Aims
Cohorts of millions of people’s health records, whole genome sequencing, imaging, sensor, societal and publicly available data present a rapidly expanding digital trace of health. We aimed to critically review, for the first time, the challenges and potential of big data across early and late stages of translational cardiovascular disease research.

Methods and results
We sought exemplars based on literature reviews and expertise across the BigData@Heart Consortium. We identified formidable challenges including: data quality, knowing what data exist, the legal and ethical framework for their use, data sharing, building and maintaining public trust, developing standards for defining disease, developing tools for scalable, replicable science and equipping the clinical and scientific workforce with new inter-disciplinary skills. Opportunities claimed for big health record data include: richer profiles of health and disease from birth to death and from the molecular to the societal scale; accelerated understanding of disease causation and progression, discovery of new mechanisms and treatment-relevant disease sub-phenotypes, understanding health and diseases in whole populations and whole health systems and returning actionable feedback loops to improve (and potentially disrupt) existing models of research and care, with greater efficiency. In early translational research we identified exemplars including: discovery of fundamental biological processes e.g. linking exome sequences to lifelong electronic health records (EHR) (e.g. human knockout experiments); drug development: genomic approaches to drug target validation; precision medicine: e.g. DNA integrated into hospital EHR for pre-emptive pharmacogenomics. In late translational research we identified exemplars including: learning health systems with outcome trials integrated into clinical care; citizen driven health with 24/7 multi-parameter patient monitoring to improve outcomes and population-based linkages of multiple EHR sources for higher resolution clinical epidemiology and public health.
Conclusion

High volumes of inherently diverse (‘big’) EHR data are beginning to disrupt the nature of cardiovascular research and care. Such big data have the potential to improve our understanding of disease causation and classification relevant for early translation and to contribute actionable analytics to improve health and healthcare.

Keywords

Electronic health records • Health informatics • Bio-informatics • e-Health • Precision medicine • Translational research

Introduction

Electronic records relevant to the understanding of health and disease are found in diverse sources including not only the formal electronic health records (EHR) used in a growing number of healthcare organizations but also in omic, imaging, wearable and other data. These record data are increasingly being used for research, beyond the primary purpose for which they were collected. ‘A new era of data-based and more precise medical treatment’ is envisaged in which the practice of medicine becomes ‘evidence generating’. One emerging prospect is the use of big record data to traverse the translational pathways from early discovery phases of translation to later implementation phases. Previous reviews on mining EHR have not had a focus on cardiovascular care without a consideration of the translational pathways. We provide, for the first time, a critical review of big health record data for cardiovascular disease research across the translational spectrum, including early phases of discovery science, drug development and repurposing, and precision medicine, and late translational phases of learning health care systems, real world evidence, citizen-centred, and public health.

We review four areas in relation to big health record data:

(i) What data resources exist for cardiovascular disease research?
(ii) What are the challenges and barriers to realizing these opportunities?
(iii) What is the potential of such data in early translational research including discovery science, drug development and repurposing, precision medicine?
(iv) What is the potential of such data in late translational research including learning health care systems, real world evidence, citizen-centred and public health?

Big health record data resources

‘Big data’ are usefully characterized by ‘variety, volume, velocity, and value’ (a fifth V, veracity, relating to data quality is dealt with below in the challenges section). EHR are intrinsically ‘big’ due to their complexity (‘variety’) and numbers of patients and amount of information on each patient (‘volume’) and are collected for a variety of purposes (such as clinical care, billing, auditing, and quality monitoring).6–9

Tradeoffs between scale and depth

Figure 1 illustrates the variety and volume of data showing the relation between scale (number of people) and depth of phenotypic and omics information in different settings: national population-based, hospital-based, and disease or procedure based registries. The amount of phenotypic information in hospital EHR is much greater than any single registry; but such deeper hospital EHR data, has been challenging for researchers to access at scale.10 Hospital EHR potentially provide phenotypically detailed data on all diseases including clinical blood laboratory values, imaging, clinically used device data, and text.11–14

EHR comprise both structured and unstructured electronic data generated and captured during routine clinical care. Structured EHR data are recorded using controlled clinical terminologies such as Systematized Nomenclature of Medicine - Clinical terms (SNOMED-CT) or statistical classification systems such as ICD-9, ICD-9-CM, or ICD-10. Unstructured clinical data such as patient medical histories, discharge summaries, handover notes, and imaging reports are captured and recorded in patient’s health records as raw unformatted text. Such varied data, from different sources, has been likened to a tapestry which can be woven together using data linkage and integration techniques into a fine-grained longitudinal picture of health over time (the ‘human phenome sequence’). Such diverse data may offer higher resolution of clinically relevant clusters of diseases, causes, and classifiers.

Figure 1 makes an important distinction between those record resources with, and without genomic information. Boxes 1 and 2 provide further details of these resources which may be accessed for translational collaborative research. Biobanks and genomics consortia increasingly rely on EHR linkages for the ascertainment, validation, and phenotyping of not only specific disease outcomes but also the entire longitudinal phenome, as captured by an growing array of digital sources.16 Thus any one data resource may include combinations of researcher-generated data (such as omics) and researcher-harnessed data from EHR. Recent initiatives, such as the Innovative Medicines Initiative Big Data for Better Outcomes ‘Big Data@Heart’,17,18 and the American Heart Association (AHA) Verily AstraZeneca ‘One Brave Idea’ initiative,19 seek to exploit different sources of records and omics data, across multiple consented and anonymized sources—using the human as the ‘new model organism’.

Digital trace of health, outwith healthcare

The resources illustrated in Boxes 1 and 2 are making increasing use of such data sources including the physical environment, consumer information, socioeconomic and behavioural factors,20,21 and user-generated data from mobile health apps, wearables, sensors and social media.22–24 In particular the ‘always on’ aspects of mobile and wearables provides major opportunities.

In order to exploit these resources for translational research there is an increasing use of computer science approaches to harness publicly available curated knowledge in different fields including the
medical literature (e.g. PubMed), catalogues of genetic variant-phenotype associations (PhenoScanner,25,26), disease-agnostic drug targets (e.g. DrugBank,27), drug compounds (CHEMBL,28) and adverse drug reactions (e.g. IMI PROTECT).29

Volume: scale with cohorts of millions of participants

Higher resolution enquiry of common and rare diseases (or rare outcomes of common diseases, including drug side effects), demands higher sample sizes: 5000 people in the Framingham cohort, 500 000 in UK Biobank,16 15 000 000 in curated, linked EHR cohorts such as CALIBER,30–32 (Figure 3) and cross-national collections of EHR cohorts in 100 000 000.33–35 An individual’s interactions with the healthcare system may also generate big data; in the general population on average one person accumulates 1000 health events over 3 years in national coded data; a single cardiac MR scan has $10^8$ voxels and a clinical grade ($\times 30$) whole genome sequence provides 15 Gb of data.36,37

Value: opportunity to disrupt current models of research and care

The value of diverse, high volume data is already changing the way that health care is delivered and is yielding insights in early and late translation (see Potential for early translational research section). There are many sources of value in big data, beyond the immediate scientific dimensions of scale and longitudinal phenotypic resolution. These include the whole-system relevance when population and healthcare system records are used: for example, in countries with nationwide health record systems, EHR are the only way of obtaining large scale representative samples. The velocity of big data is an opportunity for real time analytics with intelligent feedback loops to improve healthcare systems and individual decision making. The exploitation of such rich big record data sources is more efficient and cost-effective compared with traditional researcher-led approaches since for example, in EHR cohorts the cost to research funders of baseline and follow up data collection is zero (the data exist as part of healthcare systems). The costs however of collating, cleaning and curating these data and meeting the challenges outlined below are substantial and are further elaborated below.

Big health data challenges

In realizing the opportunities of such diverse, large volume data there are formidable challenges. These include: knowing what data are potentially available, information governance, models of data access (responsible data sharing), building and maintaining public trust, developing standards for defining disease, and developing tools for scalable, replicable science and equipping the clinical and scientific work force with new inter-disciplinary skills.

Are the data of sufficient quality for a given research question?

Challenge: The quality of EHR data can be said to be ‘in the eye of the researcher’. In any given dataset the amount of missing data, often not

Box 1  Examples of large scale genomic—electronic health record resources

A. Population-based
UK-Biobank (UK, n = 500 000) Custom exome array, and exome sequencing, panel of 32 biomarkers, activity monitors and behaviours in 500k and cardiac MR underlay in 100k, linkage to hospital and primary care EHR (http://www.ukbiobank.ac.uk/).36

UCLEB (UK, n = 30 000) 14 consented British cohorts (12 population-based and 2 randomized trials) including ~30k participants Genomics, quantitative NMR metabolomics (~18k), Somalogic-Proteomics (2k), digitalized ECGs at baseline and in some studies with multiple follow-ups, and imaging (cardiac, carotid and brain) in a sub-set and linkage to hospital EHR (http://datacompass.lshtm.ac.uk/40/).

INTERVAL (UK, n = 50 000) ‘multi-omics’ bioresource, includes whole-genome sequencing (× 20 depth), genome-wide genotypes, lipidomics, proteomics, metabolomics, accelerometry (100 Hz, 7 days). Participants are linked to electronic health records and are aged 18–80 years. This study involves the largest experiment to date using SomaLogic’s proteomics assay. (http://www.intervalstudy.org.uk/)

EPI-CVD (EU, n = 520 000) case-cohort study, embedded in the 10-country, 22-centre pan-European EPIC cohort, involving >25 000 incident CVD cases. Multiple gene arrays (GWAS, exomechip, metabochip), >75 circulating biomarkers, extensive lifestyle profiling, and large subsets with serial measurements and linkage with electronic health records. (http://www.epiccvd.eu/)

China Kadoorie Biobank (China, n = 510 000) large Biobanked cohort investigating genetic and environmental causes of common chronic diseases in the Chinese population across 10 geographic regions (http://www.ckbiobank.org/site/).

B. Hospital-based

DiscovEHR project of the Regeneron Genetics Center and the Geisinger Health System (US, n = 42k): enrollees with whole exome sequencing and linkage to electronic health records over 15 years of clinical care (http://www.discoverehshare.com/).78,165,166

US Department of Veteran Affairs—Million Veteran Program (US, n = 500k): aiming to recruit 1 million users of the VA healthcare system and collect DNA specimens, tissue samples, electronic health records from VA and survey data (https://www.research.va.gov/mvp/)

Kaiser Permanente—Research Program on Genes, Environment and Health (US, n = 500k): Based on the over six million-member Kaiser Permanente Medical Care Plan of Northern California (KPNC) and Southern California (KPSC), the completed resource will link together comprehensive electronic medical records, data on relevant behavioural and environmental factors, and biobank data (genetic information from saliva and blood) from 500 000 consenting healthplan members (http://www.rpgeh.kaiser.org/).

Vanderbilt BioVU (US): BioVU is Vanderbilt’s biorepository of DNA extracted from discarded blood collected during routine clinical testing and linked to de-identified medical records in the Synthetic Derivative. The goal of BioVU is to provide a resource to Vanderbilt investigators for studies of genotype-phenotype associations (https://victr.vanderbilt.edu/pub/biovu/).

eMERGE (US, n = 105k): consists of nine study sites, two central sequencing and genotyping facilities, and a coordinating centre. eMERGE aims to continue to develop and validate electronic phenotyping algorithms for large-scale, high-throughput genomics research; to discover genetic variants related to complex traits; to disseminate results and lessons learned to the scientific community; and to deliver state-of-the-art genomic knowledge, methods, and approaches to clinical decision support and clinical care. Specifically: (i) sequence and assess the phenotypic implication of rare variants in ~100 clinically relevant genes presumed to affect gene function in about 25 000 individuals; (ii) assess the phenotypic implications of these variants, (iii) integrate genetic variants into EMRs for clinical care; and (iv) create community resources. (https://emerge.mc.vanderbilt.edu/)

Precision Medicine Initiative Cohort Program (US): longitudinal research effort that aims to engage one million or more US participants to enable research that will, over time, improve the ability to prevent and treat disease based on individual differences in lifestyle, environment and genetics. Participants will be invited to contribute a range of data about themselves by completing questionnaires, granting access to their electronic health records, providing blood and urine samples, undergoing physical evaluations and sharing real-time information via smartphones or wearable devices.(https://allofus.nih.gov/)

C. Disease-based

GENIUS-CHD (global, n = 250k) Coronary Heart Disease (CHD) patients (of which 129k are Acute Coronary Syndrome, ACS patients) with genotyping and biobanked samples and longitudinal follow up, from over 60 studies (including observational and randomized trials); central goal is to identify genetic and non-genetic determinants of subsequent or recurrent event risk, to facilitate discovery and validation of novel molecular pathways and drug targets for CHD secondary prevention. (http://www.genius-chd.com/)

HERMES Consortium (global, n = 11k) International consortium whose main aim is to identify the genetic determinants for incident HF and recurrent events with over 11 000 heart failure cases. (http://www.hermesconsortium.org/)

AFGen Consortium (US & EU) 30 studies with Exome-chips and GWAS array. Further phenotyping underway for 40k AF cases. (https://www.afgen.org/)
missing at random, or inaccurate data, may prohibit valid inference for some but not all research questions. Linked EHR, subject to robust pre-processing and cleaning, have been shown to provide measures of risk factors and wide range of diseases, and therefore offer a common scaffold on which to build specific research questions. Solution: A data mantra is ‘collect once, use many times’; and there are calls to make good quality clinical record keeping, as ‘research grade data’. It should be noted that accurate and complete recording, though desirable, does not replace appropriate study design or resolve limitations such as confounding by indication. Validity and data quality may be assessed in multiple ways including:

- Cross referencing multiple sources of data in the same individuals (each with their own strengths and limitations): e.g. for acute myocardial infarction linking four national population based sources (primary care, hospital, heart attack and death registries) (CALIBER) shows the positive predictive value and prognostic validity of cases defined in different sources, and allows development and sharing of phenotypic algorithms. Comparisons of trial adjudicated and medical claims data have been shown to be poor for some endpoints (e.g. bleeding), a comparison of adjudicated endpoints and administrative data showed good agreement. International comparisons: for example, EHR cohorts in heart attack survivors using ICD codes from different versions (ICD-9-CM, ICD-9, ICD-10) and different countries (US, Sweden, France and England) demonstrated for 12 risk factors consistent relative risks associations with fatal and non-fatal long term outcomes. In general populations the Emerging Risk Factors Collaboration (ERFC) has shown consistency across continents of risk factor associations with CHD incidence.

- Genomic approaches to validating case definitions: across 1000s of hospital ICD codes (‘phenome-wide’), reproduce associations from genome wide association studies obtained one phenotype at a time. If big data are to disrupt current research models then there is a need for searchable catalogues of data, metadata, feasibility counts (and ideally sample data) and access arrangements. The creation of public, standards-driven metadata and data portals can assist researchers in locating the right dataset for their research question and obtaining up to date details on data availability and accessibility. For example, the IMI-funded European Medical Information Framework (EMIF) data catalogue contains

**Box 2 Examples of large scale electronic health record resources without genomic information**

A. Population-based:

**CALIBER** (UK, n = 10M) CALIBER is a population based research platform of linked EHR and administrative health data from primary care (Clinical Practice Research Datalink), secondary care (Hospital Episode Statistics), disease (Myocardial Ischaemia National Audit Project) and death (Office for National Statistics) registries with longitudinal data on all prescribed medicines, diagnoses and blood values (>300k cases of AF, HF, and ACS) and a set of computational tools and research-ready phenotyping algorithms. (https://www.caliberresearch.org)

**ABUCASIS** (ES, n = 5M) EHR of entire Valencia population, including SIA (whole data from >5.100.000 subjects when they attend the physicians’ office in primary care; hospital morbidity, CMBD diagnostics of all the hospital admissions; mortality; GAIA (all prescriptions); vaccination visits to the Health Care Centre (in 2014 >60M); laboratory tests; Clinical Risk Groups (CRG) classification in each subject.

**Mondriaan** (NL, n = 15M) Pharmacy and claims data, harmonized with >500k GP data and subset with genetics data. 15 years follow-up. (http://mondriaanfoundation.org)

B. Hospital-based:

**National Institute for Health Research Health Informatics Collaborative (HIC) (UK):** platform for extracting phenotypically rich clinical data for research from hospital care across major NHS trusts (Oxford, Cambridge, UCLH, Guy’s and Imperial) and five disease areas (acute coronary syndrome, viral hepatitis, critical care, ovarian cancer, renal transplantation). (http://www.hic.nihr.ac.uk/)

**European Society of Cardiology European Research Programme (EOPR) AF** (multinational) Multinational (31 countries) observational study including patients with atrial fibrillation since 2012 (https://www.escardio.org/Research/Registries-&-surveys/Observational-registry-programme)

**National Institute for Cardiovascular Outcomes Research (NCOR) (UK)** National cardiovascular disease and procedure registries, with data on >5m individuals: ACS- through the Myocardial Ischaemia National Audit Project registry (MINAP) >1m patients; HF Registry >100k patients; Arrhythmia registry. (https://www.ucl.ac.uk/ncor)

**Swedish Heart Registry (Swedeheart)** (SE, n = 2M) Swedeheart is a national registry, including all patients undergoing coronary angiography, percutaneous coronary intervention, heart surgery and TAVI since 1990s, and almost all patients with acute myocardial infarction. Patients with MI, <75 years of age, are also followed for 1 year regarding secondary prevention. Swedeheart collects more than 500 variables. The database is regularly validated and the agreement between the registry and the electronic health records is 95–96%. (http://www.ucr.uu.se/swedeheart/)

**Mondriaan Health Care Centre** (NL, n = 15M) Pharmacy and claims data, harmonized with >500k GP data and subset with genetics data. 15 years follow-up. (http://mondriaanfoundation.org)
| Health challenges | Example                                                                 | Author/ year | N patients | N and type of sources* | Phenotype at baseline | Longitudinal phenotypes, omics and imaging | Analysis approaches |

information on over 300 data sources ranging from EHR, consented cohort studies, and surveillance datasets.

What is the legal and ethical framework for using such data?

**Challenge:** The information governance of big health data resources presents major challenges. The need for protecting privacy, confidentiality, discrimination and other potential harms is vital. However, how the regulatory environment proportionately balances these concerns with the potential benefits of data sharing (or, indeed, the harms by not sharing) is evolving.

**Solution:** Broad consent models, such as those in UK Biobank, have an important role, recognizing that it is not possible to stipulate all the potential research uses of data, nor how they will change. Some have argued that a new social contract is required with trusted use of data under innovative, proportionate governance delivering benefits to patients and public.

How are data shared?

**Challenge:** Despite exhortation from funders, journals and the public to share data, all too often this does not happen. Once researchers have permissions to access data, the mode of data sharing may pose challenges to the researcher.

**Solution:** Data sharing may involve: (i) material transfer agreements with data being physically shared e.g. UK Biobank; (ii) role-based secure remote access; (iii) distributed analyses where data remain...
stored in individual sources. The Global Alliance for Genomics and Health is establishing a common framework for harmonized sharing of genomic and clinical data. Distributed analytical tools (e.g., DataSHIELD, i2b2) and common data models (e.g., Observational Medical Outcomes Partnership Common Data Model (OMOP CDM)) can facilitate the remote and sequestered processing of complex datasets without the direct need to transfer data directly.

**How are disease and trait phenotypes defined and shared?**

**Challenge:** There is a lack of an international framework for defining, phenotyping, sub-phenotyping and discovering disease phenotypes in the context of health records. There are multiple controlled clinical terminologies and ontologies (including SNOMED-CT, ICD-10, and the Human Phenotype Ontology), but how these terms should be combined to define meaningful entities, let alone how they should be combined with research data is unclear. Currently many diseases lack internationally agreed criteria (preferably in a machine-readable format) for defining cases and non-cases; acute myocardial infarction, type 2 diabetes are exceptions. Current definitions of many diseases such as HF, AF and ACS span heterogeneous groups of patients and describe syndromes only rather than definitions based on understanding of molecular mechanism.

**Solution:** Sharing, validating and refining replicable, scalable EHR phenotyping algorithms requires international efforts. e.g. PheKB in hospital EHR (codes and text) and national structured records e.g. CALIBER. For example, defining atrial fibrillation using structured national health records may involve several hundred codes for diagnoses, drugs, procedures in a phenotyping algorithm. Clinical information standards such as openEHR or semantic web technologies can enable researchers to create computational representations of phenotyping algorithms which facilitate their sharing across the research community.

**What are the tools, methods and analytic approaches?**

**Challenge:** There is a wide array of relevant approaches from quantitative disciplines (mathematics, computer science, statistics, software engineering) and from biological disciplines: until recently these have seldom been focused on big health record data.

**Solution:** While there are 7 million hits per day on the European Bioinformatics Institute website; such national and international resources for health informatics are lacking. There is a need for organizations to be established which provide the analogous reference data, tools and methods in health informatics in general as well as integration across cardiovascular efforts in order to scale the science.

**What skills and training are required?**

**Challenge:** Few clinicians and health care professionals have had formal training in informatics, data science, (computer) coding, software development or other increasingly relevant skills. In many countries there are large shortfalls in the number of data scientists that have been trained.

**Solution:** National efforts are likely to be important to substantially increase the number, and change the kind, of people required to deliver data-based medicine: hybrid professionals, (for example sub-specialty physician accreditation in informatics), data scientists, data wranglers, and data-savvy health care professionals. The 10x10 (‘ten by ten’) program was launched in 2005 by the American Medical Informatics Association (AMIA) and Oregon Health & Science University (OHSU). The genesis for the program came when then-President of AMIA, Dr Charles Safran, called for at least one
physician and one nurse in each of the 6000 hospitals in the US to have some training in medical informatics. The National Academy of Science has recommended the importance of agile assembly and rewarding of scientific teams across diverse disciplines including genomics, basic biology, mathematics, computer science, statistics, engineering.

**Potential for early translational research**

In this section we provide selected exemplars of the potential of big health record data arising from the variety, volume and value of the data being realized and how big data are contributing to scientific advance in cardiovascular medicine from discovery of underlying disease mechanisms, disease taxonomy, of treatment relevant sub-types of disease which underpin drug development, and precision medicine.58,59

**Discovery in genetic and EHR data**

It is important to note that it is challenging to provide deep mechanistic insight in large scale EHR data resources given the limited availability of genetic information in sufficient depth. Bespoke, recalleable investigator-led studies such as East London Genes & Health (ELGH)60 and the NIHR BioResource61 enable the coupling of EHR data with extreme genotypes (or phenotypes) and enable their in-depth study using bespoke experimental protocols.52,62 Complete gene knockouts are highly informative about gene function with a recent study of 3222 British Pakistani-heritage exome-sequenced adults with high parental relatedness, discovered 1111 rare-variant homozygous likely loss of function (rLOF) genotypes predicted to disrupt (knockout) 781 genes. Linking to EHR, investigators observed no association of rLOF genotypes with prescription- or doctor-consultation rate, and no disease-related phenotypes in 33 of 42 individuals with rLOF genotypes in recessive Mendelian disease genes. Phased genome sequencing of a healthy PRDM9 knockout mother, her child and controls, showed meiotic recombination sites localized away from PRDM9-dependent hotspots, demonstrating PRDM9 redundancy in humans. Genomic approaches to validating case definitions: across 1000s of hospital ICD codes (‘phenome-wide’), reproduce associations from genome wide association studies obtained away from PRDM9-dependent hotspots, demonstrating PRDM9

**Discovery in larger scale epidemiology**

Big health record data can contribute to the discovery of new associations, which would be hard to generate from traditional consented cohorts without record linkage. For example, Figure 3 and Table 1, Rapsomaniki et al.12 illustrates how the power of large scale health records allows enquiry into less common cardiovascular diseases such as abdominal aortic aneurysm: Here there is a marked discordance between the strong association of diastolic blood pressure with abdominal aortic aneurysm compared with the lack of association with systolic blood pressure. These findings have implications for understanding the aetiology of abdominal aortic aneurysms, screening and prevention and understanding the underlying molecular mechanisms of disease for creating interventions.

A key prerequisite for precision medicine is the estimation of disease progression from the current patient state. Disease correlations and temporal disease progression (trajectories) have mainly been analysed with focus on a small number of diseases or using large-scale approaches without time consideration, exceeding a few years. Investigators performed a discovery-driven analysis of temporal disease progression patterns using data from an electronic health registry covering the whole population of Denmark. Utilizing the entire spectrum of diseases, they convert 14.9 years of registry data on 6.2 million patients into 1171 significant trajectories. Key diagnoses such as gout and chronic obstructive pulmonary disease (COPD) were identified as central to disease progression across many of these trajectories and hence important to diagnose earlier. Such data-driven trajectory analyses may be useful for predicting and preventing future diseases of individual patients.

**Discovery with deep phenotypic data**

Most cardiovascular diseases (including acute myocardial infarction) have syndromic descriptions and labels, which may span multiple underlying pathological disease processes.64 One approach to discovering mechanistically relevant disease types is to phenomap disease. For example, Table 1, Shah et al.65 in heart failure with preserved ejection fraction machine learning on 46 continuous clinical, laboratory, electrocardiographic, and echocardiographic findings has been used to define mutually exclusive groups, which relate to subsequent outcomes.65–67 The cardiac atlas project (of normal and diseased hearts) is an example of large scale collaborations on feature extraction in imaging68,69 using data sharing in standard formats Digital Imaging and Communications in Medicine (DICOM) of pixel and non-pixel data.70 Personalization using physiological simulations71 for example for cardiac resynchronization therapy71,72 is proposed. Unstructured free-text data in EHR may add further resolution for patient stratification and disease co-occurrence estimation, which subsequently can be mapped to systems biology frameworks.67

**Drug development and repurposing**

More drugs are required to prevent and treat cardiovascular diseases. Since 2000, the FDA has approved only two new classes of cardiac drugs with widespread application: P2Y12 receptor inhibitors (such as clopidogrel, ticagrelor, prasugrel) and novel oral anti-coagulants (such as dabigatran, apixaban, rivaroxaban, edoxaban). Costly, late drug failures occurring within phase III trials have been recently seen for CETP inhibitors which raise HDL-cholesterol (HDL-C),73–75 iabradine which lowers the heart rate76 and darapladib, a selective oral inhibitor of lipoprotein-associated phospholipase A2.

**Discovering and validating drug targets**

EHR-DNA resources may play an increasingly important role in drug discovery, genomic drug target validation, marker validation and in drug repurposing. For example, NPC1L1 (Table 1, Sitzel et al.78) demonstrates the strategy that human mutations that inactivate a gene encoding a drug target can mimic the action of an inhibitory drug—here ezetemibe—and thus can be used to infer potential effects of that drug. Ezetemibe is known to affect the marker (LDL cholesterol) but, until recently, not the disease (myocardial infarction). Among the largest sources of cases of MI and controls in this study was a DNA resource integrated into a health system with rich EHR.78 The discovery of PCSK9 as a drug target to lower cholesterol,79 which could in principle have been made in EHR-DNA resources, illustrates the importance of rare variants in identification of pathways relevant to the whole population. Mendelian randomization studies are
important in evaluating whether markers—such as heart rate and HDL cholesterol—are causal for the disease of interest. Such genetic studies have questioned the role of heart rate and HDL cholesterol in the aetiology of heart attack. **Drug repurposing and PheWAS** Identifying novel disease indications for already approved drugs (repositioning or repurposing) has been successful for sildenafil and beta blockers (repurposed for heart failure). The discovery that IL-6 is causally related to myocardial infarction has led to proposals for repurposing tocilizumab, which is currently licensed for rheumatoid arthritis. Here the question is what other phenotypes are associated with the drug-relevant genetic variant? (Figure 2) For example, examining 778 disease phenotypes based on ICD codes in the EHR identified potential novel pleiotropic associations with a variant in the sodium channel gene SCN10A. This variant is associated not only with the anticipated arrhythmias, but (possibly) also with unanticipated diseases, here cholecystitis. Recent interest has been to scale this approach to systematically evaluate drugs against a wide range of untested diseases. To be successful this would require substantially larger EHR-DNA resources incorporating longitudinal disease trajectories from big record data and might aid drug repurposing efforts. **Trial endpoint optimization** Drugs may fail in phase III trials because of the composition of primary endpoints. For example, the inclusion of myocardial infarction—which is not causally related to heart rate—in the trial of the heart rate lowering drug ivabradine. In trials of treatments in type 2 diabetes the primary endpoint often includes non-fatal MI, non-fatal stroke and death from cardiovascular diseases. Large scale record cohorts however demonstrate that the initial presentation of cardiovascular disease is commonly heart failure and peripheral arterial disease—not of which are prominent components of primary trial endpoints. Moreover, inclusion of some diseases might dilute the trial endpoint since type 2 diabetes is associated with a lower risk of aneurysms. In CALIBER, the ability to reliably resolve 12 different CVDs demonstrates that the majority of incident cases of CVD are neither heart attack nor stroke and that risk factor associations are heterogeneous across different diseases. **Trials of new drugs** Once the ‘right drug, the right target and right endpoints’ have been evaluated, the next and most costly hurdle is to carry out the definitive experiment—the phase III trial. Twenty years ago the West of Scotland Coronary Prevention Study (WOSCOPS) statin trial study demonstrated the value of EHR linkage for long-term follow-up of clinical outcomes. Underpinning regulatory and data standards and interoperability issues are the focus of international initiatives, but in cardiovascular disease there has not yet been a pragmatic phase III trial of a pre-licence drug. The Safford Lung Study (GSK, relovair) is the world’s first such trial and is set in a regional ‘whole health system’ EHR. **Integrating pharmacogenomics** Multi-scale biological data, when combined with these deeper phenotypes, underpin further dissection of disease. Whole genome sequencing is beginning to be implemented in clinical care, for molecular diagnosis, identification of risk of subsequent wide range of diseases, reproductive considerations and drug response. It is in drug response that precision medicine is finding early application. Here the goal is to identify biologically relevant subgroups in which either the benefit is greater, or, more commonly, the harms are fewer (interaction on the relative risk scale). Pre-emptive genomic testing, in which actionable genetic variants have already been assessed prior to drug exposure, is beginning to be implemented in the EHR for the care of patients (Table 1, Van Driest et al. **Personalized estimates of benefits and harms** One example of the need to individualize risk comes from prolonged dual anti-platelet therapy among patients who have survived 1 year after acute myocardial infarction. For example, in prognostic models for risk of atherothrombotic and bleeding events have recently been developed and validated and allow an updatable estimation of net clinical benefits for each patient to guide the decision for prolonged dual anti-platelet therapy. Clinical record data are highly effective in distinguishing risk groups, for diverse diseases and in diverse settings and higher risk patients usually have more absolute benefit than those in lower risk groups (i.e. without biologic interaction). Clinical risk prediction algorithms and decision support are rapidly proliferating in CVD and many tools can be envisaged in the management of a single patient, spanning benefits and harms at different time points. Clinical data can outperform the Framingham risk score, and can flexibly model start point populations and endpoints and be easily updated in the light of new imaging, genetic information, and implemented in clinical practice. Predictions may be improved by incorporating clinical trajectories. For example patients in whom blood pressure declines over time, without diagnosed heart failure, have a worse survival than those whose blood pressure remains stable. Using all available data points across data modalities combined with machine learning or Bayesian network models may further add to prediction. **Potential for late translational research** Learning health care systems Increasing costs, complexity of patients and fragmentation of healthcare systems are challenges to delivering high quality care with better outcomes and value. Far from a data-based health care system, all too often there is a largely data free (or data silo’d) approach where the benefits of science and evidence, and experience of care are characterized by missed opportunities, waste and harm. The state of ‘digital maturity’ in hospitals and health eco-systems, varies hugely. Arguably, more people die from lack of use of data than misuse of any other technology. The concept of learning health systems puts informatics and big data as a central driver of quality, not only seeking to put what is known to work into practice (closing the ‘second translational gap’) but also contributing in new ways to understanding what is effective. It is worth noting that however ‘big’ the data are observational analyses will not replace the need for randomized intervention studies due to the inherent limitations of observational studies to evaluate reliably any modest effect of interventions.
## Table 2  
Late translation exemplars of big health record data research: learning health systems, citizen driven health, and public health

| Health challenges | Example | Author/ year | N patients (000’s) | N and type of sources* | Phenotype at baseline | Longitudinal phenotypes, omics and imaging | Design/Analysis/ Disciplines |
|-------------------|---------|--------------|-------------------|------------------------|-----------------------|----------------------------------------|-------------------------------|
| Learning health systems | Integrating trials in clinical care | Thrombus aspiration at the time of primary coronary intervention (TASTE trial) has no impact on short or long term outcomes\(^{\text{115}}\) | Frobert et al. 2014 | 7.244k | 3 | QR, A, M | STEMI, Angio findings | Follow up for ACM, stent restem, uf MI (1 yr) | RCT: Point of care, registry embedded, pragmatic |
| Comparing effectiveness of whole health systems | Large differences in care and outcomes between UK and Sweden (all hospitals)\(^{\text{117}}\) | Chung et al. 2014 | 500k | 2 | QR, M | NSTEMI | ACM (30 d) | Survival analysis |
| Vigilance for safety | Mining text could have detected the Vioxx – acute MI signal earlier than conventional pharmacoepidemiology approaches\(^{\text{13}}\) | Lependu et al. 2013 | 1.8k | 1 hospital records structured and text | All diagnosed diseases rofecexib | All drug safety signals including (acute MI) | Text mining |
| Targeting cost effective care | Cost effectiveness decision models provide willingness to pay estimates in different risk groups, and different treatment benefits for stable coronary disease\(^{\text{138}}\) | Asana et al. 2016 | 100k | 4 EHR-primary care, QR, A, M | Stable CAD, stable angina (xxx AMI) | All hospitals, procedures, drug use, resource use | Health economics |
| Citizen driven health | Real time real world 24/7 monitoring: the ‘sensed self’ | Pacemaker monitoring might lower event rates\(^{\text{141}}\) | Hindricks et al. 2014 | 0.716k | 4 | Implantable monitor | Heart failure Multi-parameter monitoring | Primary outcome was: ACM, hospitalization for heart failure, worsening of NYHA class. | RCT of a detailed monitoring intervention |

| | Understanding the public through social media | Twitter language might predict community heart disease rates\(^{\text{23}}\) | Eichstaedt et al. 2015 | 148 m country mapped | CDC atherosclerosis Twitter | Mapping of words used in tweets to psychological constructs | N/A | Ecological correlations at county level |
| Public health | Epidemiology of all CVDs and clinically relevant sub-types of disease | Incidence and survival of NSTEMI and STEMI ICD9-CN\(^{\text{45}}\) | Yeh et al 2010 | 3000k | 2 | HMO, M | 46 086 hospitalizations STEMI/NSTEMI | All cause mortality 30 day | Cohort |

Continued
Building trials into health systems

A trial of thrombus aspiration demonstrated the feasibility of randomizing a high proportion of patients at point of care in the setting of a national quality registry.15,116 (Table 2, Fröbert and James115). These findings and the growing evidence that EHR can provide a platform for assessing feasibility, refining protocols and recruiting patients41,90,117 have stimulated major interest because of the lower cost and higher speed of trial delivery. Pragmatic point-of-care EHR based trials are underway e.g. of high vs. low dose aspirin trial among people with stable coronary disease.118–120

Building quality into healthcare delivery: decision support and data based medicine

Early examples of data-based medicine are already here, with clinical data providing both the ‘brain’ to understand what needs fixing and the ‘spinal cord’ to help fix it. For example, analysis of health record cohorts provides understanding of the patient journey and cumulative missed opportunities of cardiovascular care over time21,122 and may provide risk prediction tools which are derived from clinical data, and used in practice to support healthcare decision making102,123.

A small but growing number of hospitals have a suite of readily modifiable information feedback loops to improve care.124 There is a need for more empirical demonstration of the impact on outcomes of these systems. A key challenge lies in intelligent real time systems.125–127 Practice-based medicine128,129 involves large-scale, real time studies (based on a health system’s own data) to generate evidence directly relevant to the patient in front of the clinician. Sometimes this observation is sufficient, sometimes it allows systematic identification of the need for trials. These trials may exploit the efficiency of big data in point-of-care individual randomized trials embedded in a learning health system or may involve randomizing clusters of health care professionals, for example to evaluate complex interventions, such as decision support.130,131

Big data for safety vigilance

Mining EHR in real time with both coded and text data is an important source of safety information. For example, Table 2, Lependu et al.13 the excess myocardial infarction risk associated with rofecoxib (Vioxx) could have been detected 1–2 years earlier had records. There are international initiatives to achieve the vast scale required to evaluate drug safety in up to 150 million patients.34,132–135 Using the Medicare Patient Safety Monitoring System there was a decline in adverse events following heart attack and heart failure, but not for pneumonia or conditions requiring surgery.136 possibly as a result of more organized quality initiatives in the cardiovascular diseases.

International comparisons of whole system care and outcomes

Nationwide, policy relevant comparisons of care and outcomes among people with CVDs across health systems have only recently been reported. For example, Table 2, Chung et al.137 using data from ongoing quality registries from all hospitals in Sweden and the UK,
including more than half a million patients, demonstrates that 30-day MI mortality was higher in the UK than in Sweden. Politicians, policy makers and health care professionals seek to make claims that their health systems deliver world class care and outcomes—ongoing, even semi-automated comparisons across countries might be used to evaluate whether such claims are ‘data-based’.

Cost effectiveness of innovation
Big data provide new opportunities in understanding the cost effectiveness of existing and new interventions. Because of the ability to assess baseline risks in unselected general populations (commonly higher risk than those reported in trials), such ‘real world evidence’ is increasingly required by payers and the regulators. As more data sources are linked, greater granularity of the care data (e.g. 67 different types of primary care ‘consultation’) may provide more accurate and more complete resource use data. For example, Table 2, Asaria et al.138 cost-effectiveness decision models can be developed before trials report to estimate the willingness to pay and pricing of a drug according to different trial benefits (relative risk reductions) applied to patients at different strata of risk.

Citizen-centred health
People increasingly have more and different information than their doctor or researcher raising new possibilities of ‘disintermediation’, potentially disrupting current models of health care and research.139 The heart and circulation are increasingly observable as a ‘sensed self’ with novel wireless devices for mobile monitoring, with huge new data streams.22,146 Smartphone apps and sensors are available to record and transmit to physician, electrocardiograms (e.g. to screen for atrial fibrillation), heart rate, blood pressure, radial artery waveforms, respiratory rate, oxygen saturation, temperature, even ultrasound.22 These may provide deeper, naturalistic phenotyping in areas often lacking in the clinical record, including: physical activity, weight, diet, sleep, quality of life, and symptoms and medication compliance. For accelerometer questions remain about how best to analyse and present such data.

Implantable devices such as pacemakers provide tele-monitoring data which might reduce the risk of fatal and non-fatal outcomes in patients with heart failure (Table 2, Hindricks et al.141). Interventions can be delivered through mobile means and text messaging may increase smoking cessation rates (Table 2, Free et al.142). Apple ResearchKit provides new ways to recruit people rapidly into studies. Open, publicly available data donated and shared by citizens is becoming increasingly available. User generated content in social media are inherently public and the language used in twitter can be used to predict community heart disease rates (Table 2, Eichstaedt et al.23) and it is plausible that Google searches24 might give clues to environmental pollution triggers of acute cardiovascular events. As patients increasingly access, own and control their health records,143 they may share their clinical records, genetic and other data through initiatives like ‘Patients like me’ and ‘23 And Me’, offering networks of individuals to develop communities of interest e.g. in rare diseases for orphan drugs. Citizens may do their own science; with schoolchildren exploiting publically available data to develop diagnostic tools using artificial neural networks.144

Public health
There are major gaps in our ability to prevent the onset of and prolong life in, many of the most common cardiovascular diseases in the 21st century including atrial fibrillation, heart failure, peripheral arterial disease. There are also gaps in our ability to measure disease and model the impact of interventions in populations. Clinicians diagnose more specific entities than ‘heart attack’, ‘CHD’ or ‘CVD’ yet conventional consented cohorts have lacked the statistical size or the phenotypic resolution to measure clinically relevant sub-types of disease. Big data can study the diseases that clinicians diagnose to provide scalable, population based, updatable measurements of modern disease burden vital for the evaluation of alternative strategies of prevention. For example, big data can be used to estimate the incidence and survival of the treatment-relevant sub-types of MI (ST elevation and non-ST elevation) (Table 2, Exemplar Yeh et al.145 or stable angina).146

Meaningfully complex models of public health
Existing models of disease prevention are simple and often focus on one disease or one risk factor at a time. Big data invite a richer understanding of the importance of: multiple diseases co-occurring;147 networks of risk factors (obesity20 and smoking148 and diseases149; fine-grained geospatial resolution; rare Table 2, Pujades-Rodriguez et al.151 and common diseases; diseases as causes or triggers of cardiovascular events152; diseases of developing151 and developed countries, and across multiple biological scales through to societal influences on health). In order to understand weather and climate big data, with appropriately complex mathematical models, are used in national institutes,153 but no such analogue exists for public health.

Big socio-economic data
Unlike many technological advances, big data may have a role in actionable understanding of, and reductions in, inequalities in health and healthcare in rich and poor countries. The opportunity to move to a neighbourhood with lower poverty may reduce obesity and diabetes.154 The data in this trial were collected through traditional means, but such data could have been captured in part with cross-government record linkages. Big data are important for achieving sustainable development goals155 and recommendations have been made for the recording social and behavioural determinants in the clinical record.156 Linking health record data to an individual’s lifelong tax contributions may provide new policy relevant insights into the relations between wealth and health.157,158 Cross-government approaches to big data might open up enquiry into neglected populations with insights to improve the cardiovascular health of those on social welfare benefits, the homeless, refugee, and prison populations.

Population impact of interventions
Big data can be used to evaluate the population impact of healthcare or public health interventions.159 For example, Table 2, Sims et al.,160 shows how health records have been used to demonstrate the impact of the public smoking ban on hospital admissions for heart attack.160–162 Importantly, big health data are a means to evaluate the impact on population health of primary care163 the state of digital maturity of a hospital or health system164 or the existence of quality and outcome registries.
Conclusion

Big health record data are beginning to disrupt the nature of cardiovascular research as well as models of care. Exploiting such data is beginning to improve understanding of cardiovascular disease causation and classification, and contributing actionable analytics to improve health and healthcare, but major challenges need to be addressed to realize more fully their potential.
