Approximate maximum entropy principles via Goemans-Williamson with applications to provable variational methods

Yuanzhi Li Andrej Risteski *
July 13, 2016

Abstract

The well known maximum-entropy principle due to Jaynes, which states that given mean parameters, the maximum entropy distribution matching them is in an exponential family, has been very popular in machine learning due to its “Occam’s razor” interpretation. Unfortunately, calculating the potentials in the maximum-entropy distribution is intractable (Bresler et al., 2014). We provide computationally efficient versions of this principle when the mean parameters are pairwise moments: we design distributions that approximately match given pairwise moments, while having entropy which is comparable to the maximum entropy distribution matching those moments.

We additionally provide surprising applications of the approximate maximum entropy principle to designing provable variational methods for partition function calculations for Ising models without any assumptions on the potentials of the model. More precisely, we show that in every temperature, we can get approximation guarantees for the log-partition function comparable to those in the low-temperature limit, which is the setting of optimization of quadratic forms over the hypercube. (Alon and Naor, 2006)

1 Introduction

Maximum entropy principle The maximum entropy principle (Jaynes, 1957) states that given mean parameters, i.e. $\mathbb{E}_\mu[\phi_t(x)]$ for a family of functionals $\phi_t(x), t \in [1, T]$, where $\mu$ is distribution over the hypercube $\{-1, 1\}^n$, the entropy-maximizing distribution $\mu$ is an exponential family distribution, i.e. $\mu(x) \propto \exp(\sum_{t=1}^T J_t \phi_t(x))$ for some potentials $J_t, t \in [1, T]$. This principle has been one of the reasons for the popularity of graphical models in machine learning: the “maximum entropy” assumption is interpreted as “minimal assumptions” on the distribution other than what is known about it.

However, this principle is problematic from a computational point of view. Due to results of (Bresler et al., 2014; Singh and Vishnoi, 2014), the potentials $J_t$ of the Ising model, in many cases, are impossible to estimate well in polynomial time, unless NP = RP – so merely getting the description of the maximum entropy distribution is already hard. Moreover, in order to extract useful information about this distribution, usually we would also like to at least be able to sample efficiently from this distribution – which is typically NP-hard or even #P-hard.

In this paper we address this issue in certain cases. We provide a “bi-criteria” approximation for the special case where the functionals $\phi_t(x)$ are $\phi_{i,j}(x) = x_i x_j$, i.e. pairwise moments: we produce an efficiently sampleable distribution over the hypercube which matches these moments up to multiplicative constant factors, and has entropy at most a constant factor smaller from from the entropy of the maximum entropy distribution. 

1There is a more general way to state this principle over an arbitrary domain, not just the hypercube, but for clarity in this paper we will focus on the hypercube only.

2In fact, we produce a distribution with entropy $\Omega(n)$, which implies the latter claim since the maximum entropy of any distribution of over $\{-1, 1\}^n$ is at most $n$.

Furthermore, the distribution we consider is very natural: the sign of a multivariate normal variable. This provides theoretical explanation for the phenomenon observed by the computational neuroscience community (Bethge and Berens, 2007) that this distribution (named *dichotomized Gaussian*) there has near-maximum entropy.

**Variational methods** The above results also allow us to get results for a seemingly unrelated problem – approximating the **partition function** $Z = \sum_{\mathbf{x} \in \{-1,1\}^n} \exp(\sum_{t=1}^T J_t \phi_t(\mathbf{x}))$ of a member of an exponential family, which is an important step to calculate marginals.

One of the ways to calculate partition function is variational methods: namely, expressing $\log Z$ as an optimization problem. While there is a plethora of work on variational methods, of many flavors (mean field, Bethe/Kikuchi relaxations, TRBP, etc; for a survey, see (Wainwright and Jordan, 2008)), they typically come either with no guarantees, or with guarantees in very constrained cases (e.g. loopless graphs; graphs with large girth, etc. (Wainwright et al., 2003; 2005; Weiss, 2000)). While this is a rich area of research, the following extremely basic research question has not been answered:

**What is the best approximation guarantee on the partition function in the worst case (with no additional assumptions on the potentials)?**

In the low-temperature limit, i.e. when $|J_t| \to \infty$, $\log Z \to \max_{\mathbf{x} \in \{-1,1\}^n} \sum_{t=1}^T J_t \phi_t(\mathbf{x})$ - i.e. the question reduces to purely to optimization. In this regime, this question has very satisfying answers for many families $\phi_t(\mathbf{x})$. One classical example is when the functionals are $\phi_{i,j}(\mathbf{x}) = x_i x_j$. In the graphical model community, these are known as Ising models, and in the optimization community this is the problem of optimizing quadratic forms and has been studied by (Charikar and Wirth, 2004; Alon and Naor, 2006; Alon et al., 2006).

In the optimization version, the previous papers showed that in the worst case, one can get $O(\log n)$ factor multiplicative factor approximation of the log of the partition function, and that unless $P = NP$, one cannot get better than constant factor approximations of it.

In the finite-temperature version, it is known that it is NP-hard to achieve a $1 + \epsilon$ factor approximation to the partition function (i.e. construct a FPRAS) (Sly and Sun, 2012), but nothing is known about coarser approximations. We prove in this paper, informally, that one can get comparable multiplicative guarantees on the log-partition function in the finite temperature case as well – using the tools and insights we develop on the maximum entropy principles.

Our methods are extremely generic, and likely to apply to many other exponential families, where algorithms based on linear/semidefinite programming relaxations are known to give good guarantees in the optimization regime.

## 2 Statements of results and prior work

**Approximate maximum entropy** The main theorem in this section is the following one.

**Theorem 2.1.** For any covariance matrix $\Sigma$ of a centered distribution $\mu : \{-1,1\}^n \to \mathbb{R}$, i.e. $\mathbb{E}_\mu[\mathbf{x}_i \mathbf{x}_j] = \Sigma_{i,j}$, $\mathbb{E}_\mu[\mathbf{x}_i] = 0$, there is an efficiently sampleable distribution $\bar{\mu}$, which can be sampled as sign($g$), where $g \sim N(0, \Sigma + \beta I)$ such that the following holds: $\frac{\mathcal{G}}{1 + \beta} \Sigma_{i,j} \leq \mathbb{E}_{\bar{\mu}}[X_i X_j] \leq \frac{1}{1 + \beta} \Sigma_{i,j}$ for a fixed constant $\mathcal{G}$, and entropy $H(\bar{\mu}) \geq \frac{n}{28} \frac{(3^{1/2} + \sqrt{7})^2}{\sqrt{4\beta}}$, for any $\beta \geq \frac{1}{3\gamma^2}$.

There are two prior works on computational issues relating to maximum entropy principles, both proving hardness results.

(Bresler et al., 2014) considers the “hard-core” model where the functionals $\phi_t$ are such that the distribution $\mu(\mathbf{x})$ puts zero mass on configurations $\mathbf{x}$ which are not independent sets with respect to some graph $G$. They show that unless $NP = RP$, there is no FPRAS for calculating the potential functions $J_t$, given the mean parameters $\mathbb{E}_\mu[\phi_t(\mathbf{x})]$.

(Singh and Vishnoi, 2014) prove an equivalence between calculating the mean parameters and calculating partition functions. More precisely, they show that given an oracle that can calculate the mean parameters up to a $(1 + \epsilon)$ multiplicative factor in time $O(\text{poly}(1/\epsilon))$, one can calculate the partition function of the same exponential family up to $(1 + O(\text{poly}(\epsilon)))$ multiplicative factor, in time $O(\text{poly}(1/\epsilon))$. Note, the $\epsilon$ in this work potentially needs to be polynomially small in $n$ (i.e. an oracle that can calculate the mean parameters to a fixed multiplicative constant cannot be used.)
Both results prove hardness for fine-grained approximations to the maximum entropy principle, and ask for outputting approximations to the mean parameters. Our result circumvents these hardness results by providing a distribution which is not in the maximum-entropy exponential family, and is allowed to only approximately match the moments as well. To the best of our knowledge, such an approximation, while very natural, has not been considered in the literature.

**Provable variational methods** The main theorems in this section will concern the approximation factor that can be achieved by degree-2 pseudo-moment relaxations of the standard variational principle due to Gibbs. (Ellis, 2012) As outlined before, we will be concerned with a particularly popular exponential family: Ising models. We will prove the following three results:

**Theorem 2.2** (Ferromagnetic Ising, informal). There is a convex programming relaxation based on degree-2 pseudo-moments that calculates up to multiplicative approximation factor $50$ the value of $\log Z$ where $Z$ is the partition function of the exponential distribution $\mu(x) \propto \exp(\sum_{i,j} J_{i,j} x_i x_j)$ for $J_{i,j} > 0$.

**Theorem 2.3** (Ising model, informal). There is a convex programming relaxation based on degree-2 pseudo-moments that calculates up to multiplicative approximation factor $O(\log n)$ the value of $\log Z$ where $Z$ is the partition function of the exponential distribution $\mu(x) \propto \exp(\sum_{i,j} J_{i,j} x_i x_j)$. 

**Theorem 2.4** (Ising model, informal). There is a convex programming relaxation based on degree-2 pseudo-moments that calculates up to multiplicative approximation factor $O(\log \chi(G))$ the value of $\log Z$ where $Z$ is the partition function of the exponential distribution $\mu(x) \propto \exp(\sum_{i,j \in E(G)} J_{i,j} x_i x_j)$ and $G = (V(G), E(G))$ is a graph with chromatic number $\chi(G)$.

Note Theorem 2.4 is strictly more general than Theorem 2.3, however the proof of Theorem 2.3 uses less heavy machinery and is illuminating enough that we feel merits being presented as a separate result.

While a lot of work is done on variational methods in general (see the survey by (Wainwright and Jordan, 2008) for a detailed overview), to the best of our knowledge nothing is known about the worst-case guarantee that we are interested in here. Moreover, other than a recent paper by (Risteski, 2016), no other work has provided provable bounds for variational methods that proceed via a convex relaxation and a rounding thereof.  

(Risteski, 2016) provides guarantees in the case of Ising models that are also based on pseudo-moment relaxations of the variational principle, albeit only in the special case when the graph is “dense” in a suitably defined sense. The results there are very specific to the density assumption and can not be adapted to our worst-case setting.

Finally, we mention that in the special case of the ferromagnetic Ising models, an algorithm based on MCMC was provided by (Jerrum and Sinclair, 1993), which can give an approximation factor of $(1 + \epsilon)$ to the partition function and runs in time $O(n^{11} \text{poly}(1/\epsilon))$. In spite of this, the focus of this part of our paper is to provide understanding of variational methods in certain cases, as they continue to be popular in practice for their faster running time compared to MCMC-based methods but are theoretically much more poorly studied.

### 3 Approximate maximum entropy principles

Let us recall what the problem we want to solve:

**Approximate maximum entropy principles** We are given a positive-semidefinite matrix $\Sigma \in \mathbb{R}^{n \times n}$ with $\Sigma_{i,i} = 1, \forall i \in [n]$, which is the covariance matrix of a centered distribution over $\{-1,1\}^n$, i.e. $\mathbb{E}_{\mu}[x_i x_j] = \Sigma_{i,j}, \mathbb{E}_{\mu}[x_i] = 0$, for a distribution $\mu : \{-1,1\}^n \to \mathbb{R}$. We wish to produce a distribution $\tilde{\mu} : \{-1,1\}^n \to \mathbb{R}$ with pairwise

\[^3\text{In some sense, it is possible to give provable bounds for Bethe-entropy based relaxations, via analyzing belief propagation directly, which has been done in cases where there is correlation decay and the graph is locally tree-like. (Wainwright and Jordan, 2008) has a detailed overview of such results.}

\[^4\text{More precisely, they prove that in the case when $\forall i,j, \Delta |J_{i,j}| \leq \Delta^2 \sum_{i,j} |J_{i,j}|$, one can get an additive $\epsilon(\sum_{i,j} J_{i,j})$ approximation to $\log Z$ in time $n^{O(\sqrt{\Delta})}$.} \]
are independent, the covariance of entropy distribution with covariance covariances that match the given ones up to constant factors, and entropy within a constant factor of the maximum entropy. \(^5\)

Before stating the result formally, it will be useful to define the following constant:

**Definition 3.1.** Define the constant \( \tilde{G} = \min_{t \in [-1,1]} \left\{ \frac{2}{\pi} \arcsin(t)/t \right\} \approx 0.64. \)

We will prove the following main theorem:

**Theorem 3.1** (Main, approximate entropy principle). For any positive-semidefinite matrix \( \Sigma \) with \( \Sigma_{i,i} = 1, \forall i \), there is an efficiently sampleable distribution \( \tilde{\mu} : \{-1,1\}^n \to \mathbb{R} \), which can be sampled as \( \text{sign}(g) \), where \( g \sim \mathcal{N}(0, \Sigma + \beta I) \), and satisfies \( \frac{\tilde{G}}{1+\beta} \Sigma_{i,j} \leq E_{\tilde{\mu}}[x_i x_j] \leq \frac{\tilde{G}}{1+\beta} \Sigma_{i,j} \) and has entropy \( H(\tilde{\mu}) \geq \frac{n}{25} (3^{3/4} \sqrt{\pi-1})^2 \), where \( \beta \geq \frac{1}{3 \sqrt{2}}. \)

Note \( \tilde{\mu} \) is in fact very close to the one which is classically used to round semidefinite relaxations for solving the MAX-CUT problem. (Goemans and Williamson, 1995) We will prove Theorem 3.1 in two parts – by first lower bounding the entropy of \( \tilde{\mu} \), and then by bounding the moments of \( \tilde{\mu} \).

**Theorem 3.2.** The entropy of the distribution \( \tilde{\mu} \) satisfies \( H(\tilde{\mu}) \geq \frac{n}{25} (3^{3/4} \sqrt{\pi-1})^2 \) when \( \beta \geq \frac{1}{3 \sqrt{2}}. \)

**Proof.** A sample \( g \) from \( \mathcal{N}(0, \bar{\Sigma}) \) can be produced by sampling \( g_1 \sim \mathcal{N}(0, \Sigma), g_2 \sim \mathcal{N}(0, \beta I) \) and setting \( g = g_1 + g_2. \)

The sum of two multivariate normals is again a multivariate normal. Furthermore, the mean of \( g \) is 0, and since \( g_1, g_2 \) are independent, the covariance of \( g \) is \( \Sigma + \beta I = \bar{\Sigma}. \)

Let’s denote the random variable \( Y = \text{sign}(g_1 + g_2) \) which is distributed according to \( \tilde{\mu} \). We wish to lower bound the entropy of \( Y \). Toward that goal, denote the random variable \( S := \{ i \in [n] : \|(g_1)_i\| \leq cD \} \) for \( c, D \) to be chosen. Then, we have: for \( \gamma = \frac{c-1}{c} \),

\[
H(Y) \geq H(Y|S) = \sum_{S \subseteq [n]} \Pr[S = S] H(Y|S = S) \geq \sum_{S \subseteq [n], |S| \geq \gamma n} \Pr[S = S] H(Y|S = S)
\]

where the first inequality follows since conditioning doesn’t decrease entropy, and the latter by the non-negativity of entropy. Continue the calculation we can get:

\[
\sum_{S \subseteq [n], |S| \geq \gamma n} \Pr[S = S] H(Y|S = S) \geq \sum_{S \subseteq [n], |S| \geq \gamma n} \Pr[S = S] \min_{S \subseteq [n], |S| \geq \gamma n} H(Y|S = S) = \Pr[|S| \geq \gamma n] \min_{S \subseteq [n], |S| \geq \gamma n} H(Y|S = S)
\]

We will lower bound \( \Pr[|S| \geq \gamma n] \) first. Notice that \( \mathbb{E}[(\sum_{i=1}^n (g_1)_i^2)] = n \), therefore by Markov’s inequality,

\[
\Pr \left[ \sum_{i=1}^n (g_1)_i^2 \geq Dn \right] \leq \frac{1}{D}. \]

On the other hand, if \( \sum_{i=1}^n (g_1)_i^2 \leq Dn \), then \( |\{ i : (g_1)^2_i \geq cD \}| \leq \frac{n}{c} \), which means that \( |\{ i : (g_1)_i^2 \leq cD \}| \geq n - \frac{n}{c} = \frac{(c-1)n}{c} = \gamma n \). Putting things together, this means \( \Pr[|S| \geq \gamma n] \geq 1 - \frac{1}{D}. \)

It remains to lower bound \( \min_{S \subseteq [n], |S| \geq \gamma n} H(Y|S = S) \). For every \( S \subseteq [n], |S| \geq \gamma n \), denote by \( Y_S \) the coordinates of \( Y \) restricted to \( S \), we get

\[
H(Y|S = S) \geq H(Y_S|S = S) \geq H_{\infty}(Y_S|S = S) = -\log(\max_{y_S} \Pr[Y_S = y_S|S = S])
\]

(where \( H_{\infty} \) is the min-entropy) so we only need to bound \( \max_{y_S} \Pr[Y_S = y_S|S = S] \)

We will now, for any \( y_S \), upper bound \( \Pr[Y_S = y_S|S = S] \). Recall that the event \( S = S \) implies that \( \forall i \in S, \|(g_1)_i\| \leq cD \). Since \( g_2 \) is independent of \( g_1 \), we know that for every fixed \( g \in \mathbb{R}^n \):

\[
\Pr[Y_S = y_S|S = S, g_1 = g] = \prod_{i \in S} \Pr[\text{sign}(g)_i + (g_2)_i = y_i]
\]

\(^5\)Note for a distribution over \( \{-1,1\}^n \), the maximal entropy a distribution can have is \( n \), which is achieved by the uniform distribution.
For a fixed $i \in [S]$, consider the term $\Pr[\sign([g]_i + [g_2]_i) = y_i]$. Without loss of generality, let’s assume $[g]_i > 0$ (the proof is completely symmetric in the other case). Then, since $[g]_i$ is positive and $g_2$ has mean 0, we have $\Pr([g]_i + (g_2)_i < 0) \leq \frac{1}{2}$.

Moreover,

$$
\Pr ([g]_i + [g_2]_i > 0) = \Pr([g_2]_i > 0) \Pr ([g]_i + [g_2]_i > 0 \mid [g_2]_i > 0) \\
+ \Pr([g_2]_i < 0) \Pr ([g]_i + [g_2]_i > 0 \mid [g_2]_i < 0)
$$

The first term is upper bounded by $\frac{1}{2}$ since $\Pr([g_2]_i > 0) \leq \frac{1}{2}$. The second term we will bound using standard Gaussian tail bounds:

$$
\Pr ([g]_i + [g_2]_i > 0 \mid [g_2]_i < 0) \leq \Pr ([|g_2|_i] \leq |[g]|_i \mid [g_2]_i < 0) \\
= \Pr ([|g_2|_i] \leq |[g]|_i) \leq \Pr ([(|g_2|)^2 \leq cD]) = 1 - \Pr ([|g_2|_i]^2 > cD] \\
\leq 1 - \frac{2}{\sqrt{2\pi}} \exp (-cD/2\beta) \left( \sqrt{\frac{\beta}{cD}} - \left( \sqrt{\frac{\beta}{cD}} \right)^3 \right)
$$

which implies

$$
\Pr([g_2]_i < 0) \Pr([g]_i + [g_2]_i > 0 \mid [g_2]_i < 0) \leq \frac{1}{2} \left( 1 - \frac{2}{\sqrt{2\pi}} \exp (-cD/2\beta) \left( \sqrt{\frac{\beta}{cD}} - \left( \sqrt{\frac{\beta}{cD}} \right)^3 \right) \right)
$$

Putting together, we have

$$
\Pr[\sign((g_1)_i + (g_2)_i) = y_i] \leq 1 - \frac{1}{\sqrt{2\pi}} \exp (-cD/2\beta) \left( \sqrt{\frac{\beta}{cD}} - \left( \sqrt{\frac{\beta}{cD}} \right)^3 \right)
$$

Together with the fact that $|S| \geq \gamma n$ we get

$$
\Pr[Y_S = y_S \mid S = s, g_1 = g] \leq \left[ 1 - \frac{1}{\sqrt{2\pi}} \exp (-cD/2\beta) \left( \sqrt{\frac{\beta}{cD}} - \left( \sqrt{\frac{\beta}{cD}} \right)^3 \right) \right]^\gamma n
$$

which implies that

$$
H(Y) \geq - \left(1 - \frac{1}{D} \right) \frac{(c - 1)n}{c} \log \left[ 1 - \frac{1}{\sqrt{2\pi}} \exp (-cD/2\beta) \left( \sqrt{\frac{\beta}{cD}} - \left( \sqrt{\frac{\beta}{cD}} \right)^3 \right) \right]
$$

By setting $c = D = 3^{1/4} \sqrt{\beta}$ and a straightforward (albeit unpleasant) calculation, we can check that $H(Y) \geq \frac{\gamma n}{25 \ (3^{1/4} \sqrt{\beta} - 1)^2}$, as we need.

\[\square\]

We next show that the moments of the distribution are preserved up to a constant $\frac{\gamma}{\beta}$.  

**Lemma 3.1.** The distribution $\tilde{\mu}$ has $\frac{\gamma}{\beta + \beta} \Sigma_{i,j} \leq E_{\tilde{\mu}} [X_iX_j] \leq \frac{1}{\beta + \beta} \Sigma_{i,j}$

**Proof.** Consider the Gram decomposition of $\tilde{\Sigma}_{i,j} = \langle v_i, v_j \rangle$. Then, $\mathcal{N}(0, \tilde{\Sigma})$ is in distribution equal to $(\sign((v_1, s)), \ldots, \sign((v_n, s)))$ where $s \sim \mathcal{N}(0, I)$. Similarly as in the analysis of Goemans-Williamson (Goemans and Williamson, 1995), if $\tilde{v}_i = \frac{1}{\|v_i\|} v_i$, we have $\tilde{G}(\tilde{v}_i, \tilde{v}_j) \leq E_{\tilde{\mu}} [X_iX_j] = \frac{2}{\pi} \arcsin (\langle \tilde{v}_i, \tilde{v}_j \rangle) \leq \langle \tilde{v}_i, \tilde{v}_j \rangle$.  

5
However, since $\langle \tilde{v}_i, \tilde{v}_j \rangle = \frac{1}{\|v_i\| \|v_j\|} \langle v_i, v_j \rangle = \frac{1}{\|v_i\| \|v_j\|} \Sigma_{i,j} = \frac{1}{\|v_i\| \|v_j\|} \Sigma_{i,j}$ and $\|v_i\| = \sqrt{\Sigma_{i,i}} = \sqrt{1 + \beta}$, $\forall i \in [1, n]$, we get that $\frac{G}{1 + \beta} \Sigma_{i,j} \leq E_\mu[X_i X_j] \leq \frac{1}{1 + \beta} \Sigma_{i,j}$ as we want.

Lemma 3.2 and 3.1 together imply Theorem 3.1.

4 Provable bounds for variational methods

We will in this section consider applications of the approximate maximum entropy principles we developed for calculating partition functions of Ising models. Before we dive into the results, we give brief preliminaries on variational methods and pseudo-moment convex relaxations.

Preliminaries on variational methods and pseudo-moment convex relaxations Recall, variational methods are based on the following simple lemma, which characterizes $\log Z$ as the solution of an optimization problem. It essentially dates back to Gibbs (Ellis, 2012), who used it in the context of statistical mechanics, though it has been rediscovered by machine learning researchers (Wainwright and Jordan, 2008):

**Lemma 4.1** (Variational characterization of $\log Z$). Let us denote by $\mathcal{M}$ the polytope of distributions over $\{-1, 1\}^n$. Then,

$$\log Z = \max_{\mu \in \mathcal{M}} \left\{ \sum_t J_t E_\mu[\phi_t(\mathbf{x})] + H(\mu) \right\}$$

(1)

While the above lemma reduces calculating $\log Z$ to an optimization problem, optimizing over the polytope $\mathcal{M}$ is impossible in polynomial time. We will proceed in a way which is natural for optimization problems – by instead optimizing over a relaxation $\mathcal{M}'$ of that polytope.

The relaxation will be associated with the degree-2 Lasserre hierarchy. Intuitively, $\mathcal{M}'$ has as variables tentative pairwise moments of a distribution of $\{-1, 1\}^n$, and it imposes all constraints on the moments that hold for distributions over $\{-1, 1\}^n$. To define $\mathcal{M}'$ more precisely we will need the following notion: (for a more in-depth review of moment-based convex hierarchies, the reader can consult (Barak et al., 2014))

**Definition 4.1.** A degree-2 pseudo-moment $^6 \tilde{E}_\nu[\cdot]$ is a linear operator mapping polynomials of degree 2 to $\mathbb{R}$, such that $\tilde{E}_\nu[x_i^2] = 1$, and $\tilde{E}_\nu[p(\mathbf{x})^2] \geq 0$ for any polynomial $p(\mathbf{x})$ of degree 1.

We will be optimizing over the polytope $\mathcal{M}'$ of all degree-2 pseudo-moments, i.e. we will consider solving

$$\max_{\tilde{E}_\nu[\cdot] \in \mathcal{M}'} \left\{ \sum_t J_t \tilde{E}_\nu[\phi_t(\mathbf{x})] + \tilde{H}(\tilde{E}_\nu[\cdot]) \right\}$$

where $\tilde{H}$ will be a proxy for the entropy we will have to define (since entropy is a global property that depends on all moments, and $\tilde{E}_\nu$ only contains information about second order moments).

To see this optimization problem is convex, we show that it can easily be written as a semidefinite program. Namely, note that the pseudo-moment operators are linear, so it suffices to define them over monomials only. Hence, the variables will simply be $\tilde{E}_\nu(\mathbf{x}_S)$ for all monomials $\mathbf{x}_S$ of degree at most 2. The constraints $\tilde{E}_\nu[x_i^2] = 1$ then are clearly linear, as is the “energy part” of the objective function. So we only need to worry about the constraint $\tilde{E}_\nu[p(\mathbf{x})^2] \geq 0$ and the entropy functional.

We claim the constraint $\tilde{E}_\nu[p(\mathbf{x})^2] \geq 0$ can be written as a PSD constraint: namely if we define the matrix $Q$, which is indexed by all the monomials of degree at most 1, and it satisfies $Q(\mathbf{x}_S, \mathbf{x}_T) = \tilde{E}_\nu[\mathbf{x}_S \mathbf{x}_T]$. It is easy to see that $\tilde{E}_\nu[p(\mathbf{x})^2] \geq 0 \iff Q \succeq 0$.

$^6$The reason $\tilde{E}_\nu[\cdot]$ is called a pseudo-moment, is that it behaves like the moments of a distribution $\nu : \{-1, 1\}^n \rightarrow [0, 1]$, albeit only over polynomials of degree at most 2.
Hence, the final concern is how to write an expression for the entropy in terms of the low-order moments, since entropy is a global property that depends on all moments. There are many candidates for this in machine learning, like Bethe/Kikuchi entropy, tree-reweighted Bethe entropy, log-determinant etc. However, in the worst case – none of them come with any guarantees. We will in fact show that the entropy functional is not an issue when we only care about worst case guarantees – we will relax the entropy trivially to an upper bound of $n$.

Given all of this, the final relaxation we will consider is:

$$
\max_{\tilde{\nu} \in \mathcal{M}'} \left\{ \sum_i J_i \tilde{E}_{\nu}[\phi_i(\mathbf{x})] + n \right\}
$$

(2)

From the prior setup it is clear that the solution to (2) is an upper bound to $\log Z$. To prove a claim like Theorem 2.3 or Theorem 2.4, we will then provide a rounding of the solution. In this instance, this will mean producing a distribution $\tilde{\nu}$ which has the value of $\sum_i J_i \tilde{E}_{\nu}[\phi_i(\mathbf{x})] + H(\tilde{\nu})$ comparable to the value of the solution. Note this is slightly different than the usual requirement in optimization, where one cares only about producing a single $\mathbf{x} \in \{-1, 1\}^n$ with comparable value to the solution. Our distribution $\tilde{\nu}$ will have entropy $\Omega(n)$, and preserves the “energy” portion of the objective $\sum_i J_i \tilde{E}_{\nu}[\phi_i(\mathbf{x})]$ up to a comparable factor to what is achievable in the optimization setting.

**Warmup: exponential family analogue of MAX-CUT** As a warmup, to illustrate the basic ideas behind the above rounding strategy, before we consider Ising models we consider the exponential family analogue of MAX-CUT. It is defined by the functionals $\phi_{i,j}(\mathbf{x}) = (x_i - x_j)^2$. Concretely, we wish to approximate the partition function of the distribution $\mu(\mathbf{x}) \propto \exp \left( \sum_{i,j} J_{i,j}(x_i - x_j)^2 \right)$. We will prove the following simple observation:

**Observation 4.1.** The relaxation (2) provides a factor 2 approximation of $\log Z$.

**Proof.** We proceed as outlined in the previous section, by providing a rounding of (2). We point out again, unlike the standard case in optimization, where typically one needs to produce an assignment of the variables, because of the entropy term here it is crucial that the rounding produces a distribution.

The distribution $\tilde{\nu}$ we produce here will be especially simple: we will round each $x_i$ independently with probability $\frac{1}{2}$. Then, clearly $H(\tilde{\nu}) = n$. On the other hand, we similarly have $\Pr_{\tilde{\nu}}[(x_i - x_j)^2 = 1] = \frac{1}{2}$, since $x_i$ and $x_j$ are rounded independently. Hence, $E_{\tilde{\nu}}[(x_i - x_j)^2] \geq \frac{1}{2}$. Altogether, this implies $\sum_{i,j} J_{i,j} E_{\tilde{\nu}}[(x_i - x_j)^2] + H(\tilde{\nu}) \geq \frac{1}{2} \left( \sum_{i,j} J_{i,j} E_{\nu}[(x_i - x_j)^2] + n \right)$ as we needed.

\[\square\]

### 4.1 Ising models

We proceed with the main results of this section on Ising models, which is the case where $\phi_{i,j}(\mathbf{x}) = x_i x_j$. We will split into the ferromagnetic and general case separately, as outlined in Section 2.

To be concrete, we will be given potentials $J_{i,j}$, and we wish to calculate the partition function of the Ising model $\mu(\mathbf{x}) \propto \exp(\sum_{i,j} J_{i,j} \mathbf{x}_i \mathbf{x}_j)$.

**Ferromagnetic case**

Recall, in the ferromagnetic case of Ising model, we have the conditions that the potentials $J_{i,j} > 0$. We will provide a convex relaxation which has a constant factor approximation in this case. First, recall the famous First Griffiths inequality due to Griffiths (Griffiths, 1967) which states that in the ferromagnetic case, $E_\nu[\mathbf{x}_i \mathbf{x}_j] \geq 0$, $\forall i, j$.

Using this inequality, we will look at the following natural strengthening of the relaxation (2):

$$
\max_{E_{\nu}[\mathbf{x}_i \mathbf{x}_j] \geq 0, \forall i, j} \left\{ \sum_i J_i \tilde{E}_{\nu}[\phi_i(\mathbf{x})] + n \right\}
$$

(3)

We will prove the following theorem, as a straightforward implication of our claims from Section 3:

**Theorem 4.1.** The relaxation (3) provides a factor 50 approximation of $\log Z$. 

7
Proof. Notice, due to Griffiths’ inequality, (3) is in fact a relaxation of the Gibbs variational principle and hence an upper bound of $\log Z$. Same as before, we will provide a rounding of (3). We will use the distribution $\tilde{\mu}$ we designed in Section 3 the sign of a Gaussian with covariance matrix $\Sigma + \beta I$, for a $\beta$ which we will specify. By Lemma 3.2, we then have $H(\tilde{\mu}) \geq \frac{n}{25} \frac{(3^{1/4}\sqrt{n}-1)^2}{\sqrt{\beta}}$ whenever $\beta \geq \frac{1}{3\sqrt{T}}$. By Lemma 3.1, on the other hand, we can prove that $E_{\tilde{\mu}}[x_i x_j] \geq \frac{G}{1 + \beta} \tilde{E}_\nu[x_i x_j]$

By setting $\beta = 21.8202$, we get $\frac{n}{25} \frac{(3^{1/4}\sqrt{n}-1)^2}{\sqrt{\beta}} \geq 0.02$ and $\frac{G}{1 + \beta} \geq 0.02$, which implies that

$$\sum_{i,j} J_{i,j} E_{\tilde{\mu}}[x_i x_j] + H(\tilde{\mu}) \geq 0.02 \left( \sum_{i,j} J_{i,j} \tilde{E}_\nu[x_i x_j] + n \right)$$

which implies the claim we want. \qed

Note that the above proof does not work in the general Ising model case: when $\tilde{E}_\nu[x_i x_j]$ can be either positive or negative, even if we preserved each $\tilde{E}_\nu[x_i x_j]$ up to a constant factor, this may not preserve the sum $\sum_{i,j} J_{i,j} \tilde{E}_\nu[x_i x_j]$ due to cancellations in that expression.

**General Ising models case**

Finally, we will tackle the general Ising model case. As noted in the previous section, the straightforward application of the results proven in Section 3 doesn’t work, so we have to consider a different rounding – again inspired by roundings used in optimization.

The intuition is the same as in the ferromagnetic case: we wish to design a rounding which preserves the “energy” portion of the objective, while having a high entropy. In the previous section, this was achieved by modifying the Goemans-Williamson rounding so that it produces a high-entropy distribution. We will do a similar thing here, by modifying roundings due to (Charikar and Wirth, 2004) and (Alon et al., 2006).

The convex relaxation we will consider will just be the basic one (2), and we will prove the following two theorems:

**Theorem 4.2.** The relaxation (2) provides a factor $O(\log n)$ approximation to $\log Z$ when $\phi_{i,j}(x) = x_i x_j$.

**Theorem 4.3.** The relaxation (2) provides a factor $O(\log(\chi(G)))$ approximation to $\log Z$ when $\phi_{i,j}(x) = x_i x_j$ for $i, j \in E(G)$ of some graph $G = (V(G), E(G))$, and $\chi(G)$ is the chromatic number of $G$.

Since the chromatic number of a graph is bounded by $n$, the second theorem is in fact strictly stronger than the first, however the proof of the first theorem uses less heavy machinery, and is illuminating enough to be presented on its own.

Before delving into the proof of Theorem 4.2, we review the rounding used by (Charikar and Wirth, 2004) in the case of maximizing quadratic forms:

**Algorithm 1** Quadratic form rounding by (Charikar and Wirth, 2004)

1: Input: A pseudo-moment matrix $\Sigma_{i,j} = E_\nu[x_i x_j]$
2: Output: A sample $x$ from a distribution $\rho$
3: Sample $g$ from the standard Gaussian $N(0, I)$.
4: Consider the vector $h$, such that $h_i = g_i / T$, $T = \sqrt{4 \log n}$
5: Consider the vector $r$, such that $r_i = \frac{h_i}{|h_i|}$, if $|h_i| > 1$, and $r_i = h_i$ otherwise.
6: Produce the rounded vector $x \in \{-1, 1\}^n$, s.t.

\[
x_i = \begin{cases} +1, & \text{with probability } \frac{1+r_i}{2} \\ -1, & \text{with probability } \frac{1-r_i}{2} \end{cases}
\]
Algorithm 2 Scaled down quadratic form rounding

1: Input: A pseudo-moment matrix \( \Sigma_{ij} = \mathbb{E}_{\nu}[x_i x_j] \)
2: Output: A sample \( x \) from a distribution \( \tilde{\mu} \)
3: Sample \( g \) from the standard Gaussian \( N(0, I) \).
4: Consider the vector \( h_i \), such that \( h_i = g_i / T, T = \sqrt{4 \log n} \)
5: Consider the vector \( r_i \), such that \( r_i' = \frac{1}{2} |h_i| \), if \(|h_i| > 1\), and \( r_i' = \frac{1}{2} h_i \), otherwise.
6: Produce the rounded vector \( x \in \{-1, 1\}^n \), s.t.

\[
  x_i = \begin{cases} 
    +1, & \text{with probability } \frac{1 + r_i}{2} \\
    -1, & \text{with probability } \frac{1 - r_i}{2}
  \end{cases}
\]

With that in hand, we can prove Theorem 4.2

Proof of Theorem 4.2. The proof again consists of exhibiting a rounding. Our rounding will essentially be the same as (Charikar and Wirth, 2004), except in step 3, we will produce a vector \( r_i' \) by scaling down the vector \( r_i \) by 2 coordinate-wise. For full clarity, the rounding is presented in Algorithm 2.

We again, need to analyze the entropy and the moments of the distribution \( \tilde{\mu} \) that this rounding produces. Let us focus on the entropy first.

Since conditioning does not decrease entropy, it’s true that \( H(\tilde{\mu}) = H(x) \geq H(x|r) \), so it suffices to lower bound that quantity. However, note that it holds that \( r_i \leq \frac{1}{2} \), and each \( x_i \) is rounded independently conditional on \( r_i \), so we have:

\[
  H(x|r) = \sum_i H(x_i|r_i) = \sum_i \left( \frac{1 + r_i}{2} \log \left( \frac{1 + r_i}{2} \right) + \frac{1 - r_i}{2} \left( \frac{1 - r_i}{2} \right) \right) \geq \left( 2 - \frac{3}{4} \log 3 \right) n
\]

Consider now the moments of the distribution.

Let us denote the distribution that the rounding 1 produces by \( \rho \). By Theorem 1 in (Charikar and Wirth, 2004), we have

\[
  \sum_{i,j} J_{i,j} \mathbb{E}_\rho[x_i x_j] \geq O \left( \frac{1}{\log n} \right) \sum_{i,j} J_{i,j} \mathbb{E}_\nu[x_i x_j]
\]

Additional, both our and the (Charikar and Wirth, 2004) roundings are such that \( \mathbb{E}_\rho[x_i x_j] = \mathbb{E}_\nu \mathbb{E}_{x|r}[x_i x_j] \) and \( \mathbb{E}_\rho[x_i x_j] = \mathbb{E}_\nu \mathbb{E}_{x|r}[x_i x_j] \). Furthermore, as noted in (Charikar and Wirth, 2004), it is easy to check that \( \mathbb{E}[x_i x_j|r'] = r_i' r_j' \) and obviously \( r_i' = 2r_i, \forall i \) in distribution, so we have:

\[
  \mathbb{E}_\rho[x_i x_j] = \mathbb{E}_\rho \mathbb{E}_{x|r}[x_i x_j] = \frac{1}{4} \mathbb{E}_\rho \mathbb{E}_{x|r}[x_i x_j] = \frac{1}{4} \mathbb{E}_\rho[x_i x_j]
\]

But, this directly implies

\[
  \sum_{i,j} J_{i,j} \mathbb{E}_\rho[x_i x_j] = \frac{1}{4} \sum_{i,j} J_{i,j} \mathbb{E}_\rho[x_i x_j] \geq O \left( \frac{1}{\log n} \right) \sum_{i,j} J_{i,j} \mathbb{E}_\nu[x_i x_j]
\]

as we needed.

Next, we prove the more general Theorem 4.3.

Before proceeding, let’s recall for completeness the following definition of a chromatic number.

Definition 4.2 (Chromatic number). The chromatic number \( \chi(G) \) of a graph \( G = (V(G), E(G)) \) is defined as the minimum number of colors in a coloring of the vertices \( V(G) \), such that no vertices \( i, j : (i, j) \in E(G) \) are colored with the same color.
Also, let us denote by $S^{n-1}$ the set of unit vectors in $\mathbb{R}^n$ and $L_\infty[0,1]$ the set of (essentially) bounded functions: the functions which are bounded except on a set of measure zero.

Then, we can recall Theorem 3.3 from (Alon et al., 2006):

**Theorem 4.4** (Alon et al., 2006). There exists an absolute constant $c$ such that the following holds: Let $G = (V(G), E(G))$ be an undirected graph on $n$ vertices without self-loops$^7$, let $\chi(G)$ be the chromatic number of $G$. Then for every function $f : V(G) \rightarrow \mathbb{R}^n$, there exists a function $F : V \rightarrow L_\infty[0,1]$ so that for every $i \in V(G)$, $\|F(i)\|_\infty \leq \sqrt{c\chi(G)}$ and for every $(i,j) \in E(G)$,

$$
\langle f(i), f(j) \rangle = \int_0^1 F(i)(t)F(j)(t)dt
$$

Now, we can prove Theorem 4.3

**Proof of Theorem 4.3.** The proof is similar, though a little more complicated than the proof of Theorem 4.2.

Let $\hat{E}_\nu[\cdot]$ be the solution of the relaxation. By matrix formulation of the pseudo-moment relaxation in Section 4, we know that $\hat{E}_\nu[x, x] = \langle f(i), f(j) \rangle$ for some unit vectors $f(i), f(j)$.

Hence, by theorem 4.4, there exists a function $F : V \rightarrow L_\infty[0,1]$ so that for every $i \in V(G)$, $\|F(i)\|_\infty \leq \sqrt{c\chi(G)}$ and for every $(i,j) \in E(G)$,

$$
\hat{E}_\nu[x, x] = \int_0^1 F(i)(t)F(j)(t)dt
$$

Consider the following rounding:

- Pick a $t$ uniformly at random from $[0,1]$.
- Consider the function $h_t : V \rightarrow \mathbb{R}$, such that $h_t(i) = \frac{F(i)(t)}{2\sqrt{c\chi(G)}}$
- Produce the rounded vector $x \in \{-1,1\}^{V(G)}$, s.t.

$$
x_i = \begin{cases} 
+1, & \text{with probability } \frac{1+h_t(i)}{2} \\
-1, & \text{with probability } \frac{1-h_t(i)}{2}
\end{cases}
$$

Note importantly that the algorithm does not need to perform this rounding – it is for the analysis of the approximation factor of the relaxation. Therefore, we need not construct it algorithmically.

Let us denote this distribution as $\tilde{\nu}$. We first show that $\tilde{\nu}$ has entropy at least $(2 - \frac{3}{4} \log 3) n$. Note that each $x_i$ are round independently conditional on $t$. Moreover, since $\|F(v)\|_\infty \leq \sqrt{c\chi(G)}$, we know that $h_t(v) \leq \frac{1}{2}$. Therefore, for every fixed $t_0 \in [0,1]

$$
H(\tilde{\nu} \mid t = t_0) = \sum_{i \in V(G)} H(x_i \mid t = t_0) \\
= \sum_{i \in V(G)} \left( \frac{1 + h_{t_0}(v)}{2} \log \frac{1 + h_{t_0}(v)}{2} + \frac{1 - h_{t_0}(v)}{2} \log \frac{1 - h_{t_0}(v)}{2} \right) \\
\geq \left( 2 - \frac{3}{4} \log 3 \right) n
$$

Integrating over $t_0$ we get that $H(\tilde{\nu}) \geq (2 - \frac{3}{4} \log 3) n$.

Next, we will show that $\tilde{\nu}$ preserves the “energy” part of the objective up to a multiplicative factor $O(\log \chi(G))$:

Consider each edge $(i,j) \in E(G)$. We have:

$$
E[\tilde{\nu}[x_ix_j] = 
$$

$^7$Meaning no edge connects a vertex with itself
\[ \int_0^1 \left( \frac{(1 + h_t(i))(1 + h_t(j))}{4} + \frac{(1 - h_t(i))(1 - h_t(j))}{4} - \frac{(1 + h_t(i))(1 - h_t(j))}{4} - \frac{(1 - h_t(i))(1 + h_t(j))}{4} \right) dt \]

\[ = \int_0^1 h_t(i)h_t(j) dt = \frac{1}{4\chi(G)} \int_0^1 F(i)(t)F(j)(t) dt = \frac{1}{4\chi(G)} \mathbb{E}[x_i|x_j] \]

This implies that

\[ \sum_{i,j \in E(G)} J_{i,j} \mathbb{E}[x_i|x_j] \geq \frac{1}{4\chi(G)} \sum_{i,j \in E(G)} J_{i,j} \mathbb{E}[x_i|x_j] \]

Therefore, the relaxation provides a factor \( O(\chi(G)) \) approximation of \( \log Z \), as we wanted.

\[ \square \]

5 Conclusion

In summary, we presented computationally efficient approximate versions of the classical max-entropy principle by (Jaynes, 1957): efficiently sampleable distributions which preserve given pairwise moments up to a multiplicative constant factor, while having entropy within a constant factor of the maximum entropy distribution matching those moments. Additionally, we applied our insights to designing provable variational methods for Ising models which provide comparable guarantees for approximating the log-partition function to those in the optimization setting. Our methods are based on convex relaxations of the standard variational principle due to Gibbs, and are extremely generic and we hope they will find applications for other exponential families.
