Abstract
Background: Given the active research on targeted therapy using tyrosine kinase (TK) inhibitors (TKIs) in the field of oncology, further studies have recently been conducted to evaluate their use in autoimmune disorders. Based on immunological investigations, previous studies have suggested that granulomatous meningoencephalomyelitis (GME) and necrotizing encephalomyelitis (NE) are similar to multiple sclerosis (MS), which is a human autoimmune demyelinating central nervous system disease. 

Objectives: Considering this perspective, we hypothesized that canine GME and NE have significant expression of one or more TKs, which are associated with human MS pathogenesis.

Methods: To determine the possible use of conventional multi-targeted TKIs as a treatment for canine GME and NE, we characterized the immunohistochemical expression of platelet-derived growth factor receptor (PDGFR)-α, PDGFR-β, vascular endothelial growth factor receptor (VEGFR)-2, c-Abl and c-Kit in GME and NE samples.

Results: Histological samples from four dogs with GME and three with NE were retrieved. All samples stained positive for PDGFR-β (7/7 [100%]), PDGFR-α and c-Kit were expressed in 3/7 (42.8%) samples each. c-Abl was identified in 2/7 (28.5%) samples; no sample showed VEGFR-2 (0%) expression. Co-expression of TKs was identified in 6/7 (85.7%) dogs.

Conclusions: All samples were positive for at least one or more of PDGFR-α, PDGFR-β, c-Kit and c-Abl, which are known as the target TKs of conventional multi-targeted TKIs. Their presence does suggest that these TKs may play a role in the pathogenesis of GME and NE. Therefore, multi-targeted TKIs may provide benefits in the treatment of canine GME and NE by suppressing the activity of these TKs.

1 | INTRODUCTION

Granulomatous meningoencephalitis (GME) and necrotizing encephalitis (NE) are common idiopathic inflammatory diseases of the central nervous system (CNS) in dogs (Talarico and Schatzberg, 2010). A histopathologic diagnosis is generally not available for ante-mortem examination; meningoencephalomyelitis of unknown etiology (MUE) has been used as an umbrella term that encompasses GME and NE before histopathologic confirmation (Adamo, Rylander, & Adams, 2007). It usually involves the brain, spinal cord and/or meninges, and clinical signs typically depend upon the location and severity of the CNS lesions (Granger, Smith, & Jeffery, 2010). A presumptive diagnosis in the clinical setting is usually achieved through a multimodal approach that includes signalment, advanced imaging and cerebrospinal fluid analysis (Talarico & Schatzberg, 2010). The exact pathogenesis of GME and NE is still not fully understood; however, it has long been assumed to involve autoimmune-mediated disorders, and based on immunopathological analysis, several studies have suspected common aberrant immune responses against CNS tissues (Park, Uchida, & Nakayama, 2014; Suzuki et al., 2003; Uchida, Park, Tsuboi, Chambers, & Nakayama, 2016).

Systemic medical therapy using a combination of glucocorticoids and immunosuppressive agents is the current mainstay of treatment of MUE in dogs, despite the less-well-understood pathogenic mechanisms (Dewey, 2015; Granger et al., 2010; Jung et al., 2007). The reported immunosuppressive drugs include cytotoxic agents, azathoprine, lomustine, procarbazine, mycophenolate mofetil, leflunomide and cyclosporine (Adamo et al., 2007; Sospenda, Konkuk University Veterinary Pathology Laboratory (Seoul, National University Animal Medical Center (Jinju, Republic of Korea) (Talarico et al., 2016)). Samples were obtained from the pathology files at the Gyeongsang National University Animal Medical Center (Jinju, Republic of Korea) and Konkuk University Veterinary Pathology Laboratory (Seoul, Korea).

Subjects and tissue samples

Formalin-fixed (in 4% paraformaldehyde in phosphate-buffered saline [PBS]), paraffin-embedded sections from four GME and three NE (total 7) samples were obtained from the pathology files at the Gyeongsang National University Animal Medical Center (Jinju, Republic of Korea) and Konkuk University Veterinary Pathology Laboratory (Seoul, Korea).
SONG et al. Republic of Korea (Table 1). The data retrieved from the medical records included signalment data and definitive histopathologic diagnoses. For all samples, the corresponding hematoxylin and eosin-stained slides were reviewed by two pathologists to confirm the diagnosis and to separate the lesioned tissue from areas of normal tissue.

2.2 | Immunohistochemical staining

Immunohistochemical staining was performed on 5 µm paraffin-embedded sections. Sections were mounted on positively charged glass slides. The slides were then deparaffinized in xylene and rehydrated in ethanol. Hydrogen peroxide (3%) in phosphate-buffered saline (PBS) was applied to inhibit endogenous peroxidase activity for 20 min at room temperature. Slides were then washed three times with PBS. Antigen retrieval was performed subsequently using the heat-induced epitope retrieval method for 20 min with a citric acid buffer at pH 6.0 for PDGFR-α/PDGFR-β/VEGFR-2/c-Abl and an ethylenediaminetetraacetic acid (EDTA) buffer at pH 9.0 for c-Kit. After antigen retrieval, the slides were cooled for 20 min and washed three times in PBS. The slides were then incubated with 5% goat serum (protein blocking agent) in PBS for 30 min to reduce nonspecific binding. Next, the sections were incubated with the appropriate diluted antibodies: polyclonal rabbit anti-PDGFR-α (dilution 1:2,000; Lifespan BioSciences) for 120 min, polyclonal rabbit anti-PDGFR-β (dilution 1:700; Abcam) for 120 min, polyclonal rabbit anti-VEGFR-2 (dilution 1:100; Abcam) for 90 min, polyclonal rabbit anti-c-Abl (dilution 1:800; Santa Cruz Biotechnology) for 90 min and polyclonal affinity isolated rabbit anti-c-Kit (dilution 1:300; DAKO, Glostrup, Denmark) for 180 min at room temperature. The sections were washed in PBS and stained with 3,3’-diaminobenzidine tetrahydrochloride colorimetric reagent (DAB, Vector Laboratories). Finally, sections were counterstained with Gill’s hematoxylin for 5 s, dehydrated through an ethanol series and mounted with Permount (Fisher, Scientific, Grand Island).

Appropriate known antigen-positive tissues were used as positive controls (including canine cerebellar Purkinje cells for PDGFR-α, canine renal tubule for PDGFR-β, canine mammary adenocarcinoma for VEGFR-2 and c-Abl and canine mast cell tumor tissue for c-Kit) to confirm antibody staining. Negative control experiments were carried out by replacing the primary antibody with the antibody dilution buffer.

2.3 | Immunohistochemical evaluation

Immunohistochemical evaluation assessed the staining positivity of each TK and the staining intensity and distribution of TK-positive cells based on previously described methods (Walters, Martin, Price, & Sula, 2018). Overall staining intensity was graded as no immunostaining, weak immunostaining or moderate and intense immunostaining at ×40 magnification and given a score ranging from 0 to 3 (Table 2). The distribution of positively stained cells (% cells affected) was evaluated in randomly selected five separate fields at ×200 magnification and was graded as follows: 0%, 1%–9%, 10%–50% or 51%–100% and given a score ranging from 0 to 3 (Table 2). The immunohistochemical results were reviewed by two pathologists.

2.4 | Statistical analysis

Fisher’s exact tests were used to determine if the immunohistochemical evaluation was statistically associated with sample groups (GME and NE) for each of the five TKs. Statistical analysis was performed using SPSS 19 software statistics, and P-values < .05 were considered statistically significant.

3 | RESULTS

3.1 | Sample demographics

Tissue samples were available for this study from seven dogs that had died from MUE. Affected tissue samples were obtained after

### Table 1: Signalment characteristics and definitive diagnoses of dogs enrolled in this study

### Table 2: Immunohistochemistry scoring protocol

| Parameter on × 40 magnification | Intensity score | Staining distribution | Parameter on × 200 magnification | Distribution score |
|---------------------------------|-----------------|-----------------------|----------------------------------|--------------------|
| Staining intensity              |                 |                       |                                  |                    |
| No immunostaining               | 0               | 0%                    |                                  | 0                  |
| Weak                             | 1               | 1%–9%                 |                                  | 1                  |
| Moderate                        | 2               | 10%–50%               |                                  | 2                  |
| Intense                         | 3               | 51%–100%              |                                  | 3                  |
necropsy, and a definitive diagnosis was achieved by histopathologic examination. Of these seven samples, four were from dogs with GME and three with NE (Table 1). Six different breeds were present, and all the breeds were small breeds. The median age was five years (range, 1–10 years). Six dogs were female (85.7%), and one dog was male (14.3%).

3.2 | Immunohistochemistry

Affected brain tissues were separated from areas of normal brain tissue and used for immunohistochemical staining. Table 3 summarizes the immunohistochemical results of all seven tissue samples.

PDGFR-ß was expressed in seven of seven (100%) cases, including four cases of GME and three of NE (Figure 1 and Table 4). All samples showed moderate to intense staining intensity; three of seven (42.9%) had moderate expression, and four of seven (57.1%) had intense expression. In three (42.9%) cases, between 1% and 9% of cells expressed PDGFR-ß, whereas in two (28.6%) samples, 10%-50% of cells and in two (28.6%) samples, 51%-100% of cells expressed PDGFR-ß.

PDGFR-α was expressed in three of seven (42.9%) cases, including one of GME and two of NE (Figure 2 and Table 4). Of these, one of seven (14.3%) had weak expression, and two of seven (28.6%) had moderate expression. In one (14.3%) case between 1% and 9% of cells expressed PDGFR-α; in one (14.3%) case, 10%-50% of cells and in another (14.3%), 51%-100% of cells expressed PDGFR-α.

c-Kit was expressed in three of seven (42.9%) cases, including one of GME and two of NE (Figure 2 and Table 4). Of these, one of seven (14.3%) had weak expression, and two of seven (28.6%) had moderate expression. In one dog (14.3%), between 1% and 9% of cells, and in two (28.6%) dogs, between 10% and 50% of cells expressed c-Kit.

c-Abl was identified in two of seven (28.6%) cases, including one of GME and one of NE (Figure 2 and Table 4). Among these, one of seven (14.3%) had weak staining, and one (14.3%) had moderate staining intensity. In one case (14.3%), between 1% and 9% of cells and in another case (14.3%), between 10% and 50% of cells expressed c-Abl.

VEGFR-2 was not detected in any of the GME and NE cases (0%) (Table 4).

There was no statistically significant association between GME and NE samples in terms of expression positivity for each of the five TKs (all \( p > .05 \)).

Co-expression of TKs was identified in six dogs (85.7%). One dog (14.3%) expressed three TKs; five dogs (71.4%) expressed two TKs; in one case (14.3%), only one TK (PDGFR-ß) was expressed. Of the co-expressed samples with PDGFR-ß expression, three cases (42.9%) showed co-expression of PDGFR-α; three cases (42.9%) showed co-expression of c-Kit and two cases (28.6%) showed co-expression of c-Abl.

4 | DISCUSSION

It is well known that TKs play an important role in the pathogenesis of malignant tumors and inflammatory processes and in human and veterinary medicine. To date, many novel TKIs are being increasingly developed by pharmaceutical companies, and several TKIs have

| Dog | PDGFR-α | PDGFR-ß | VEGFR-2 | c-Abl | c-Kit |

Abbreviations: D, Distribution; I, Intensity; PDGFR, Platelet-Derived Growth Factor Receptor; VEGFR, Vascular Endothelial Growth Factor Receptor.
been officially approved for the treatment of human and animal cancers. With active research on targeted therapy using TKIs in the field of oncology, further studies have recently been conducted to evaluate their use in autoimmune disorders. Among the autoimmune diseases, neuroinflammation in MS is one of the most promising research fields for TK and TKI applications (Liu et al., 2014). Despite this ongoing research on the application of TKIs in human and animal models of MS, the role of TKs and their efficacy in canine GME and NE have not yet been evaluated.

We have attempted to assess the expression of PDGFR-α, PDGFR-β, VEGFR-2, c-Abl and c-Kit in canine GME and NE using immunohistochemical staining. These TKs are the therapeutic targets for widely used multi-targeted TKIs (e.g. imatinib, toceranib and masitinib) in veterinary medicine. Based on the expression of these

| Expression of TK | Expression | GME (n = 4) | NE (n = 3) | Total (n = 7) | %  |
|------------------|-----------|-------------|------------|--------------|----|
| PDGFR-α          | Expression (total) | 1 (1/4) | 2 (2/3) | 3 (3/7) | 42.9 |
| Staining intensity | Weak (1) | 0 | 1 | 1 | 14.3 |

TKs, we tried to show the applicability of TKIs in therapy for GME and NE and surmised their potential role in disease pathogenesis. To the authors’ knowledge, this is the first study to describe the expression of TKs in canine GME and NE.

In this current study, two different subtypes were compared, and there was no significant difference in the expression positivity of each TKs between GME and NE. All samples stained positive for PDGFR-ß (100%), with the majority of samples exhibiting relatively intense staining and broad distribution. This result was more evident than the expression of other TKs, and there was no significant difference in the PDGFR-ß positivity between GME and NE. PDGFR-α, which is the isoform receptor of PDGFR-ß, was expressed in 42.9% of the samples, but was relatively less intensely and broadly expressed than PDGFR-ß. Based on these results, we suspected that each PDGFR has a different role in the disease process. These two receptor isoforms bind differently with each PDGF ligand and elicit its biological activity through signal transduction (Claesson-Welsh, 1994). Although the specific role of the two different PDGFRs in the autoimmune disease process is still under investigation, astrocyte proliferation largely depends on signaling mediated by both PDGFRs, and strong upregulation of PDGFRs was well described by a previous study of experimental autoimmune encephalomyelitis (EAE), a mouse model of MS (Koehler et al., 2008; Luo & Miller, 2001). Similarly, the activation of astrocytes is closely related to the pathology of canine MUE (Coates & Jeffery, 2014). Astrocytes were considered as a common target cell type of autoantibodies in GME and NE, suggesting a vital role in the autoimmune CNS disease process (Matsuki et al., 2004; Matsuki, Takahashi, Yaegashi, Tamahara, & Ono, 2009). According to this perspective, we could also observe the area of prominent inflammatory cell infiltration around the astrocytes and these astrocytes showed high expression levels of PDGFRs (Figures 1 and 2a–c). Therefore, the overexpression of PDGFRs and the related astrocyte activation are thought to play a significant role in canine GME and NE pathogenesis.

A few studies investigating PDGFR have demonstrated that up-regulated PDGFR-α promotes oligodendrocyte maturation and remyelination (Maeda et al., 2001; Wilson, Scolding, & Raine, 2006), suggesting a beneficial effect of PDGFR-α in the MS disease process. In contrast, recent studies have emphasized that PDGFR-ß is crucial for vascular stabilization and that aberrant expression of this receptor contributes to the pathogenesis of immune-mediated disorders, including EAE (Carmeliet, 2005; Crespo et al., 2011; Zhang et al., 2009). Thus, it is speculated that the overexpression of PDGFR-ß in the lesions could have a more detrimental effect on disease status than that of PDGFR-α. In addition, given the strong expression of PDGFR-ß in all samples of our study, we surmised that this TK could be involved in key aspects of the pathogenesis of GME and NE, and targeted therapy for overexpressed PDGFR-ß may contributing factors of MS deterioration (Crespo et al., 2011). The compromise of the blood-brain barrier (BBB) is another negative pathogenic process of astroglialosis (Williams et al., 2007). Astroglialosis also contributes to the disruption of immune responses and glutamate homeostasis in CNS (Kariq, Bridges, & Eyer, 2001; Nair et al., 2008; Werner, Pitt, & Raine, 2001). Similarly, the activation of astrocytes is closely related to the pathology of canine MUE (Coates & Jeffery, 2014). Astrocytes were considered as a common target cell type of autoantibodies in GME and NE, suggesting a vital role in the autoimmune CNS disease process (Matsuki et al., 2004; Matsuki, Takahashi, Yaegashi, Tamahara, & Ono, 2009). According to this perspective, we could also observe the area of prominent inflammatory cell infiltration around the astrocytes and these astrocytes showed high expression levels of PDGFRs (Figures 1 and 2a–c). Therefore, the overexpression of PDGFRs and the related astrocyte activation are thought to play a significant role in canine GME and NE pathogenesis.

A few studies investigating PDGFR have demonstrated that up-regulated PDGFR-α promotes oligodendrocyte maturation and remyelination (Maeda et al., 2001; Wilson, Scolding, & Raine, 2006), suggesting a beneficial effect of PDGFR-α in the MS disease process. In contrast, recent studies have emphasized that PDGFR-ß is crucial for vascular stabilization and that aberrant expression of this receptor contributes to the pathogenesis of immune-mediated disorders, including EAE (Carmeliet, 2005; Crespo et al., 2011; Zhang et al., 2009). Thus, it is speculated that the overexpression of PDGFR-ß in the lesions could have a more detrimental effect on disease status than that of PDGFR-α. In addition, given the strong expression of PDGFR-ß in all samples of our study, we surmised that this TK could be involved in key aspects of the pathogenesis of GME and NE, and targeted therapy for overexpressed PDGFR-ß may

![FIGURE 2](https://i.imgur.com/3Q5Z5y.png) Expression of PDGFR-α (A to C; cases 2, 6 and 7), c-kit (d to f; cases 1, 5 and 7) and c-Abl (g to h; cases 4 and 7) for each brain parenchymal tissue sample. All TK-expressing samples showed mild to moderate staining intensity (Intensity score 1 to 2). All except one (c; Case 7, Distribution score 3) of the samples had 1%–50% staining distribution (distribution score 1 to 2). Magnification, ×200; Scale bar size, 70 μm.
have potential as an effective treatment modality for GME and NE. However, further studies will be required to fully understand the relationship between the expression of each PDGFR and immune-mediated CNS inflammation in dogs.

c-Kit expression was found in a moderate number of samples (42.9%, 3/7) with relatively moderate staining intensity and distribution in this study. Up to now no studies have ever tried to evaluate the role of c-Kit in canine immune-mediated CNS inflammation. However, in the last few years, several articles have been devoted to the study of c-Kit in autoimmune disorders including MS and EAE, and the role of c-Kit in autoimmune disease pathogenesis through mast cells is well described (Benoist & Mathis, 2002; Piconese et al., 2011). c-Kit is a stem cell factor receptor and acts as a key controller receptor for mast cell development and functioning (Maeda, Nishiyama, Ogawa, & Okumura, 2010; Maeda et al., 2001). The high expression of c-kit in mast cells enhances their cell development, degranulation and release of chemokines and cytokines (Safari et al., 2015). Mast cells are a dense cell population in the meninges and near the vessels involved in MS and EAE (Sayed, Christy, Quirion, & Brown, 2008). Mast cells play an important role in CNS demyelination and the initial entrance of myelin-specific T-cells by disrupting BBB permeability in the initial phases of MS (Bebo, Yong, Orr, & Linthicum, 1996; Hershko & Rivera, 2010; Sayed, Christy, Walker, & Brown, 2010). Their other contribution to the disease process is releasing large amounts of proinflammatory mediators and recruiting other inflammatory cells; therefore, they play a critical role in sustaining CNS inflammation (Kinet, 2007). For instance, the presence of mast cells and the percentage of degranulated mast cells in the CNS have been found to correlate with the severity and clinical onset of immune-mediated neuroinflammatory disease (Brenner, Soffer, Shalit, & Levi-Schaffer, 1994; Secor, Secor, Gutekunst, & Brown, 2000). Although it has not yet been studied in NE, a study on GME showed mast cell infiltration in the lesions in all cases (20/20), and a significantly larger number of mast cells was found in dogs with the acute form of the disease (Demierre et al., 2001). Based on these perspectives, we hypothesized that mast cells might also influence the disease pathogenesis and clinical status of canine GME and NE. Although mast cells were not evaluated in this study, c-Kit expression was clearly identified in partial samples with moderate intensity and distribution. Therefore, targeted therapies directed at blocking c-Kit and/or mast cell action, in conjunction with the standard treatment of disease, may provide more efficacious treatment options for GME and NE. Furthermore, conventional multi-targeted TKIs mentioned above such as imatinib, toceranib and mastinib, which can directly block both c-Kit and PDGFR-β may also be a meaningful aid in treatment of GME and NE. However, the relevant c-Kit and mast cell functions in these diseases have remained elusive, and further well-designed studies are required to confirm the clinical importance of these factors in canine GME and NE.

c-Abl is a member of the Src family of non-receptor TKs and participates in diverse signalling pathways that govern cellular proliferation, differentiation and apoptosis. c-Abl has been shown to play a fundamental role in the development and function of the CNS (Koleske et al., 1998), and several studies have been conducted to reveal its role in various neurological diseases. However, the association of c-Abl with immune-mediated CNS diseases has not yet been studied. Although one recent study has suggested the role of c-Abl in autoimmunity (Veillette, Rhee, Souza, & Davidson, 2009), further studies are needed to help clarify the role of this TK in canine MUE.

VEGF is a multifunctional mediator of blood vessel physiology, including vasculogenesis and angiogenesis. VEGF induces endothelial-specific mitogenesis and vascular hyperpermeability and acts as a chemoattractant to inflammatory cells (Clauss, 2000). A previous study of autoimmune CNS disease suggested that the overexpression of VEGF may exacerbate the inflammatory response by multiple bioactivities: increased vascular permeability, BBB breakdown, the expression of major histocompatibility complex (MHC), the upregulation of adhesion molecules on endothelial cells and macrophage chemotraction (Proescholdt, Jacobson, Tresser, Oldfield, & Merrill, 2002). Particularly, the BBB has been considered an important pathologic site in CNS autoimmunity (Gay & Esiri, 1991; Moor, de Vries, de Boer, & Breimer, 1994). BBB disruption and perivascular abnormality have also been considered typical features of canine GME and NE, and these abnormalities are known as key factors in the disease process (Plummer, Wheeler, Thrall, & Kornegay, 1992; Sorjonen, 1990). VEGFR-2, the receptor of VEGF, was not detected in GME and NE samples in this study. The VEGFR-2 expression was not detected even in the sites with marked perivascular mononuclear cell infiltration (Figure 1a,d,g), suggesting that the results might be more meaningful. According to this result, although various factors are known to affect the vascular and BBB integrity of the CNS, it may be suggested that VEGF is not always associated with the pathogenesis of GME and NE. Moreover, it is unlikely that therapy targeted to VEGFR will always be rewarding for subjects with GME and NE.

The relatively small sample size and selective sampling from individual tissue sections were the most marked limitations of this study. The small sample size limited sufficient comparisons of the expression rates of each TK and made a sufficient comparison between the two subgroups difficult. Furthermore, as the samples used in the study were collected from the most prominent lesion in each case and were evaluated in randomly selected microscopic fields, there was a clear limit to representing the TK expression in the entire specimen. Another weakness of this study was the lack of information about the histopathologic features, treatment and survival of the subjects. The changes in TK expression pattern according to histopathological feature, treatment used and clinical course are expected to be meaningful in canine GME and NE. Thus, further large retrospective studies with detailed medical records are needed to clarify the role of TKs.

5 | CONCLUSION

Known targets of conventional multi-targeted TKIs were found to be expressed in canine GME and NE in this study. It was found that
all samples exhibited positive immunostaining for at least one TK, and various co-expression patterns were identified in each of the seven cases analysed. Although positive expression of PDGFR-α, PDGFR-β, c-Kit and c-Abl does not suggest specific functional activities, their presence does suggest that these kinases may play a role in the pathogenesis and development of GME and NE. Furthermore, PDGFR-β staining was significantly more intense and diffuse than that of other TKs in all samples, indicating that PDGFR-β may be involved in key aspects of the disease. We thus conclude that multi-targeted therapy with TKIs may provide benefits in the treatment of canine GME and NE by suppressing the activity of these TKs. An investigation of the clinical application of TKIs in dogs with GME and NE should also be pursued in the future.
