Aim: Toll-like receptor 2 (TLR2) signaling plays a critical role in the initiation of atherosclerosis. The aim of this study was to investigate whether blocking TLR2 activity could produce therapeutic effects on advanced atherosclerosis.

Methods: Forty-week old apolipoprotein E-deficient (ApoE–/–) mice fed on a normal diet were intravenously injected with a TLR2-neutralizing antibody or with an isotype-matched IgG for 18 weeks. Double-knockout ApoE–/– Tlr2–/– mice were taken as a positive control. At the end of the treatments, the plasma lipid levels were measured, and the plaque morphology, pro-inflammatory cytokines expression and apoptosis in arteries were analyzed. In the second part of this study, 6-week old ApoE–/– and ApoE–/– Tlr2–/– mice fed on a high-cholesterol diet for 12 to 24 weeks, the expression levels of TLR2 and apoptotic markers in arteries were examined.

Results: Blockade of TLR2 activity with TLR2-neutralizing antibody or knockout of Tlr2 gene did not alter the plasma lipid levels in ApoE–/– mice. However, the pharmacologic and genetic manipulations significantly reduced the plaque size and vessel stenosis, and increased plaque stability in the brachiocephalic arteries. The protective effects of TLR2 antagonism were associated with the suppressed expression of pro-inflammatory cytokines IL-6 and TNF-α and the inactivation of transcription factors NF-κB and Stat3. In addition, blocking TLR2 activity attenuated ER stress-induced macrophage apoptosis in the brachiocephalic arteries, which could promote the resolution of necrotic cores in advanced atherosclerosis. Moreover, high-cholesterol diet more prominently accelerated atherosclerotic formation and increased the expression of pro-apoptotic protein CHOP and apoptosis in ApoE–/– mice than in ApoE–/– Tlr2–/– mice.

Conclusion: The pharmacologic or genetic blockade of TLR2 activity diminishes and stabilizes advanced atherosclerotic lesions in ApoE–/– mice. Thus, targeting TLR2 signaling may be a promising therapeutic strategy against advanced atherosclerosis.

Introduction
Atherosclerosis is a common cause of cardiovascular disease. Cardiovascular disease is the leading cause of death and poses an increasing threat to human health worldwide[31]. Epidemiological and experimental studies have established a predominant role for inflammation in all stages of atherosclerosis, from the formation of early stable atherosclerotic plaques to advanced plaques that are prone to rupture[2,3]. Recently, several studies have focused on the effects of pharmacological interventions on the stability of advanced plaques because the rupture of unstable lesions contributes to acute coronary syndrome[4,6,7]. Unstable plaques are characterized by large, lipid-filled necrotic cores encapsulated by a thin fibrous cap, high levels of pro-inflammatory mediators and matrix proteases, and apoptosis. The development of unstable plaques is associated with the involvement of both the innate and adaptive immune systems.

Toll-like receptors (TLRs) are a family of pattern-recognition receptors that play a key role in innate immunity and initiate inflammatory responses. The ligation of these receptors initiates the activation of nuclear factor-κB (NF-κB), resulting in the expression of a wide array of inflammatory genes[8,9]. Among the characterized TLRs, TLR2 is unique by virtue of its ability to heterodimerize with TLR1 or TLR6, resulting in relatively broad ligand specificity, including both endogenous and exogenous ligands[10,11]. It is noteworthy that all of the...
potential endogenous TLR2 agonists, including biglycan, high-mobility box chromosomal protein 1 (HMGB1) and components of oxidized lipoproteins, are found in atherosclerotic lesions\cite{12-14}. In addition, the TLR2 signaling pathway is associated with the endoplasmic reticulum (ER) stress response. ER stress can increase TLR2 expression \textit{in vitro} and \textit{in vivo}, and TLR2 contributes to apoptosis in macrophages undergoing lipid-triggered ER stress\cite{15}. Thus, TLR2 may be a potential target for therapeutic interventions in the treatment of atherosclerosis.

Indeed, TLR2 ligands and increased TLR2 expression have been observed in human atherosclerotic plaques, and the important role of TLR2 in inflammation and matrix degradation is indicated by the cells found in human carotid atherosclerotic lesions\cite{16,17}. Moreover, TLR2 gene deficiency in a mouse model significantly inhibited the progression of early atherosclerosis\cite{18,19}. However, there are limited data regarding the effects of TLR2 on advanced lesions in animal models. Using pharmacological and genetic inhibition of TLR2 activity, we investigated the therapeutic and prophylactic effects of TLR2 blockade on advanced atherosclerotic plaques in the brachiocephalic artery of chow-fed apolipoprotein E (ApoE)-deficient mice, which have never been evaluated before. We found that blocking TLR2 activity reduces and stabilizes advanced atherosclerotic lesions in ApoE-deficient mice via the attenuation of inflammation and ER-stress in blood vessels. Our work indicates that TLR2 activity plays a crucial role in the pathogenesis of advanced atherosclerosis and that blocking this signaling pathway may be a promising strategy for the treatment of atherosclerosis and its complications.

\textbf{Materials and methods}

\textbf{Animals and experimental design}

\textit{ApoE\textsuperscript{−/−}/Tlr2\textsuperscript{−/−}} mice were generated from heterozygous intercrosses of \textit{ApoE\textsuperscript{−/−}} mice (C57BL/6 background, Jackson Laboratory) and \textit{Tlr2\textsuperscript{−/−}} mice (C57BL/6 background, Jackson Laboratory). The genotypes of the homozygous double-knockout or ApoE single-knockout mice were confirmed using PCR, as previously described\cite{20,21}. All animals were housed under standard conditions for humidity, room temperature, and dark-light cycles, with access to water and food \textit{ad libitum}. The studies were conducted according to the principles outlined by the Institutional Committee for the Ethics of Animal Care and Treatment in Biomedical Research (Beijing, China).

For the first experiment, all of the mice were maintained on a normal chow diet (4\% (wt/wt) fat, 20\% (wt/wt) protein, GB-14924). At 40 weeks of age, the \textit{ApoE\textsuperscript{−/−}/Tlr2\textsuperscript{−/−}} mice were randomly divided into 3 groups (n=16 per group) and treated with saline, an isotype-matched IgG antibody (SouthernBiotech, Birmingham, AR, USA), or a TLR2-neutralizing antibody (R&D System, Minneapolis, MN, USA) intravenously. The dosing and timing of antibody (ab) administration were determined based on our previous studies\cite{20,21}. The first dose treatment regimen was 200 µg/kg every 4 d for 2 weeks, and the remaining doses were 100 µg/kg given once per week for an additional 16 weeks. The \textit{ApoE\textsuperscript{−/−}/Tlr2\textsuperscript{−/−}} mice, termed the double-knockout (DK) group, were kept under the same conditions. All of the mice were sacrificed at 58 weeks of age. In the second experiment, the \textit{ApoE\textsuperscript{−/−}/Tlr2\textsuperscript{−/−}} and \textit{ApoE\textsuperscript{−/−}/Tlr2\textsuperscript{−/−}} mice were fed an atherogenic high-cholesterol (HC) diet (15.8\% (wt/wt) fat, 1.25\% (wt/wt) cholesterol) from 6 weeks of age and were sacrificed for analysis at 12, 18, and 24 weeks of age (n=8 per group).

\textbf{Tissue collection and processing}

After the mice had fasted for 4 h, blood was obtained via the retro-orbital venous plexus for lipid measurements. The mice were then anesthetized using 50 mg/kg ip pentobarbital and perfused through the left cardiac ventricle with ice-cold phosphate-buffered saline under physiological pressure. The aortas were excised quickly, snap frozen from the aortic arch to the iliac bifurcation, and maintained at -80°C prior to protein analysis. The entire brachiocephalic artery from each animal was fixed in 4\% paraformaldehyde for 24 h at 4°C, embedded in paraffin, and serially sectioned (5 µm thickness).

\textbf{Biochemical analysis}

The levels of total cholesterol, high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C) and triglycerides in the plasma were determined using commercial kits (Biosino, Beijing, China) according to the manufacturers’ instructions.

\textbf{Histological and immunohistochemical staining}

Every fifth section of the serial sections was stained with a modified Movat’s pentachrome stain or Sirius red to evaluate the composition and stability of advanced atherosclerotic plaques in the brachiocephalic artery, and 12-15 sections per mouse were analyzed for each stain. The stained sections were photographed under 200×magnification, and 2–3 fields of view per section that contained the full lesional area were captured and analyzed using Image-Pro Plus 5.0 (Media Cybernetics, Bethesda, MD, USA). The average of all sections represented the atherosclerotic lesion of one mouse.

For immunohistochemical staining, at least 4 sections of the brachiocephalic artery per mouse were incubated with a rat anti-mouse macrophage antibody (Mac-3, 1:50, BD, Franklin Lakes, NJ, USA), a mouse monoclonal antibody to smooth muscle actin (α-SMA, 1:100, Santa Cruz Biotechnology, CA, USA), or a rabbit anti-matrix metalloproteinase (MMP)-2 antibody (1:100, Abcam, Cambridge, UK). The bound antibodies were complexed with peroxidase-linked secondary antibodies and detected using diaminobenzidine. The stained sections were then anesthetized using 50 mg/kg ip pentobarbital and perfused through the left cardiac ventricle with ice-cold phosphate-buffered saline under physiological pressure. The aortas were excised quickly, snap frozen from the aortic arch to the iliac bifurcation, and maintained at -80°C prior to protein analysis. The entire brachiocephalic artery from each animal was fixed in 4\% paraformaldehyde for 24 h at 4°C, embedded in paraffin, and serially sectioned (5 µm thickness).

The average of all sections represented the atherosclerotic lesion of one mouse.

To assess the co-localization of macrophages and C/EBP homologous protein (CHOP), a rat anti-mouse macrophage antibody (Mac-3, 1:50, BD, Franklin Lakes, NJ, USA) and a mouse monoclonal antibody to CHOP (1:100, Cell Signaling...
Technology, Danvers, MA, USA) were used as the primary antibodies. Four tissue sections per mouse were incubated with Alexa 647-labeled chicken anti-rat and Alexa 488-labeled rabbit anti-mouse secondary antibodies (1:200, Invitrogen, Carlsbad, CA, USA). The sections were imaged using an E2000U confocal microscope and evaluated using Leica TCS SP2 software.

**In situ TdT-mediated dUTP nick-end labeling assays**

Apoptotic cells in atherosclerotic lesions were detected with the TdT-mediated dUTP nick-end labeling (TUNEL) technique using kits (Promega, Madison, WI, USA). The nuclei were stained with DAPI. TUNEL-positive nuclei were counted under an Olympus I720 inverted fluorescent microscope. To assess macrophage co-localization, the macrophages were detected using a rat anti-mouse macrophage antibody (Mac-3, 1:50, BD, Franklin Lakes, NJ, USA) followed by an Alexa 647-labeled chicken anti-rat secondary antibody (1:200, Invitrogen, Carlsbad, CA, USA).

**Western blots**

After tissue homogenization, the extracted proteins were separated using 12% SDS-PAGE and subjected to immunoblotting with specific antibodies, including anti-MMP-2 (Abcam, Cambridge, UK), anti-phospho-NF-kB p65, anti-NF-kB p65, anti-cleaved caspase-3, anti-CHOP (Cell Signaling Technology, Danvers, MA, USA), anti-phospho-Stat3, anti-Stat3, anti-interleukin (IL)-6, anti-IL-10 or anti-tumor necrosis factor (TNF)-α (Santa Cruz Biotechnology, CA, USA). The secondary antibody signals were detected using ECL Plus Western blot reagents (Amersham Biosciences, PA, USA) according to the manufacturer’s instructions.

**Statistical analysis**

The data are presented as the mean±SEM. The comparisons among several groups were performed with a one-way ANOVA using SPSS. Data that did not demonstrate a normal distribution were analyzed using a Mann-Whitney U test. \(P<0.05\) was considered to be significant.

**Results**

**Blocking TLR2 activity reduces and stabilizes atherosclerotic lesions in the brachiocephalic artery**

At the time of sacrifice, mice that had been treated with a TLR2-neutralizing antibody and TLR2-deficient mice displayed similar plasma levels of total cholesterol, LDL-C, HDL-C, and triglycerides as their ApoE-deficient littermates (Figure 1), indicating that TLR2 blockade did not significantly alter the blood lipid profile. Movat’s staining was used to evaluate plaque composition during brachiocephalic atherosclerosis in each group (Figures 2A and 2B). As expected, blocking TLR2 activity through either TLR2ab administration for 18 weeks or TLR2 gene depletion significantly decreased atherosclerotic lesion formation, as evidenced by the reductions in the mean lesion area, and maximum lesion stenosis, compared to mice that had been treated with IgG or saline (\(P<0.05\), Figures 2C and 2D). In addition, significant reductions in the size of necrotic cores (normalized to lesion area) and increases in media integrity were observed in the TLR2ab-treated and TLR2-deficient groups compared to the IgG- and saline-treated groups (\(P<0.05\), Figures 2E and 2F), suggesting that the blockade of TLR2 activity promotes plaque stability in advanced atherosclerotic lesions in ApoE-deficient mice. This finding was further supported by the histological analysis of collagen and α-SMA, which may protect atherosclerotic plaques from rupture, as well as macrophage accumulation, which contributes to plaque rupture in brachiocephalic lesions. The collagen content and α-SMA expression were both significantly increased, and the accumulation of mac-
rophones was significantly suppressed in TLR2ab-treated and TLR2-deficient mice compared with the other groups (P<0.05, Figures 3).

**TLR2 blockade attenuates inflammation in atherosclerotic arteries**

Because no significant differences in the lipid levels were observed, the therapeutic efficacy of targeting TLR2 may depend on the alteration of the inflammatory response. In addition to the diminished accumulation of macrophages, the expression of MMP-2, one of the most important MMPs, was significantly suppressed in the lesions of ApoE-deficient mice treated with the TLR2ab and those lacking the TLR2 gene, as demonstrated by both the immunohistochemical staining and immunodetection of aorta protein extracts (P<0.05, Figures 4A and 4B). Although the expression of the pro-inflammatory transcription factor NF-κB p65 subunit was not significantly altered, its phosphorylation level was significantly decreased by TLR2 inhibition, as compared to mice treated with IgG or saline (P<0.05, Figure 4C). To further analyze the effects of

**Figure 2.** TLR2 blockade reduces and stabilizes advanced atherosclerotic plaques in the brachiocephalic artery. (A and B) Movat’s staining showed the composition of advanced lesions from saline-, IgG-, and TLR2ab-treated and TLR2-deficient groups. The arrows indicate erosion of the media. The scale bars represents 200 µm in Panel A and 50 µm in Panel B. TLR2ab administration for 18 weeks and TLR2 deficiency significantly reduced the mean lesion area (C), maximum lesion stenosis (D), maximum necrotic cores/plaque (E), and minimum media thickness (F) in ApoE-deficient mice. L, lumen; M, media. The data are shown as the mean±SEM (n=10 mice/group). \(^{b}P<0.05\) vs the saline-treated group.
TLR2 blockade on inflammation in atherosclerosis, the levels of the pro-inflammatory cytokines IL-6 and TNF-α were measured in aorta protein extracts from the different groups. Blocking TLR2 activity significantly reduced IL-6 and TNF-α expression, compared with IgG or saline treatment (P<0.05, Figure 4E). Interestingly, we found that the expression or phosphorylation of the immunosuppressive cytokine IL-10 and transcription factor Stat3 (signal transducer and activator of transcription-3) were significantly inhibited in the TLR2ab-treated and TLR2-deficient groups, as compared to the IgG- or saline-treated groups (P<0.05, Figure 4D and 4E). This finding indicates that the therapeutic effect of blocking TLR2 activity on atherosclerotic lesions is also associated with an attenuation of the immunosuppressive environment, in which Stat3 and IL-10 play critical roles.

TLR2 blockade decreases macrophage apoptosis and CHOP expression in advanced atherosclerotic lesions

In advanced atherosclerotic lesions, macrophage apoptosis is associated with the development of plaque necrosis, a key feature of plaque rupture. Therefore, TUNEL analysis was used to assess the effect of TLR2 blockade on lesional macrophage apoptosis. The quantification of the data, represented as the percentage of apoptotic cells, revealed an approximately 64.4% decrease in the TLR2ab-treated group and an approximately 59.6% decrease in the TLR2-deficient group compared with the IgG- or saline-treated groups (P<0.05, Figures 5A and 5B). Cellular immunostaining revealed that many of the TUNEL-positive nuclei were located in macrophage-rich regions (Figure 5A). Similar results were obtained from the aorta protein extracts using activated caspase-3 as a marker for apoptosis (Figure 5C). To determine whether the anti-apoptotic effects of blocking TLR2 activity were associated with CHOP signaling, CHOP expression was analyzed at the protein level. A large inhibitory effect was observed in mice treated with the TLR2ab and in TLR2-deficient mice, compared to mice that had been treated with IgG or saline (P<0.01, Figure 5D). Double immunostaining for CHOP and Mac-3 in plaques revealed partial co-localization of both proteins, suggesting that CHOP was induced in macrophages that invaded atherosclerotic lesions. In addition, TLR2 inhibition resulted in visibly weaker co-localization of CHOP and macrophages (Figure 5E).

TLR2 mediates accelerated atherosclerotic formation and regulates CHOP expression and apoptosis in ApoE-deficient mice fed HC diets

Six-week-old ApoE<sup>−/−</sup> Tlr2<sup>+/+</sup> and ApoE<sup>−/−</sup> Tlr2<sup>−/−</sup> mice were fed an atherogenic HC diet to accelerate lesion formation. Consistent with previous studies, after 18 weeks on the atherogenic diet, TLR2 deficiency resulted in decreased mean lesion areas and necrotic core sizes, as indicated by Movat’s staining (Figures 6A–6C). Along with the development of atherosclerosis, TLR2 and macrophage co-localization in plaques was observed in ApoE<sup>−/−</sup> Tlr2<sup>−/−</sup> mice via double immunofluorescence staining (Figure 6D). To provide further evidence of the relevance of TLR2 and macrophages in apoptosis during atherosclerosis,
the expression of activated caspase-3, the proapoptotic protein CHOP and its main downstream signaling molecule Bcl-2 were detected. The greater levels of activated caspase-3 indicated that apoptosis had increased, and CHOP expression was also significantly elevated in the aortas of ApoE−/− Tlr2+/+ mice after the HC diet was introduced. In addition to its protective effects against lesion formation, TLR2 deficiency decreased the expression of activated caspase-3 and CHOP and enhanced the expression of the survival signal Bcl-2, compared with ApoE−/− Tlr2+/+ mice, especially at 24 weeks of age (P<0.05, Figures 6E–6G).

Discussion
Growing evidence of the involvement of TLR2 activation in atherogenesis has been obtained using mouse models. The targeted deletion of TLR2 in ApoE−/− or Ldlr−/− mice resulted in a significant reduction in the number of atherosclerotic lesions within aortas, as assessed by en face or aortic sinus analysis, in mice on an HC diet or a normal chow diet[18, 19]. In addition, the administration of TLR2 ligands, including synthetic compounds and live bacteria, significantly aggravated atherosclerosis[22, 23]. However, these studies were only concerned with the pathogenesis of early atherosclerosis, and there are no reports about the effects of TLR2 on plaque stability during advanced atherosclerosis. Chow-fed older ApoE-deficient mice that develop advanced atherosclerotic lesions in the brachiocephalic artery were recently reported to share many of the morphologic features of advanced disease in humans[24–26]. Compared with lesions within the aortas and aortic sinus, which are analogous to early fibrous cap atheromas in humans, plaques in the brachiocephalic arteries exhibit more features of advanced disease, such as necrotic cores, media erosion and the loss of fibrous cap continuity[7]. Using this animal model, we demonstrated that TLR2 deficiency reduces and stabilizes advanced atherosclerotic lesions in the brachiocephalic artery of older ApoE-deficient mice by decreasing the plaque size and the number of necrotic cores, maintaining media integrity and elevating the expression of collagen and α-SMA. Importantly, we found that the therapeutic inhibition of TLR2 activity by a TLR2-neutralizing antibody produced anti-atherosclerotic effects on established atherosclerosis in ApoE-deficient mice and that these effects were identical to those induced by TLR2 gene depletion. Our work may pave the way for a pharmacological intervention of advanced atherosclerosis.

Inflammatory processes play a pivotal role in the devel-
Figure 5. TLR2 blockade inhibits macrophage apoptosis and CHOP expression in atherosclerotic lesions in the brachiocephalic artery. (A) TUNEL analysis showed reduced macrophage apoptosis in the plaques of \textit{ApoE}^{−/−} mice treated with the TLR2ab and in \textit{ApoE}^{−/−}\textit{Tlr2}^{−/−} mice. The statistical analysis is shown in (B). Cleaved caspase-3 (C) and CHOP (D) expression in the aortas and the co-localization of macrophages (Mac-3) and CHOP (E) in advanced plaques were evaluated for the four sample groups. The scale bars represent 37.5 µm. The data are shown as the mean±SEM (\(n\)=6 mice/group). *\(P\)<0.05 vs the saline-treated group.
Development of atherosclerosis. TLR2 has been demonstrated to participate in this process\cite{11, 27}. Consistent with previous studies of the early phases of atherosclerosis, blocking TLR2 activity reduced the infiltration of macrophages into plaques;
the expression of inflammatory mediators, including MMP-2, TNF-α and IL-6; and the inactivation of the transcription factor NF-κB[20, 21, 23]. Moreover, TLR2 antagonism also inhibited the expression of the immunosuppressive mediators IL-10 and transcription factor Stat3, indicating that the benefits of blocking TLR2 are dependent on the extensive inhibition of inflammation. This study provides the first evidence for TLR2-induced inflammation in advanced lesions, which would complement the previously revealed contributory role of TLR2 in early atherosclerosis.

TLR2 signaling activates pro-inflammatory genes in multiple cell types within the lesions, including endothelial cells, macrophages, vascular smooth muscle cells (VSMCs) and dendritic cells, but the key determinants of atherogenesis and plaque rupture are still unknown. Curtiss et al reported that TLR2 deficiency in BM-derived cells generated no impact on lesion size in Ldlr−/− mice during early atherosclerosis[31]. Consistent with this finding, the same group also demonstrated that the dramatic up-regulation of TLR2 is confined to endothelial cells in disturbed flow regions and does not occur in intimal leukocytes during the early progression of the disease[28]. These data suggest that endothelial TLR2 expression plays a key role in the initiation of atherosclerosis. However, TLR2 has been detected both in the endothelium and in inflammatory cells that infiltrated advanced atherosclerotic plaques obtained from patients undergoing endarterectomy[36]. Therefore, we hypothesized that the progression of advanced atherosclerosis involves the expression and activation of TLR2 in immune cells. Activated VSMC is another important contributor to atherogenesis and restenosis by multiple mechanisms, including extracellular matrix synthesis, release of pro-inflammatory mediators, proliferation and migration. Endogenous TLR2 ligands, such as heat shock protein 60, could stimulate venous SMC proliferation through TLR2 and TLR4[29]. In addition, ligand-activated TLR2 drives VSMC migration dependent on the production of IL-6[30]. Using mouse models Schoneveld et al demonstrated that the vascular intimal hyperplasia, which is characterized by VSMC migration and proliferation, is enhanced by TLR2 activation[31]. However, VSMC is required for the structural integrity of the fibrous cap in advanced atherosclerosis to prevent the development of unstable lesions. Apoptosis of VSMC may also lead to plaque instability and rupture, which may result in acute atherothrombotic events[32]. The plaque content of VSMC is therefore considered an important determinant of plaque stability. In this study we found that the accumulation of VSMC was significantly increased in advanced plaques, thereby maintaining the plaque stability after blocking TLR2 activity. Moreover, the inhibition of VSMC proliferation and migration may also occur in advanced plaques because TLR2 blockade accompanies the decreased expression of IL-6 in aorta. It is unknown specifically how VSMC participates in the complex progress of advanced atherosclerosis and how TLR2 blockade affects it. An extensive study to focus on these issues should be taken in the near future.

Plaque instability is an important feature of advanced atherosclerosis. Although the mechanisms underlying plaque rupture remain elusive, many factors have been demonstrated to contribute to this process, including macrophage accumulation, high levels of pro-inflammatory mediators, excess activation of MMPs, and apoptosis of VSMCs and macrophage. In addition to the regulation of inflammatory responses, we observed that TLR2 blockade decreased macrophage apoptosis using TUNEL analysis and immunofluorescence.

Recently, ER stress-induced macrophage apoptosis has been considered to be a key event in plaque rupture[33, 34]. Hypoxia-, oxidative stress-, and hypoglycemia-induced ER stress is universal in various diseases, including atherosclerosis. Sustained ER stress may result in apoptosis in a variety of cell types, including macrophages, through the activation of its downstream transcription factor CHOP. Generally, apoptotic cells are rapidly disposed via phagocytic clearance by macrophages that have infiltrated into tissues. However, apoptotic macrophages result in a loss of phagocytic function in advanced atherosclerotic lesions. Dying macrophages become necrotic, and cellular debris left in the plaques causes the necrotic core to expand. Many CHOP-expressing macrophages have been demonstrated to undergo apoptosis in advanced lesions in both humans and mice[35–37]. In addition to macrophage apoptosis, ER stress also enhances the expression of TLR2 and the production of TLR-2 dependent pro-inflammatory cytokines in vitro and in vivo, suggesting a contributory role of ER stress in the regulation of TLR2-dependent inflammation[38]. In contrast, TLR2 activation by atherogenic lipoproteins may promote the apoptosis of ER-stressed macrophages and plaque necrosis during advanced atherosclerosis[31]. TLR2 activation acts in a synergistic fashion with ER stress to produce pro-inflammatory cytokines[39]. These data suggest that TLR2 signaling is associated with ER stress, although the exact mechanism remains unclear.

In our study, decreased CHOP and macrophage co-localization was observed in the lesions of the treated groups, suggesting that the plaque-stabilizing effect of TLR2 blockade may rely on the inhibition of ER stress-induced macrophage apoptosis. Given that there is no direct evidence for the impact of TLR2 signaling on ER stress in atherosclerosis, we provided preliminary evidence of this relationship using ApoE−/−/Tlr2−/− mice with atherosclerosis accelerated by HC diets. We confirmed that cell apoptosis and the expression of CHOP were significantly inhibited and that the expression of Bcl-2, a key cell survival molecule that is related to downstream CHOP-mediated apoptosis, was elevated in ApoE−/−/Tlr2−/− mice. Furthermore, we found that during the early phases of atherosclerosis in ApoE-deficient mice at 12 weeks of age, TLR2 expression was mainly detected in the endothelial and smooth muscle cells within the plaques, which was consistent with the results of other studies[28]. After another 6 to 12 weeks on the HC diet, the accumulation of vessel-infiltrating macrophages was dramatically increased, and the co-localization of TLR2 and macrophages was also detected in atherosclerotic vessels. Thus, TLR2 expressed on macrophages in advanced atherosclerotic lesions mediates cell apoptosis triggered by endog-
enous stimuli, especially excess ER stress, and contributes to the growth of necrotic cores and plaque instability.

In summary, we have demonstrated that the knockout of TLR2 gene in ApoE−/− mice reduced the plaque size and increased plaque stability in the brachiocephalic artery during advanced atherosclerosis as a result of the inhibition of inflammation and of ER-stress-induced macrophage apoptosis. Notably, the treatment of these mice with a TLR2-neutralizing antibody produced therapeutic beneficial effects and may serve as a promising therapeutic strategy against advanced atherosclerosis. Because the enhanced expression of TLR2 on endothelial cells is required for disease initiation, TLR2 may mediate or amplify the apoptotic signals induced by ER stress in advanced atherosclerotic lesions. Our work suggests that pharmacological blockade of TLR2 signaling is an attractive approach for the future treatment of atherosclerosis.
