Abstract

Cardiac innervation density generally reflects the levels of nerve growth factor (NGF) produced by the heart—changes in NGF expression within the heart and vasculature contribute to neuronal remodelling (e.g. sympathetic hyperinnervation or denervation). Its synthesis and release are altered under different pathological conditions. Although NGF is well known for its survival effects on neurons, it is clear that these effects are more wide ranging. Recent studies reported both in vitro and in vivo evidence for beneficial actions of NGF on cardiomyocytes in normal and pathological hearts, including prosurvival and antiapoptotic effects. NGF also plays an important role in the crosstalk between the nervous and cardiovascular systems. It was the first neurotrophin to be implicated in postnatal angiogenesis and vasculogenesis by autocrine and paracrine mechanisms. In connection with these unique cardiovascular properties of NGF, we have provided comprehensive insight into its function and potential effect of NGF underlying heart sustainable/failure conditions. This review aims to summarize the recent data on the effects of NGF on various cardiovascular neuronal and non-neuronal functions. Understanding these mechanisms with respect to the diversity of NGF functions may be crucial for developing novel therapeutic strategies, including NGF action mechanism-guided therapies.

Keywords NGF; Cardiovascular disease; Heart homeostasis; Neuroprotection; Metabotrophin

Introduction

Neurotrophins (NTs) are a highly homologous family of dimeric polypeptides, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin 3, and neurotrophin 4/5. Neurotrophic factor activity is mediated by binding to two types of cell surface receptors, the p75 neurotrophin receptor (p75NTR) and receptor tyrosine kinases (Trks), which display high affinity and specificity for mature forms of NTs.1–3 NGF preferentially binds to TrkA, BDNF, and neurotrophin 4/5 preferentially activate TrkB, and neurotrophin 3 acts via TrkC4, and has lower affinity for TrkA and TrkB.5 On the other hand, p75NTR, which lacks intrinsic enzymatic activity,5 binds all NTs with similar affinity, including proneurotrophins.1,6

The activity of NTs has been implicated in several functions, including axonal growth, synaptic plasticity, survival, myelination, and differentiation7,8 in the central nervous system and peripheral nervous system.9 Individual members of this family sustain differentiation and survival of distinct but overlapping populations of sensory and sympathetic neurons.10 Strong evidence has emerged that NTs exert important cardiovascular functions, which largely exceed their roles in the neural regulation of heart function.7,11,12 The first evidence of secretion of neurotrophic factors by heart cells was obtained in 1979, when Eberdal et al. showed that heart explants support neurite extension from sensory neurons in vitro.13 The heart is innervated by sympathetic, parasympathetic, and sensory neurons derived from neural crest cells, all of which may require NTs during development. Indeed, NTs play an important role in the regulation of the sympathetic nervous system, acting as trophic survival factors but also as regulators of cardiac nerve outgrowth and axonal arborization.14,15

Apart from their neuronal functions, NTs exert cardiovascular actions under both physiological and pathological...
conditions. In early cardiovascular development, NTs and their receptors are essential for the appropriate formation of the heart and the regulation of vascular growth. In postnatal life, these factors control the survival of endothelial cells (ECs), vascular smooth muscle cells (VSMCs), and cardiomyocytes and regulate angiogenesis and vasculogenesis by autocrine and paracrine mechanisms. In connection with these unique cardiovascular properties of NTs, we have provided comprehensive insight into NGF functions and potential effects of NGF underlying heart sustainable/failure conditions. The angiogenic actions of NGF are mediated through direct effects on vascular ECs through regulation of the EC survival, proliferation, and migration or indirectly by influencing the action of other endogenous growth factors, such as vascular endothelial growth factor (VEGF). Moreover, recent studies reported both in vitro and in vivo evidence for beneficial actions of NGF on cardiomyocytes in normal and pathological hearts, including pro-survival and antiapoptotic effects.

Identification of the molecular mechanisms involved in the interactions between cardiomyocytes and other types of cells, such as neurons, and exploration of the extensive and diverse effects exerted by NGF within the cardiovascular niche may enhance our understanding of heart development, function, and disease. Cardiac innervation density generally reflects the levels of NGF produced by the heart. Furthermore, NGF supply from the innervation field influences the neuronal plasticity that allows the adult nervous system to modify its structure and function in response to stimuli. Unbalanced heart innervation may occur in a wide variety of cardiovascular pathologies due to prevalent impairment of NGF expression by the myocardium (e.g. in diabetes), uncontrolled norepinephrine (NE) release by neurons [e.g. in heart failure (HF)] or local myocardial remodelling that follows ischaemic injury or NGF-associated hypertrophy [i.e. myocardial infarction (MI)]. Therefore, we reviewed recent progress on the roles of NGF in cardiovascular development, function, and pathology as potent therapeutic targets for accelerating nerve regeneration and functional heart recovery by promoting myocardial neovascularization and inhibiting myocardial apoptosis.

**Cardiac autonomic nervous system**

The heart is innervated by sympathetic, parasympathetic, and sensory neurons, all of which may require NTs during development and in postnatal life. Sympathetic innervation of the heart originates mainly from the right and left stellate ganglia (SG). Cardiac parasympathetic activity is mediated through the vagus nerve, which originates in the medulla (Figure 1). Sympathetic axons innervate the atria, cardiac conduction system and ventricles, where they stimulate increased heart rate (chronotropy), conduction velocity (dromotropy), and contractility (inotropy) via NE activation of β1-adrenergic receptors. Cholinergic nerve fibres are most abundant in the sinoatrial and atroventricular (AV) nodes, the atrial myocardium, and the ventricular conducting system. Stimulation of cardiac parasympathetic nerves projecting to these regions leads to acetylcholine release, which evokes prominent bradycardia (slow heart rate), negative dromotropic responses (delayed AV conduction) and inotropy (decreased atrial contractility) via activation of postjunctional M2 muscarinic receptors.

Cardiac diseases such as chronic HF and MI are associated with abnormal cardiac autonomic control, including high levels of sympathetic activity, impaired parasympathetic control and subnormal arterial baroreflex sensitivity. Sympathetic nerve sprouting and perturbed innervation are thought to play a role in arrhythmias. With the increasing understanding of the autonomic nervous system (ANS) and its role in the pathophysiology of cardiac diseases, autonomic modulation may play an important role in the treatment of various cardiovascular diseases. The role of cardiac target-derived factors as regulators of neuronal maturation, synaptic transmission, neuronal elongation, and axonal collateral sprouting has been well established. Changes in neurotrophic factor expression within the heart and vasculature, such as NGF, contribute to neuronal remodelling (e.g. sympathetic hyperinnervation or denervation). These issues have been reviewed in detail in this paper and will be summarized here briefly.

**Intrinsic cardiac nervous system**

Heart innervation consists of extrinsic (nerves coming from the brain and thoracic paravertebral ganglia) and intrinsic ANS. The intrinsic cardiac nervous system (ICNS) that has been collectively called the heart’s ‘little brain’ is a neural network that consists of epicardial ganglionated plexi (GP) and the ligaments of Marshall. The ganglia contain efferent postganglionic parasympathetic and sympathetic neurons, local circuit neurons, and afferent neurons and act as an integrating network that processes afferent and efferent information involved in cardiac regulation. The function of GP is to modulate the autonomic interactions between the extrinsic and intrinsic ANS, which affects the sinus rate, AV conduction, refractoriness, and inducibility of atrial fibrillation (AF). GPs are connected with each other by interconnecting neurons and create an extensive and complicated epicardial neural network. The number of cardiac ganglia is
species-dependent, ranging from 19 in the mouse to over 800 in humans. Ganglia contain 200 to 1000 neurons that innervate neighbouring cardiac structures and connect with sympathetic and parasympathetic nerve fibres from the extrinsic ANS. They are surrounded by a fat pad composed of epicardial fat and ligament and are mostly positioned near the large vessels and posterior surface of the atrium, and 50% of all cardiac ganglia are located near the heart hilum, especially on the dorsal and dorsolateral surfaces of the left atrium.

For instance, the sinus node is primarily innervated by the right atrial GP, whereas the AV node is innervated by the inferior vena cava-inferior atrial GP (also known as the inferior right or right inferior GP).

Cardiac ganglia are much more than a vagal relay station but are highly complex structures including efferent pre-ganglionic and post-ganglionic parasympathetic neurons and presumed putative post-ganglionic sympathetic neurons, all of which all lie in close proximity to the sensory nerves. Ganglia show immunoreactivity to neuromodulators and neurotransmitters including, but not exclusively to choline acetyltransferase, vasoactive intestinal peptide, tyrosine hydroxylase, neuropeptide Y, neuronal nitric oxide synthase, synaptophysin, substance P, and calcitonin gene-related peptide. In contrast to the situation in the atria where cholinergic somata and nerve fibres dominate, the situation in the cardiac ventricles is reversed; there is a dominance of adrenergic nerve fibres within the left and right coronary subplexuses that innervate the ventricles as well around the blood vessels.

Recently, it has been shown that atrial GP neurons are hypertrophied following HF, providing evidence of anatomical and neurochemical changes following cardiac disease. Not only do the intrinsic GPs participate in triggering and initiating AF, but they also modulate the electrical remodelling of the atria. These changes would be expected to affect neuronal cell communication, detrimentally affecting ganglionic physiology, and could in part, explain the attenuation in GP neurotransmission following HF. Clinical studies demonstrate that the dysfunction of the ICNS is associated with cardiac diseases, including AF and VF.
The role of NGF in regulating cardiac functions

Nerve growth factor/TrkA axis in cardiac development and physiology: The effect on different cell types within the cardiovascular niche

Proangiogenic effects

Increasing evidence has suggested that NGF plays an important role in the crosstalk between the nervous and cardiovascular systems. Accordingly, NGF is an essential factor in heart formation and exerts a variety of effects on peripheral tissues, including the vasculature. NGF was the first NT to be implicated in post-natal angiogenesis and vasculogenesis by autocrine and paracrine mechanisms. Raychaudhuri et al. first described the proliferative action of NGF as a rapid phosphorylation of TrkA and through ERK1/2 activation in human dermal microvascular ECs. This was later confirmed in human umbilical vein ECs, human choroidal ECs, and rat brain ECs. Through TrkA, NGF supports EC survival in vitro and in vivo and induces angiogenesis, which is, at least in part, mediated by increased VEGF-A and possibly VEGF receptors. More interestingly, NGF apparently increases the ratio of large mature vessels and enhances the maturation of VEGF-induced neo-vessels. Additionally, NGF is a chemoattractant that is able to induce the migration of human and pig aortic ECs and human aortic VSMCs, which in turn leads to repair of the cardiovascular niche, thus exerting cardioprotective effects.

Nerve growth factor as a prosurvival factor for cardiomyocytes

It is worth noting that among its pleiotropic effects, one cardiovascular-associated property of NGF is its autocrine prosurvival effect on cardiomyocytes. The secretion of neurotrophic factors by heart cells was first discovered in 1979 by Ebendal et al. It is known that heart cells express and release NGF and express its receptor TrkA, through activation of this receptor, NGF triggers pro-survival and antiapoptotic effects on cardiomyocytes in normal and pathological hearts in vitro and in vivo. NGF overexpression is widely observed in cardiac pathologies (MI, diabetes, and etc.) and likely plays a beneficial role in cardiac cell survival and heart function in contrast to normal, homeostatic cardiac tissue conditions in which cardiomyocytes exhibit very weak NGF expression and secretion. Accordingly, in infarcted human hearts and in mice with infarcted hearts treated with an antibody against NGF or the TrkA inhibitor K252a, there was cardiomyocyte apoptosis and worsened cardiac function. However, increased NGF levels obtained by either gene transfer or supplementation with recombinant NGF protein protected neonatal and adult cardiomyocytes from apoptosis and conferred immediate protection against injury caused by ischaemia/reperfusion in the heart, showing a potential therapeutic role for NGF in MI. Various cardiac non-neuronal cells, such as cardiomyocytes, ECs, macrophages, and myofibroblasts, have been shown to participate in NGF secretion in cardiac tissue in pathophysiological situations. The ability of fibroblasts to secrete NGF has already been reported in different fibroblastic cell lines. In recent studies, clear evidence has been provided that NGF is cardioprotective.

Cardiac sympathetic nerve activity

Nerve growth factor is also a particularly important signalling molecule in the crosstalk between the nervous and cardiovascular systems. Sympathetic neurons in the adult heart are important mediators of cardiac function. The cardiac sympathetic nerve is composed of preganglionic sympathetic neurons, which innervate the heart via the cardiac nerves. These neurons are known to be involved in the regulation of cardiac function, blood pressure, and heart rate. NGF is expressed in the heart and is involved in the development and maturation of sympathetic neurons. NGF has been shown to be expressed in the heart and to be involved in the development and maturation of sympathetic neurons. Additionally, NGF is involved in the maintenance of sympathetic neurons in the heart and is involved in the regulation of sympathetic neurotransmission.

Cardiac parasympathetic nerve activity

Nerve growth factor also increases the excitability of airway parasympathetic neurons and augments dendritic growth. However, sympathetic neurons are significant in promoting NGF synthesis by parasympathetic neurons. Sympathetic and parasympathetic fibres are closely apposed in effector pacemaker and conduction areas, and maintenance of this spatial association occurs through NGF synthesis and release by cardiac ganglion (CG) neurons, which utilize NGF to maintain the integrity of the parasympathetic innervation. Therefore, NGF plays a crucial role in maintaining the balance between sympathetic and parasympathetic activity in the heart.
NGF as an autocrine/paracrine factor. In addition to regulating NGF expression, Hasan and Smith demonstrated that the consequence of cardiac sympathectomy is a decrease in the cholinergic phenotype of rat CG neurons. While NGF is expressed by intact sympathetic innervation then allows for the formation of axo-axonal synapses and reciprocal modulation of heart function. Although NGF exerts a powerful trophic effect on sympathetic neurons, its release from CG neurons may be critical for maintaining axo-axonal apposition and parasympathetic inhibition of sympathetic function in congestive heart failure (CHF). The relative expression of mature and pro-NGF forms may also determine the extent of sympathetic-parasympathetic axo-axonal associations in CHF.

Cardiac sensory nerve activity

Nerve growth factor synthesis in the heart is also critical for the development of the sensory nervous system because cardiac sensory nerves develop in parallel with the NGF synthesized in the heart, and cardiac sensory innervation is rich both at epicardial sites and in the ventricular myocardium. Cardiac nociceptive sensory nerves that are immunopositive for calcitonin gene-related peptide, including the dorsal root ganglion and dorsal horn, are markedly impaired in NGF-deficient mice, while cardiac-specific overexpression of NGF rescues the heart from these deficits. Moreover, NGF has been shown to regulate the expression of many neuropeptides in dorsal root ganglion neurons and modulate their sensitivity to noxious stimuli. It was also found that the reduced NGF expression in diabetic hearts might explain the cardiac sensory denervation and neuropathy in diabetic mice, and overexpression of NGF in the hearts reversed sensory denervation and diabetic neuropathy in the mouse. The cardiac sensory nervous system is responsible for pain perception and for the initiation of the protective cardiovascular response during MI. Therefore, a main cause of SCD in diabetes is silent myocardial ischaemia (characterized by the loss of pain perception caused by sensory nerve impairment, but according to the study by leda et al., NGF gene therapy of the heart rescues neuropathy in diabetic rats, which improves the electrophysiological activity of cardiac afferent nerves during MI. Taken together, these findings indicate that NGF, in addition to its eminent role in neuronal growth, survival, and neuroprotection, has direct impact on the cardiovascular system in terms of pro-survival and proangiogenic effects. This unique crosstalk between the cardiovascular and nervous systems with respect to the many functions of NGF could be useful in designing new preventive and therapeutic strategies for vascular and heart dysfunction.

The role of nerve growth factor in response to pathological cardiac stress

Ischaemic injury/myocardial infarction

Angiogenesis

While NGF is expressed in normal hearts, its synthesis and release are altered under different pathological conditions. NGF plays an important role in post-infarction remodelling. Beyond its actions on cardiomyocytes, NGF exerts beneficial actions via vascular effects, including the stimulation of angiogenesis and pro-survival actions following MI and increasing the density of both capillaries and mature vessels (such as arterioles) in response to hindlimb ischaemia and arterioles in rats in which the increased expression level of NGF and TrkA persist during neointimal formation. Similarly, Diao et al. found significantly milder muscle atrophy, EC proliferation, and angiogenesis after NGF and VEGF gene transfection in hindlimb ischaemic mice, suggesting the angiogenic functions of NGF and VEGF. Moreover, type 1 diabetes down-regulates the levels of NGF and TrkA in ischaemic skeletal muscles and concomitantly induces p75NTR expression in capillary ECs, suggesting that p75NTR is responsible for diabetes-induced impairment in neovascularization of ischaemic limb muscles. In contrast to Trk actions, ligand (NGF and pro-NGF)-dependent activation of p75NTR, which is increased following vascular injury (in pathological conditions such as diabetes or atherosclerosis), reportedly induces EC proliferation and neointimal smooth muscle cell death. Interestingly, rather than initiating apoptosis of diabetic ECs via p75NTR, NGF supplementation down-regulates p75NTR expression by a mechanism that has not yet been clarified and promotes EC survival and vascular regeneration. Studies examining the angiogenic actions of NGF have demonstrated that NGF gene delivery to the infarcted hearts of mice and rats increase capillary density and inhibit EC apoptosis in the peri-infarct areas, ameliorate cardiomyocyte survival and improve myocardial blood flow. Furthermore, exogenous administration of recombinant mature NGF in the ischaemic rodent hindlimb model induced a marked increase in arteriole length density.

Sympathetic nerve remodelling

Myocardial infarction-associated complications are correlated with anatomical (myocardial, vascular, and neural) and cardiac electrical remodelling initiated by the infarction. As a member of the NT family, NGF is critical for the differentiation, survival, and synaptic activity of sympathetic nerves during human development and after cardiac injury. In MI, persistent up-regulation of NGF expression (produced via macrophages and myofibroblasts) is observed within the ischaemic area of infarcted hearts, underscoring its involvement
in post-infarction sympathetic nerve sprouting and regeneration. Endothelin-1, a key regulator of NGF expression in cardiomyocytes and a cardiac hypertrophic factor, is strongly induced in pathological conditions, and the endothelin-1/NGF pathway may also be involved in NGF up-regulation and nerve regeneration after MI. After MI, despite the increased expression of NGF-induced sympathetic hyperinnervation, this alternation may also represent an adaptive mechanism by which the heart tries to maintain ventricular contractility at the cost of eventually triggering life-threatening ventricular arrhythmias (VA), VF, and SCD. Novel findings indicate that modulation of NGF expression may regulate sympathetic innervation patterns, providing potential access points for novel therapeutic strategies to prevent lethal arrhythmias and SCD. Hu et al. revealed that targeted intracardiac administration of NGF small interfering RNA in a rat MI model reduced nerve sprouting, decreased sympathetic nerve density, attenuated angiogenesis, augmented infarct size, and exacerbated cardiac dysfunction. Intriguingly, NGF may also modulate beta-adrenergic receptors (β-AR) expression in cardiomyocytes, which is a finding that has possible ramifications for arrhythmia generation because β-AR expression is increased in some cardiac pathological states. Interestingly, while NGF stimulates axonal growth, its precursor pro-NGF triggers axon degeneration and may be involved in post-MI denervation.

**Oxidative stress**

Previous studies showed that the mechanisms underlying myocardial ischaemic injury might be associated with calcium overload, mitochondrial dysfunction, increased reactive oxygen species (ROS), activation and adhesion of neutrophils, increased levels of NGF protein may attract TrkA-expressing neutrophils/monocytes into the border zone complement activation, endothelial dysfunction, cytokine release, or cellular apoptosis. The NGF promoter contains activator protein-1, which is subjected to redox regulation through its conserved cysteine residue. Peroxynitrite induces activator protein-1 activation, which in turn activates the NGF promoter and enhances the transcription of NGF. According to numerous studies, in the border zone of the myocardium during reperfusion NGF protects sensory and sympathetic neurites against ROS, which are deleterious to cardiac cells. Abe et al. showed that intracoronary administration of NGF during brief episodes of ischaemia can protect against post-ischaemic sympathetic dysfunction. It might be speculated that, similarly to brain insult, up-regulation of NGF within the failing heart can induce the activation of ROS-detoxifying enzymes and ameliorate ongoing neuronal injury by suppressing the actions of ROS in nerve terminals, however, this mechanism has not been clearly explained and verified. Contrary to this mechanism, it is a well-investigated phenomenon that oxidative stress is increased and has a critical role in sympathetic neural remodelling (hyperinnervation) following MI and augments the expression of NGF in infarcted rat hearts (more in paragraph 4.2). The inhibition of the superoxide generation decreased the expression of NGF and attenuated sympathetic neural remodelling following MI.

**Autophagy**

Many studies have also suggested that autophagy plays an adaptive role in protecting cardiomyocytes after ischaemic injury and suppresses the acceleration of HF. In a recent study, Wang et al. found that NGF improves myocardial ischaemia reperfusion injury in a mouse model and that the protective effect of NGF is associated with increased autophagy-mediated ubiquitination. Collectively, up-regulation of NGF expression in post-infarcted hearts exerts both harmful (pro-arrhythmia effects, SCD, and fibrillation) and protective effects, such as myocardial and vascular repair, diminished oxidative stress, and autophagy stimulation.

**Ventricular and atrial arrhythmias**

Nerve growth factor is a key cytokine thought to promote autonomic nerve sprouting in the ventricle and atrium, and its production in target organs determines the density of innervation by the sympathetic nervous system. Cardiac sympathetic left stellate ganglion (LSG) activity increases markedly before VA onset in an ischemia model, and the inhibition of LSG activity effectively reduces the incidence of VA. Accordingly, it was recently reported that non-invasive light-emitting diode therapy might significantly reduce both sympathetic activation, manifested by a decrease in LSG neural activity and expression of NGF, and inflammatory response in the myocardium, thus reducing the incidence of acute MI-induced VAs. Cao et al. demonstrated that heterogeneous cardiac nerve sprouting and sympathetic hyperinnervation play important roles in arrhythmogenesis and SCD in both human patients and the animal models of MI. In a canine post-MI model, they demonstrated that the induction of nerve sprouting by infusion of NGF into the LSG resulted in an increased incidence of ventricular tachycardia and VF. Furthermore, diffuse ventricular sympathetic hyperinnervation following MI is secondary to the local secretion of NGF in the peri-infarct region. Retrograde transport of NGF by sympathetic nerve fibers from the infarcted region to the SG results in hypertrophy of postganglionic neurons in SG (Figure 2A). This, in turn, leads to the diffuse sympathetic hyperinnervation of the left ventricle at regions remote from the infarct region, thereby promoting VA. Nguyen et al. also reported that MI results in an increased serum NGF level and can exert...
trophic effects in inducing neural remodelling in the SG after MI in rabbits. Nerve sprouting and sympathetic hyperinnervation were associated with the dispersion of repolarization, changes in calcium currents, and increased VF incidence. Collectively, this evidence indicates that heterogeneous remodelling and hyperadrenergic innervation are likely to play significant adverse roles in the increased risk of life-threatening arrhythmias after MI.

Therefore, new therapeutic approaches to abolish an unbalanced crosstalk between SG and infarcted myocardium might prevent sympathetic neural remodelling and cardiac cell dysfunction.

There has also been increasing evidence that abnormalities of the ANS, which includes sympathetic, parasympathetic, and intrinsic neural network are involved in the pathogenesis of AF. The cardiac ANS plays an essential role in epicardial GP regulation of AF onset and progression. AF-associated oxidative stress may cause cardiac nerve injury, which triggers the re-expression of NGF or other neurotrophic factors in the non-neuronal cells around the site of injury. NGF over-expression is associated with myocardial hyperinnervation and atrial fibrosis, whereas increase in atrial sympathetic innervation contribute to the generation and maintenance of AF by exerting significant effects on automaticity, refractoriness, and conduction velocity. It is known that increased parasympathetic signalling is a key contributor to the refractory period shortening in the atrium. Accordingly, the activity of GP, which provides the majority of parasympathetic innervation to the atria, is increased in the animal models of AF, and the heightened vagal tone was shown to precede the onset of AF paroxysms in patients. Similarly, as demonstrated in dogs, there is sympathetic hyperinnervation in the fibrillating atrium, with evidence of the heightened sympathetic discharge from SG with rapid atrial pacing-induced AF. Gussak et al. explain that NGF released from fibrillating atrial myocytes in the left atrial appendage is taken up by parasympathetic and sympathetic nerve fibrils in the atrial myocardium and is retrogradely transported to the atrial GPs and the SG, respectively, thereby leading to hypertrophy of postganglionic neurons in these structures. This hypertrophy of the ‘parent’ ganglia then leads to the diffuse parasympathetic and sympathetic hyperinnervation through all regions of the left atrium. These findings suggest that dysregulation and imbalance of autonomic nervous function are key factors regulating the occurrence and persistence of AF. Consequently, damage to the GP network could also reveal the inhibition of the onset and progression of the AF.

Recent years have seen the emergence of ablation as a major therapeutic advance in the treatment of AF. Unfortunately, both pharmacological and ablative therapies for AF have suboptimal efficacy in patients with persistent AF. Moreover, partial vagal denervation may facilitate rather than prevent vagally mediated AF by increasing the heterogeneity of refractoriness within the atria. Numerous studies have demonstrated that myocardial injuries, such as the previously mentioned MI or radiofrequency catheter

Figure 2 The role of NGF in response to pathological cardiac stress. (A) NGF induces complex, autonomic changes occurring secondary to acute myocardial infarction, like the sympathetic hyperinnervation and hypertrophy of postganglionic neurons in SG. These effects may promote arrhythmias that may be responsible for sudden cardiac death. (B) NGF exerts a protective effect on tissue repair like vascular endothelial dysfunction during atherogenesis (detailed description in the text). MC, mast cell; NGF, nerve growth factor
ablation, lead to cardiac nerve sprouting and sympathetic hyperinnervation in the animal models, which has been known to be related to the rises of the level of NGF. Radiofrequency catheter ablation for AF increases the plasma concentration of NGF. High plasma levels of NGF were found to be associated with high sympathetic nerve activity estimated by heart rate variability and high number of atrial premature contractions after ablation.

To summarize, the heterogeneity in afferent neural signals, along with the remodelling of convergent neurons, may play an important role in the genesis of arrhythmias and progression to HF. Due to the complexity of the pathogenesis underlying AF, there are few effective therapies available. Therefore, a better understanding of the molecular mechanisms underlying the genesis and maintenance of the AF disease state and the NGF role in the creation of electrical/structural remodelling in the fibrillating atrium would facilitate the development of newer, dedicated therapies for this arrhythmia.

Congestive heart failure

A key component of altered sympathetic nervous system pathology is a reduction in sympathetic nerve density, which is associated with a reduction in the tissue levels of NGF both in experimental animals and humans. In CHF, NGF protein expression is decreased in ventricles, resulting in reduced trophic support for sympathetic neurons. Functionally, sympathetic nerves in CHF convert from a balanced NE synthesis, release, and reuptake system to the one that predominantly releases NE, resulting in excessive myocardial stimulation and catecholamine toxicity. Govoni et al. explained that the reduction in NGF levels may be caused by the fact that high catecholamine levels inhibit NGF expression. Pro-NGF has been shown to promote pruning, degeneration, and apoptosis of sympathetic axons in the relative absence of the mature form and a reduction in mature NGF, accompanied by stable levels of the pro-form, would potentially decrease sympathetic-parasympathetic apposition in the failing heart and disrupt autonomic crosstalk. Accordingly, changes in mature NGF and pro-NGF within CG neurons from CHF rats in a study by Hasan and Smith were similar to those observed after sympathectomy, suggesting a common mechanism is at play. Similarly, during the progression of HF, HF induced by NE infusion leads to a decline in NGF expression and production by cardiomyocytes, which is mediated by alpha-1-adrenergic receptor activation. Intriguingly, while beta-ARs have been shown to promote NGF expression, alpha-1-adrenergic receptor stimulation promotes an attenuation of NGF in the heart. This may be favoured by increased apoptosis of myocytes and widespread myocardial denervation as a ramification of chronic elevated adrenergic tone and mechanical stretch. Moreover, mechanical stretching is a pathophysiological stimulus that is correlated with several cardiac diseases, such as MI, HF, or arterial hypertension, and Rana et al. discovered that in cardiomyocytes, cellular stretching leads to a decrease in NGF mRNA and protein expression.

Atherosclerosis/acute coronary syndrome

Basic and clinical studies indicate that atherosclerosis is an inflammatory-fibroproliferative disease initiated by endothelial dysfunction and develops as a result of a complex interaction between various growth factors/cytokines, VSMCs, and immune cells. NGF is secreted by both types of cells that participate in the inflammatory process, structural cells (i.e. ECs, smooth muscle cells, and fibroblasts) and cells of the haemopoietic immune system that infiltrate into the site of inflammation, such as mast cells (MCs), macrophages, and lymphocytes. In fact, NGF mediates many inflammatory and autoimmune states in conjunction with increased accumulation of MCs that appear to be involved in neuroimmune interactions and tissue inflammation. Because MCs are known to be a cellular component of the coronary artery and these cells not only respond to NGF but also produce and release NGF, the presence and distribution of MCs in atherosclerotic and control coronaries have been also examined. NGF, acts as a chemoattractant, thereby causing an increase in the number of MCs as well as their degranulation, inducing the release of various mediators from MC. Interestingly, NGF receptors on MCs act as autoreceptors, regulating MC NGF synthesis and release, while at the same time being sensitive to NGF from the environment. The fact that the number of MCs increases, whereas the availability of NGF decreases, suggests that MCs do not play a decisive role in NGF synthesis in atherosclerotic vascular tissue. However, it is still open to further research to determine whether these MC populations, via their potential to synthesize and release NGF, attempt to compensate for the reduced NGF in the coronary wall and prevent atherosclerosis.

Accordingly, recent studies have reported the potential importance of NTs in atherosclerosis and related disorders, which leads to the hypothesis that NTs undergo significant changes in acute coronary syndromes (ACS), the major clinical complications of coronary artery disease and atherosclerosis. Chaldakov et al. were the first to demonstrate that the level of NGF was significantly reduced in human coronary arteries with advanced atherosclerotic lesions. These results also revealed that the coronary adventitia of atherosclerotic subjects displayed an overexpression of p75NTR immunoreactivity and a significantly greater number of MCs and vasa vasorum than those of...
controls. There is a possibility that the secretion of NGF in pathological tissues is reduced because VSMCs, which are the main vascular source of NGF, undergo atrophy in atherosclerosis and/or the NGF turnover is higher in atherosclerotic arteries than in normal arteries. It has been reported that NGF derived from MCs and T lymphocytes exerts a protective effect on tissue repair. Similarly, Chaldakov et al. recently reported that the plasma levels of NGF and BDNF are significantly reduced in patients with metabolic syndrome and ACS.

The decreased vascular tissue content of NGF in human coronary atherosclerosis suggests that a metabolic imbalance due to the reduction in NT availability may operate in the pathogenesis of obesity and related metabolic diseases, such as type 2 diabetes, metabolic syndrome, and atherosclerosis. Important lines of evidence to support this hypothesis include the following: (1) NGF shares a striking structural homology with proinsulin and exerts certain effects on lipid metabolism and energy homeostasis; (2) pancreatic beta cells secrete NGF and express its receptor, TrkA, and NGF enhances glucose-induced insulin secretion via an autocrine/paracrine pathway (it is possible that pancreatic NGF may be exported to the bloodstream where it functions as an endocrine messenger; decreased NGF serum levels was observed in diabetic patients); (3) NGF up-regulates the expression of low-density lipoprotein (LDL) receptor-related protein; (4) NGF inhibits glucose-induced down-regulation of caveolin-1, which plays a critical role in TrkA and p75NTR signalling, LDL receptor signalling, and lipid metabolism and obesity; (5) NGF, through its serine protease activity, converts plasminogen into plasmin, which is a crucial factor for the activation of transforming growth factor-beta (a key inhibitor of atherogenesis), strongly up-regulates interleukin-10, another inhibitor of atherogenesis, and induces the expression of urokinase plasminogen activator receptor (Figure 2B).

In summary, the studies carried out in the past three decades have revealed that the key NT NGF not only stimulates nerve growth and survival but also exerts trophic effects on ECs, acting as angiogenic factor, and is involved in the maintenance of glucose, lipid and energy homeostasis, and regulation of pancreatic beta cells and the cardiovascular system, and is thus designated metabotrophin (from the Greek word meaning ‘nutritious for metabolism’). Indeed, NGF may operate as a metabotrophin, which means that it is involved in the maintenance of cardiometabolic homeostasis (glucose and lipid metabolism as well as energy balance, cardioprotection, and wound healing), and the reduction in NGF availability and/or utilization may play a critical role in the pathogenesis of cardiometabolic dysfunctions, such as coronary artery disease and atherosclerosis.

Altogether, NGF is an important factor in the degenerative and regenerative processes that occur in the heart. NGF suppression is related to abolishment of the angiogenic repair process, elevation of cardiomyocyte apoptosis and generally worsened cardiac function. Understanding these complex cell–cell interactions and molecular mechanisms leading to NGF-mediated cell dysfunction might provide insight into new therapeutic approaches and treatments for cardiovascular diseases.

Conclusions

Although NTs are well known for their survival effects on neurons, it is clear that their properties are more wide ranging. Here, we focused on outlining the importance of the first discovered member of this class of growth factors, NGF, in determining and maintaining cardiovascular phenotypes and homeostasis. Strong evidence has emerged that NGF exerts important cardiovascular activities and unique ‘tropisms’ to many cells within the cardiovascular niche. In addition to its neuronal functions, NGF is an essential factor in heart formation and triggers a variety of effects on peripheral tissues, including the vasculature and ECs and regulates angiogenesis and vasculogenesis. This molecule contributes to the maintenance of proper heart rate, conduction velocity, and contractility or, conversely, heart function disruption and disease, which depends on its concentration within the niche; its synthesis and release are altered under different pathological conditions. The altered presence of NGF and/or its receptors may be involved in the pathogenesis of vascular/heart diseases, including hypertension, MI, HF, cardiac hypertrophy, atherosclerosis, or ACS. Individual differences of NGF expression might also be responsible for differential nerve sprouting, heterogeneous remodelling and hyperadrenergic innervation and susceptibility to arrhythmia. Identification of the molecular mechanisms involved in the interactions between cardiomyocytes and other types of cells and exploration of the extensive and diverse effects exerted by NGF within the cardiovascular niche may enhance our understanding of heart development, function, and disease and may lead to the design of new effective therapeutic strategies. A further challenge is represented by the increasing knowledge of the role of NGF in vascular, immune, metabolic, or nervous system regulation, opening an interesting field for the development of innovative NGF-based therapies in cardiovascular diseases and a novel and demanding clinical aspect of the use of NGF.

Conflict of interest

The authors declare that they have no competing interests.
Funding

The project was financed from the programme of the Minister of Science and Higher Education under the name ‘Regional Initiative of Excellence’ in 2019–2022 project number 002/RID/2018/19 amount of financing 12 000 000 PLN.

Author contributions

E.P.S. searched of the literature, wrote, drafted, and revised of the manuscript and prepared figure. B.M. contributed to all aspects of the manuscript preparation, from conception and design, to review and correction of the final manuscript. All authors read and approved the final manuscript.
