host-galaxy reddening is from the NaI D $\lambda\lambda5889, 5896$ interstellar absorption doublet observed in the SN spectrum at the host-galaxy redshift. Whenever the line was detected we measured its equivalent width (EW); in those cases where we did not detect the NaI D line we assigned it a null value. In all cases, we estimated the uncertainty in the EW based on the S/N of the continuum around this line. We converted these measurements into visual extinctions, $A_V$(NaI D), using the calibration of Barbon et al. (1990):

$$E(B-V) \approx 0.25 \text{EW} \text{(NaI D)},$$

(8)

where the units of $E(B-V)$ and EW are mag and Å, re-

| SN Name | $A_V$(spec)$^a$ | Subclass | $A_V$(Na I D)$^b$ | $A_V(V-I)^c$ |

$^d$ SNe selected to determine the intrinsic color.
Figure 7. Comparison between two dereddening techniques via $A_V$ (mag): the spectrum-fitting method (ordinate) and our technique (abscissa; Section 3.2). Shown are three subclasses defined by the quality of the spectroscopic data used: the gold (gray filled circles), silver (light gray open circles), and bronze (black triangles) samples (see Section 4.1). The solid line is fixed to show a slope of unity. (A color version of this figure is available in the online journal.)

Figure 8. Comparison between two dereddening techniques via $A_V$ (mag): the Na i D interstellar line (ordinate) and our technique (abscissa; Section 3.2). In each case, the EW of the Na i D interstellar line is transformed into a visual extinction according to the calibration given by Barbon et al. (1990). (A color version of this figure is available in the online journal.)

Figure 9. BVI-band absolute magnitudes (ordinate) against the Fe ii expansion velocity (abscissa) for 29–30 SNe. We use magnitudes corrected for Galactic extinction, K-terms, and host-galaxy extinction together with a value of the Hubble constant of $70 \text{ km s}^{-1}\text{ Mpc}^{-1}$. The dashed line in the middle panel represents the LEV relation for the V band found by Hamuy & Pinto (2002), obtained from magnitudes and velocities measured at day 50 past the explosion (approximately day $-60$ on our own timescale). (A color version of this figure is available in the online journal.)

After developing the dereddening method based on late-time colors, we can now revisit the LEV relation originally discovered by Hamuy & Pinto (2002), which is at the core of the SCM. For this purpose, we applied AK A corrections to our photometry (Olivares 2008, Chapter 3.1), we used our analytic fits (Section 3.1.1) to interpolate $BVI$ magnitudes on day $-30$, and we employed the cosmic microwave background (CMB) redshifts\footnote{The CMB redshifts were computed by adding the heliocentric redshifts given in Table 2 and the projected velocity of the Sun relative to the CMB in the direction of the SN host galaxy. For the latter, we adopted a velocity of $371 \text{ km s}^{-1}$ in the direction $(l, b) = (264:1, 48:3)$ given by Fixsen et al. (1996) plus the uncertainty of the Local Group velocity ($187 \text{ km s}^{-1}$).} in Table 5 to convert apparent magnitudes to absolute values (assuming $H_0 = 70 \text{ km s}^{-1}\text{ Mpc}^{-1}$ from our final result).

In order to assess the dereddening technique, we preserved the relative reddening estimations by keeping the negative values of host-galaxy absorption. We performed a power-law fit to interpolate a velocity contemporaneous with the photometry...
(day $-30$) as described in Section 3.1.1. Only for SN 1999cr did we have to use an extrapolated velocity (see top right panel in Figure 3). From our original sample of 37 SNe IIP we were able to use 30 SNe to build this relation, since five of them do not have measured Fe II velocities at day $-30$, and two others have extremely low redshifts ($cz_{CMB} < 300 \text{ km s}^{-1}$).

Figure 9 shows the resulting LEV relation (absolute magnitude versus expansion velocity) for all BVI bands. Evidently we recover the result of Hamuy & Pinto (2002), namely that the most luminous SNe have greater expansion velocities. In their case the data were modeled with a linear function. Our sample suggests that the relation may be quadratic, but we need more SNe at low expansion velocities to confirm this suspicion. Linear least-squares fits to our BVI data yield the following solutions:

$$M(B)_{-30} - 5 \log(H_0/70) = 3.50(\pm0.30)$$ $$\times \log[\nu_{\text{Rest}}(-30)/5000] - 16.01(\pm0.20),$$

(9)

$$M(V)_{-30} - 5 \log(H_0/70) = 3.08(\pm0.25)$$ $$\times \log[\nu_{\text{Rest}}(-30)/5000] - 17.06(\pm0.14),$$

(10)

$$M(I)_{-30} - 5 \log(H_0/70) = 2.62(\pm0.21)$$ $$\times \log[\nu_{\text{Rest}}(-30)/5000] - 17.61(\pm0.10),$$

(11)

which are shown with solid lines in Figure 9. The relation found by Hamuy & Pinto (2002) for the V band is indicated with the dashed line in the middle panel of the same figure. Given that the study of Hamuy & Pinto (2002) was performed using data at day 50 after explosion (around day $-60$ on our time scale), it is not unexpected that their LEV relation is shifted to higher expansion velocities. Some of the difference in slope is initially reported by Hamuy & Pinto (2002) for the $V$-band data. Evidently we have extremely low redshifts ($cz_{CMB} < 300 \text{ km s}^{-1}$).

An inspection of the $V$-band diagram (Figure 11) shows a large scatter of 0.54 mag in the top left panel. When we correct for expansion velocities, the scatter drops to 0.50 mag. This is certainly not unexpected given the LEV relation reported in the previous section. It is encouraging to note that the dispersion drops from 0.50 to 0.45 mag when we include our host-galaxy extinction corrections; this indicates the utility of our color-based dereddening technique. The reduced $\chi^2$ value of 2.45 implies that most of the scatter is caused by the observational errors. We performed the same analysis using other epochs and found that day $-30$ yielded the lowest dispersion.

If we turn our attention to the I band (Figure 12), the final dispersion is 0.45 mag, identical to that found in the V band. It seems that the dispersion could have some dependence on wavelength, since it decreases from 0.45 in $VI$ to 0.36 mag in $B$. The scatter of $\sim0.4$ mag in $BVI$ is comparable to, but somewhat larger than, the $\sim0.34$ mag dispersion obtained in previous SCM studies (Hamuy & Pinto 2002; Hamuy 2003b, 2005). It is important to note that the dispersions are independent of the intrinsic $(V-I)_0$ colors calculated in Section 3.2.

In the bottom right panels of Figures 10–12 we examine the SCM using the spectroscopic reddenings determined for a set of 28 SNe IIP from Table 4 instead of our color-based extinctions. The resulting dispersions in $BVI$ are (0.67, 0.54, 0.42 mag) compared with (0.36, 0.45, 0.45 mag) when using color-based extinctions. All of the fitting parameters derived from both dereddening techniques are compiled in Table 6.

### 4.3.2. Leaving $RV$ as a Free Parameter

The previous analysis suggests that the dispersions are somewhat larger than the observational errors. One possible source of scatter could be the reddening law. As shown in Section 3.2 and Figure 5, we have evidence for a somewhat different extinction law in the SN hosts compared to the Galaxy. Here, we take this idea a step further and analyze the HD leaving $RV$ as a free parameter. To accomplish this we model the data with the expression

$$m + \alpha \log(\nu_{\text{Rest}}/5000) - \beta(V-I) = 5 \log cz + zp,$$

(12)

where $m$ is the apparent magnitude corrected for $K$-terms and Galactic absorption, $\nu_{\text{Rest}}$ is the expansion velocity, $z_{\text{host}}$ is the host-galaxy absorption, and $z$ is the CMB redshift. Note that the SN redshift enters logarithmically in this model, implying that low-redshift SNe carry less weight in the fit. The only fitting parameters are $\alpha$ and the zero point ($zp$), but in the top left panel we set $\alpha = 0$ and we fit only for the $zp$. The significant decrease in the dispersion, from 0.72 to 0.36 mag, clearly demonstrates the need to add the velocity and host-galaxy extinction terms.

An inspection of the $V$-band diagram (Figure 11) shows a large scatter of 0.54 mag in the top left panel. When we correct for expansion velocities, the scatter drops to 0.50 mag. This is certainly not unexpected given the LEV relation reported in the previous section. It is encouraging to note that the dispersion drops from 0.50 to 0.45 mag when we include our host-galaxy extinction corrections; this indicates the utility of our color-based dereddening technique. The reduced $\chi^2$ value of 2.45 implies that most of the scatter is caused by the observational errors. We performed the same analysis using other epochs and found that day $-30$ yielded the lowest dispersion.

If we turn our attention to the I band (Figure 12), the final dispersion is 0.45 mag, identical to that found in the V band. It seems that the dispersion could have some dependence on wavelength, since it decreases from 0.45 in $VI$ to 0.36 mag in $B$. The scatter of $\sim0.4$ mag in $BVI$ is comparable to, but somewhat larger than, the $\sim0.34$ mag dispersion obtained in previous SCM studies (Hamuy & Pinto 2002; Hamuy 2003b, 2005). It is important to note that the dispersions are independent of the intrinsic $(V-I)_0$ color calculated in Section 3.2.

### 4.3.2. Leaving $RV$ as a Free Parameter

The previous analysis suggests that the dispersions are somewhat larger than the observational errors. One possible source of scatter could be the reddening law. As shown in Section 3.2 and Figure 5, we have evidence for a somewhat different extinction law in the SN hosts compared to the Galaxy. Here, we take this idea a step further and analyze the HD leaving $RV$ as a free parameter. To accomplish this we model the data with the expression

$$m + \alpha \log(\nu_{\text{Rest}}/5000) - \beta(V-I) = 5 \log cz + zp,$$

(12)

Note that we are replacing $A_{\text{host}}$ in Equation (12) with the term $\beta(V-I)$. The $\beta$ factor is a new free parameter to be marginalized along with $\alpha$ and $zp$, and $V-I$ is the color on day $-30$ uncorrected for host-galaxy dust absorption. This is the same approach adopted by Tripp (1998) for SNe Ia but using decline rate instead of expansion photospheric velocity. The underlying assumption in our case is that the absolute magnitudes of SNe IIP are a two-family function of Fe II expansion velocity and $V-I$ color. The latter is interpreted as a
color excess which varies according to dust in the host galaxy. Once $\beta$ is known we can use it to solve for host-galaxy extinction from $A(V) = \beta (V - I) - 0.656$, where 0.656 is the intrinsic $V - I$ color of SNe IIP (see Equations (6) and (7) in Section 3.2).

Figure 13 shows the $BVI$ HDs for our set of 30 SNe IIP. We obtain dispersions of (0.28, 0.31, 0.32 mag) in $BVI$, respectively, compared with (0.36, 0.45, 0.45 mag) when $R_V$ is kept fixed. The $\chi^2$ values increase from (1.6, 2.5, 2.5) to (2.8, 5.4, 8.7). This change is due to the fact that we are not using the intrinsic color, which gives the major contribution to the errors, even more in the $I$ band. Although we expect a reduction in the scatter due to the inclusion of an additional parameter, the large drop in the dispersion is remarkable. The last three lines of Table 6 show the parameters we obtain by minimizing the dispersion in the HD for each band. When we restrict the sample to objects with $cz_{\text{CMB}} > 3000$ km s$^{-1}$ (leaving aside SNe with potentially greater peculiar velocities), we end up with 19 SNe in the $B$ band and 20 SNe in the $VI$ bands. The resulting HDs in $BVI$ show dispersions of (0.25, 0.28, 0.30 mag), respectively, and the zero points of the HDs change by only 0.02 mag. Not surprisingly, these are lower than the (0.28, 0.31, 0.32 mag) dispersions obtained from the whole sample.

Efforts to remove the peculiar velocities of low-redshift galaxies were made by means of the parametric model for peculiar flows of Tonry et al. (2000). The ingredients of this model are (1) the observed recession velocity of the galaxy, (2) the Hubble constant, and (3) the surface-brightness-fluctuations distance from Tonry et al. (2001). The output is an estimate of the peculiar velocity of the galaxy (see Hamuy 2003a, Section 1.4 for details). After correcting 10 host galaxies in our sample, the results are not conclusive. The scatter in the HDs decreased only 0.01 mag for the $I$ band.

Our assumption is that the term $\beta (V - I)$ in Equation (13) corresponds to the extinction in a broadband magnitude (with
central wavelength $\lambda$). Thus, $\beta$ is the ratio $A(\lambda)/E(V-I)$ (see Equation (6) in Section 3.2) and is related to the shape of the extinction law. For each of the $BVI$ bands, we used our library of SN II spectra to compute synthetically the value of $\beta_b$ as a function of $R_V = A_V/E(B-V)$; see Figure 14. This allowed us to convert the $\beta_b$ values resulting from our fits into $R_V$ values. Our fits yield $\beta_b = (2.67 \pm 0.13, 1.67 \pm 0.10, 0.60 \pm 0.09)$ for the $BVI$ bands, respectively, which translate into $R_V = (1.38^{+0.27}_{-0.24}, 1.44^{+0.11}_{-0.14}, 1.36^{+0.11}_{-0.12})$. These values are remarkably consistent with each other and significantly lower than the $R_V = 3.1$ value of the standard reddening law. Independent evidence for a low-$R_V$ law has already been reported from studies of SNe Ia (see Section 5).

The dispersion of 0.28–0.32 mag in the HDs translates into a precision of 13%–14% in the determination of relative distances. However, as noticed after inspection of Figure 15, the magnitude residuals are highly correlated among $BVI$ and generally decrease with increasing redshift. The likely explanation is that we are seeing the effects of peculiar velocities of the host galaxies, in which case the precision of the SCM could be better than the 13%–14% derived from the scatter in the HDs. To examine this point, for each SN we took the $cz_{CMB}$ values from Table 5, and calculated the distance modulus residual

$$\Delta\mu = m + \alpha \log (v_{hel}/5000) - \beta(V-I) - 5 \log cz - zp,$$  \hspace{1cm} (14)

for all $BVI$ bands. Figure 16 shows strong correlations of these magnitude differences against each other. The rms scatter in the $\Delta\mu(B)$ versus $\Delta\mu(V)$ relation is 0.12 mag, and for $\Delta\mu(B)$ versus $\Delta\mu(I)$ it is 0.19 mag. This translates into 6% and 9% in distance, respectively. If this correlation of the residuals is due to peculiar velocities, then the true distance precision of SCM is 6%–9%, and not 13%–14% as derived from the HDs (which include scatter produced by the peculiar velocities). This result is very close to the $\sim7$%–10% precision of methods using SNe Ia (e.g., Phillips 1993; Hamuy et al. 1996; Riess et al. 1996; Phillips et al. 1999) when they were first used to reveal the acceleration of the universe, which demonstrates that SNe IIP have great potential for determining extragalactic distances and therefore cosmological parameters.

![Figure 10. B-band HDs. The top left panel shows magnitudes interpolated to day –30 previously corrected for Galactic extinction and $K$-terms; the top right panel shows magnitudes additionally corrected for expansion velocities; the bottom left panel includes further corrections for color-based host-galaxy extinction (using the $V-I$ color calibration given in Section 3.2); and the bottom right panel replaces the color-based extinction for the spectroscopic reddenings. The horizontal bars in each panel correspond to an adopted uncertainty of 187 km s$^{-1}$ in the CMB redshift.](image)

4.4. The Hubble Constant

The Hubble constant is a parameter of central importance in cosmology which can be determined from our HDs. This can be accomplished as long as we can convert apparent magnitudes into distances. The calibration was done with two objects for which we found Cepheid distances in the literature: SN 1999em ($\mu = 30.34 \pm 0.19$ mag; Leonard et al. 2002a) and SN 2004dj ($\mu = 27.48 \pm 0.24$ mag; Freedman et al. 2001). For each calibrating SN we can solve for $H_0$ using the expression

$$\log H_0 = 0.2\{m + \alpha \log (\nu_{\text{eff}}/5000) - \beta (V-I)\} - \alpha zp + 25\},$$

where $m$ is the apparent magnitude, $\nu_{\text{eff}}$ is the expansion velocity, and $V-I$ is the color of the calibrating SN, all measured on day $-30$ and given in Table 5; $\alpha$, $\beta$, and $zp$ are the fitting parameters given in the bottom three lines of Table 6.

Table 7 summarizes our calculations for the two calibrators. We see that the corrected $BVI$ absolute magnitudes of SN 1999em and SN 2004dj differ from each other by 0.86–1.13 mag. This is considerably greater than the scatter of 0.3 mag in the LEV relation, but statistically not impossible; see Figure 15, where we plot with triangles the corrected absolute magnitudes of the two calibrating SNe, on top of the whole sample of SNe employed in the HDs. This difference leads to $H_0$ values in the range 62–105 km s$^{-1}$ Mpc$^{-1}$. With only two calibrating SNe, the SCM still has much room for delivering a more accurate and precise value for $H_0$.

4.5. Distances

We are in a position to calculate distances to all of the SNe of our sample. This can be done with the expression

$$\mu = m + \alpha \log (\nu_{\text{eff}}/5000) - \beta (V-I) - \langle M_{\text{corr}} \rangle,$$

where $\langle M_{\text{corr}} \rangle$ is the corrected absolute magnitude of SNe IIP on day $-30$. For this purpose, we employ the weighted mean of the two calibrating SNe given in Table 7. The resulting values are given in Table 8 for 32 SNe IIP; the last column shows the weighted average of their distance moduli and its uncertainty, assuming no covariance. As Equation 16 shows, it is straightforward to shift the resulting distance moduli to accommodate a new value for $\langle M_{\text{corr}} \rangle$. Unfortunately, we are not able to estimate expansion velocities for five objects, and consequently not their distances as well.

As mentioned in Section 1, we can evaluate the accuracy of the SCM from a comparison with EPM distances. For this purpose, we employ EPM distances recently calculated by Jones et al. (2009), which are summarized in Table 9 along with our distances for the 11 objects in common between SCM and EPM. Jones et al. (2009) determine EPM distances with two different sets of atmosphere models, both developed based on an analytic approach to calculate dilution factors as a function of a color temperature in order to correct the assumed blackbody emission. Their EPM distances were derived from average dilution factors and not from specific models for each SN. The EPM distances obtained using the models of Eastman et al. (1996, E96; Column 2) are 12% ± 5% shorter than our SCM distances. On the other hand, the EPM distances determined using the models of Dessart & Hillier (2005, D05; Column 3) are 40% ± 10% greater than our SCM distances. Both percentage shifts are calculated weighted by the uncertainty in the EPM and SCM distances. These systematic differences can be seen in the top panel of Figure 17, and more clearly in the fractional differences $(d_{\text{EPM}} - d_{\text{SCM}})/d_{\text{SCM}}$ plotted in the bottom panel.

The systematic differences among the two sets of EPM distances can be solely attributed to the atmosphere models.

**Table 7**

| SN    | $B$  | $V$  | $I$  | $H_0(B)$ | $H_0(V)$ | $H_0(I)$ |
|-------|------|------|------|----------|----------|----------|
| 1999em| $-17.94 \pm 0.20$ | $-18.41 \pm 0.20$ | $-18.24 \pm 0.19$ | 64.7 ± 6.8 | 62.2 ± 6.1 | 62.9 ± 6.0 |
| 2004dj| $-17.08 \pm 0.30$ | $-17.28 \pm 0.27$ | $-17.13 \pm 0.26$ | 95.7 ± 14.0 | 104.5 ± 13.7 | 104.8 ± 12.9 |
| Average| $-17.67 \pm 0.39$ | $-18.02 \pm 0.53$ | $-17.84 \pm 0.53$ | $71 \pm 12$ | $69 \pm 16$ | $70 \pm 16$ |

**Notes.** The uncertainties in $(H_0)$ and $(\langle M_{\text{corr}} \rangle)$ (the corrected absolute magnitude for $BVI$ in the second column) correspond to the weighted dispersion in each pair of values, which are a factor of 2–3 greater than the formal errors. This is a conservative uncertainty which takes into account the larger than expected discrepancy in absolute magnitude between the two objects.

Notes. Uncertainties are given in parentheses.

$a$ EPM distances from atmosphere models by Eastman et al. (1996); see Jones et al. (2009).

$b$ EPM distances from atmosphere models by Dessart & Hillier (2005); see Jones et al. (2009).
Figure 15. BVI-corrected absolute magnitudes (ordinate) against the Fe ii expansion velocity (abscissa) for 29–30 SNe (gray dots). We use the H0 values of Table 7 and the CMB redshifts to compute the distance moduli. The dashed lines show the mean corrected absolute magnitude for the gray data points. The black triangles are the two calibrating SNe, whose corrected absolute magnitudes were calculated using their Cepheid distances (see Table 7). Note that, as expected, the two calibrating SNe fall on each side of the corrected absolute magnitude distributions.

(A color version of this figure is available in the online journal.)

Figure 16. Residuals from the BVI HDs. The correlation between the V-filter and I-filter residuals against the B-filter residuals is shown in the upper and lower panels, respectively. The gray lines represent the fit from which the scatter is measured.

(A color version of this figure is available in the online journal.)

Figure 17. Direct comparison between SCM and EPM distances in Mpc calculated by Jones et al. (2009). Gray circles show the EPM distances computed from the atmosphere models of E96, while the black triangles represent EPM distances obtained from the D05 models. The bottom panel shows the fractional differences between both techniques against log(dSCM). In both panels, the dotted lines trace the systematic shifts of the EPM distances with respect to the SCM distances, ~40% and ~12%, using D05 and E96 atmosphere models, respectively. The dashed line in the top panel is fixed to show a slope of unity.

(A color version of this figure is available in the online journal.)

Figure 18. Similar to Figure 17, after removing systematic differences by bringing the EPM distances to the SCM scale (all in Mpc). Only random differences between EPM and SCM distances remain. For the E96 case, the discrepancies have a spread of 16%, while for the D05 case the scatter is 13%. The dashed line in the top panel is fixed to show a slope of unity.

(A color version of this figure is available in the online journal.)
of E96 and D05. New radiative transfer models of SNe IIP are necessary to understand the origin of this discrepancy. Besides the systematic errors in both EPM implementations, we can gain an understanding of the internal precision of EPM and SCM after removing the systematic differences and bringing all distances to a common scale. For this purpose, we correct the EPM distances to the SCM distance scale by removing the percentage shifts. The comparison is shown in Figure 18; the distance differences have dispersions of \( \sim 13\% \) and \( \sim 16\% \) using D05 and E96, respectively. This implies that SCM and EPM produce relative distances with an internal precision \( < 13\% - 16\% \). This agrees with the dispersions of 0.25–0.30 mag seen in the HDs restricted to SNe with \( c_{\text{CMB}} \geq 3000 \text{ km s}^{-1} \).

Further comparison between EPM and SCM can be made by taking the distance determination to SN 1999em. While Dessart & Hillier (2006) give a value of 11.5 \( \pm \) 1.0 Mpc, our SCM returns 12.6 \( \pm \) 0.6 Mpc. This agreement has a significance better than \( \sigma \), taking into account both sources of error.

5. DISCUSSION

5.1. Variations of the Extinction Law

The reddening law that minimizes the dispersion in the \( BVI \) HDs (\( R_V = 1.4 \pm 0.1 \)) turns out to be very different from the standard Galactic extinction law (\( R_V = 3.1 \); Cardelli et al. 1989). Recently, Poznanski et al. (2009) carried out a similar analysis using SNe IIP, which confirmed the low value obtained for \( R_V \) presented by Olivas (2008). There have also been several studies on this subject using SNe Ia. Most recently, Folatelli et al. (2010) solved for \( R_V \) in the same manner as our approach (i.e., by minimizing the dispersion in the HD) and obtained a value of \( R_V \approx 1.5 \), remarkably consistent with our value. Further evidence for low \( R_V \) values using SNe Ia were reported by others applying a similar procedure (Phillips et al. 1999; Altavilla et al. 2004; Reindl et al. 2005; Hicken et al. 2009; Wang et al. 2009).

Other studies of dust reddening based on diverse methods were performed for nearby galaxies giving values for \( R_V \) ranging between 2.4 and 4.3 (Rifatto 1990; Della Valle & Panagia 1992; Brosch & Loinger 1991; Finkelman et al. 2008). The ratio of total to selective absorption varies significantly over the range \( R_V \approx 2.6 - 5.5 \) even within our own Galaxy (Clayton & Cardelli 1988).

A lower value of \( R_V \) could be due to dust grains smaller than those in our Galaxy, since for a given value of \( A_V \) the \( E(B-V) \) reddening increases if the size of the grains decreases (Draine 2003). However, it would be very unlikely that our Galaxy is so special.

Most probably we are dealing with normal dust grains in the circumstellar medium, and therefore multiple scattering of photons makes the reddening law steeper and \( R_V \) smaller (Wang 2005; Goobar 2008). This effect should be opposite in the ultraviolet, hence it could be further tested with photometry at such wavelengths.

5.2. Internal Precision of the SCM

The \( BVI \) HDs have a scatter of \( \sim 0.3 \) mag, implying a precision in individual distances of \( \sim 15\% \). Part of this scatter might be due to the peculiar velocities of the SN host galaxies, and the intrinsic precision of SCM could be even better. In fact, when we perform a comparison for SNe in common between SCM and EPM, the distance differences are \( 13\% - 16\% \) (after removing the systematic difference among the SCM and EPM). This comparison is independent of the SN host-galaxy redshifts and implies that the internal precision in either of these two techniques must be lower than 13%–16%, since these differences comprise the combined uncertainties of both methods. This is an encouraging result; it implies that both EPM and SCM can produce high-precision relative distances, thus offering a new route to cosmological parameters.

5.3. The LEV Relation

We note that the dispersion in the HDs increases with wavelength. This seems contrary to expectations given that (1) the extinction effects decrease with wavelength and (2) metallicity affects the \( B \) band more than the other optical bands. Perhaps the luminosity is a function of not only velocity but also metallicity: \( M_V = f(\nu, [\text{Fe}/H]) \). If so, the velocity term in Equations (12) and (13) might be removing metallicity effects more efficiently at shorter wavelengths. This could be tested with \([\text{Fe}/H]\) measurements of SNe IIP. On the other hand, hydrodynamical simulations of SNe IIP suggest that there is an intrinsic scatter in the relation, which does not seem to be driven by any parameter of the model. Given the evidence we have, we can only claim a dependence of \( L \) on \( \nu \). The obvious physical explanation is that the internal energy is correlated with the kinetic energy, implying that the ratio of the internal energy to the kinetic energy is approximately independent of the explosion energy. As SN 1999br may suggest underluminous events might (1) change the shape of the LEV relation or (2) require a different explosion mechanism.

6. CONCLUSIONS

We established a library of 196 SN II optical spectra and developed a code which allows us to correct the observed photometry for Galactic extinction, \( K \)-terms, and host-galaxy extinction. We developed fitting procedures to the light curves, color curves, and velocity curves which allow us to precisely determine the transition time between the plateau and the tail phases. The use of this parameter as the time origin permitted us to line up the SNe to a common phase. The additional benefit of these fits is the interpolation of magnitudes, colors, and velocities over a wide range of epochs. The methodology explained above yields the following conclusions.

1. The comparison between our color-based dereddening technique and the spectroscopic reddenings is satisfactory within the uncertainties of both techniques. This is particularly encouraging since our method uses late-time photometric information, while the other method uses completely independent early-time spectroscopic data.

2. Using our new sample of SNe we recover the luminosity versus expansion-velocity trend (LEV relation) previously found by Hamuy & Pinto (2002).

3. We construct \( BVI \) HDs using two sets of host-galaxy reddenings. We demonstrate that the extinction corrections based on \( V-I \) color do a better job than the spectroscopic determinations, reaching dispersions of \( \sim 0.4 \) mag in the HDs. This scatter is somewhat higher than the 0.35 mag found previously by Hamuy (2003b, 2005). A much smaller dispersion of 0.3 mag is achieved when we use \( V-I \) colors to estimate reddening and allow \( R_V \) to vary. We obtain \( R_V = 1.4 \pm 0.1 \), much smaller than the Galactic value of 3.1. The low value of \( R_V \) can be explained by a different nature of the dust grains in the host galaxies of SNe IIP or
by scattering of light by circumstellar dust clouds (Wang 2005; Goobar 2008).

4. A clear correlation is found among residuals of $BVI$ HDs. After removing the correlation, the rms in the HDs decreases to 6\%–9\% in distance, comparable to the precision achieved with SNe Ia.

5. After calibrating our HDs with Cepheid distances to SN 1999em and SN 2004dj, our $BVI$ photometry leads to a Hubble constant in the range 62–105 km s$^{-1}$ Mpc$^{-1}$; this agrees with most of the values obtained by means of diverse modern techniques.

6. Finally, we calculate the distance moduli to our SNe and make a comparison against EPM distances from Jones et al. (2009). The 11 SNe in common show a systematic difference in distance between EPM and SCM, depending on the atmosphere models employed by EPM. Correcting for these shifts we bring the EPM distances to the SCM distance scale, from which we measure a dispersion of 13\%–16\%. This spread reflects the combined internal precision of EPM and SCM. Therefore, the internal precision in either of these two techniques must be $<13\%–16\%$.

This analysis confirms the utility of SNe IIP as cosmological probes, providing strong encouragement to future high-redshift studies. We find that one can determine relative distances from SNe IIP with a precision of 15\% or better. This uncertainty could be further reduced by including more SNe in the Hubble flow. In its current form the SCM requires both photometric and spectroscopic data. Since the latter are expensive to obtain (especially at high redshifts), it would be desirable to look for a photometric observable as a luminosity indicator instead of the expansion velocities.

We thank Luc Dessart, who generously provided the reddening estimates calculated by means of spectral fitting and the models plotted in Figure 4. F.O.E. also thanks him for stimulating discussions, as well as for accurate comments and suggestions. We are grateful to D. Leonard, J. Vinkó, D. Sahu, and A. Pastorello for providing digital spectra of SN 1999gi, SN 2004dj, SN 2004et, and SN 2005cs, respectively. F.O.E., M.H., G.P., and J.M. acknowledge support from the Millennium Center for Supernova Science through grant Pas06–045–F funded by “Programa Bicentenario de Ciencia y Tecnología de CONICYT” and “Programa Iniciativa Científica Millennium de MIDEPLAN,” as well as support provided by Centro de Astrofísica FONDAP 15010003 and by FondoCyt through grant 1060808 from the Center of Excellence in Astrophysics and Associated Technologies (PBFI 06). The supernova research of G.P. acknowledges partial support from Comité Mixto ESO-GOBIERNO DE CHILE. This paper is based in part on observations taken at the Cerro Tololo Inter-American Observatory, National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc. (AURA) under cooperative agreement with the NSF. Partly based on observations collected at the European Southern Observatory, Chile, in the course of program 163.H-0285.
