Slow flows of yield stress fluids:
complex spatio-temporal behaviour within a simple elasto-plastic model

(Dated: April 29, 2019)

A minimal athermal model for the flow of dense disordered materials is proposed, based on two
generic ingredients: local plastic events occurring above a microscopic yield stress, and the non-local
elastic release of the stress these events induce in the material. A complex spatio-temporal rheo-
logical behaviour results, with features in line with recent experimental observations. At low shear
rates, macroscopic flow actually originates from collective correlated bursts of plastic events, taking
place in dynamically generated fragile zones. The related correlation length diverges algebraically
at small shear rates. In confined geometries bursts occur preferentially close to the walls yielding
an intermittent form of flow localization.

PACS numbers: 83.50.-v, 81.40.Lm,62.20.Fe

Disordered dense systems often exhibit a peculiar flowing behaviour which strongly departs from the academic
Newtonian description. A non linear rheology, with a shear rate dependence of the viscosity, or the existence of a
yield stress are typical features of such systems. Moreover, it has been recognized recently that these global
characteristics are, in most cases, associated with a peculiar spatial behaviour, in the form of heterogeneous
flow behaviour, where a frozen region coexists with a flowing one (the so-called ”shear band”). A striking remark
is that such generic behaviours are observed in a wide class of experimental systems, with very different
length/time/interaction scales, such as foams, granular systems, emulsions, colloidal glasses, polymers, but also in simulations of granular systems, foams and model glasses. These generic features suggest an underlying common scenario for the flow properties, and has motivated various macroscopic phenomenological approaches (see eg refs. cited in [5] and [8]). However a consistent framework linking the global rheology to the local microscopic dynamics is still lacking, although some progress in this direction has been made in recent years [12, 13, 14]. In particular studies have put forward the role of local plastic rearrangements in the global flow behaviour [12, 13, 14]. Such an idea actually goes back to the Princen model for the deformation of foams [17]: flow occurs via a succession of reversible elastic deformations and irreversible plastic events (“T1” events in foams), associated with the existence of a local yield stress. However, if the corresponding physical picture seems a priori quite clear, a gap still persists between this simple microscopic scenario and the complex spatio-temporal organization responsible for the rheology of these materials at finite shear rates.

In this letter, we propose a simple mesoscopic model, constructed on the basis of two minimal and generic ingredients: localized plastic events associated with a microscopic yield stress, and the resulting elastic relaxation of the stress over the system. We then show that the simplicity of the description contrasts with the complex rheological behaviour deriving from it. In particular we find the global rheology to be associated with a complex spatio-temporal organization which builds up as the system is sheared steadily, with an intermittent behaviour corresponding to ”bursts” of correlated events, the typical size of which diverges at small shear rate. We argue that in its present simple form our model seems to capture many observed experimental features and thus stands as a promising starting point for the elaboration of a generic scenario for the slow flow of yield stress fluids.

Let us now precise the ingredients of our approach, which we implement here in the simplified frame of a 2D scalar approach, focusing only on the simple shear components of the stress and strain. We consider a two dimensional material to which a global shear rate $\dot{\gamma}$ is applied (corresponding to a z dependent displacement in the x direction). The material is described at a coarse grained level, intermediate between the microscopic (particle) and macroscopic scale. The quantity of interest is the component of the time dependent local shear stress $\sigma(x, z; t)$. First, without entering into details at this level, a few basic rules are stated : (i) below a (locally defined) yield stress $\sigma_Y$, the system responds elastically to the imposed deformation; (ii) above $\sigma_Y$, plastic events may occur in the system (along laws discussed in the following); (iii) plastic events take the form of a localized shear strain; (iv) such a plastic event induces a long range elastic perturbation of the shear stress field in the material.
A few remarks can be done at this level. First, although the notion of individual events is quite intuitive, in particular in foams, it has been evidenced unambiguously only recently at the microscopic level in disordered systems \[ \text{[11, 16]} \]. Second, the shear stress perturbation alluded to in (iv) is computed exactly within the framework of tensorial linear elasticity for an isotropic incompressible material as reported in Ref. \[ \text{[18]} \]. This provides the explicit Green function, \( G_{xz} \), relating the stress variation, \( \delta \sigma \), at any point in the system, to the \( x \) component of the plastic strain \( \varepsilon^{pl}(\{x', z'\}; t) \), associated with the plastic event localized at \( \{x', z'\} \). Using the simpler notation \( G \) for this function yields

\[
\delta \sigma(\{x, z\}; t) = 2\mu \int dx' \, G(x, x', z, z') \varepsilon^{pl}(\{x', z'\}; t) \quad (1)
\]

The shear modulus \( \mu \) has been exhibited for convenience. In a 2D infinite system, \( G \) decreases as \( G(r) = 1/(\pi r^2 \cos(\theta)) \) in cylindrical coordinates \( \{r, \theta\} \) (in agreement with refs \[ \text{[14, 15]} \]). In general, its precise form depends on the specific geometry of the system: infinite, periodic or confined between two rigid walls \[ \text{[18]} \]. Summing up at this point, the evolution of the shear stress field results from the global elastic loading \( \gamma \) plus the perturbations induced by the localized plastic events:

\[
\partial_t \sigma(\{x, z\}, t) = \mu \gamma + 2\mu \int dx' \, G(x, x', z, z') \varepsilon^{pl}(\{x', z'\}; t) \quad (2)
\]

The last part of the modelization is the choice of a dynamical law for the plastic events, i.e. the feedback law relating the plastic relaxation \( \varepsilon^{pl}(\{x, z\}; t) \) to the stress field \( \sigma(\{x', z'\}; t' < t) \). As in the Princen model, we choose a local relation with a threshold stress value \( \sigma_Y \). In addition, an intrinsic time scale \( \tau \) is introduced to describe the dynamics of the event. We anticipate that this will lead to a shear rate dependence of the dynamical structure in the flow, driving the system away from the critical quasi-static limit (self-organized criticality in a related quasi-static model was reported in \[ \text{[20]} \]) to a more homogenous situation at large shear rate. Another important outcome is that the local stress may exceed the yield stress \( \sigma_Y \) for a finite time interval so that the averaged stress can also grow beyond this value, as observed experimentally.

There are actually many possibilities to introduce such an intrinsic time scale for plastic events, and few guides as to how should do so. We make here a simple arbitrary choice and assume that the system locally alternates between a purely elastic state and a plastic state (during which stress is released), with finite transition rates: \( \tau_{plast}^{-1} \) is the rate of transitions from elastic to plastic, while the reverse transition is characterized by a time \( \tau_{elast} \). Since plastic events only occur above the yield stress \( \sigma_Y \), we take \( \tau_{plast}(\sigma) = \infty \) if locally \( \sigma < \sigma_Y \). We otherwise assume for sake of simplicity fixed values for the \( \tau_{elast} \) and \( \tau_{plast} \), independent of the local stress. In order to finalize our model, we eventually have to quantify the amount of plastic strain released in an event and simply assume a Maxwell, visco-elastic like relaxation of the material in the plastic state \( \dot{\varepsilon}_{plast} = \frac{1}{2\mu \tau} \sigma \), with \( \tau \) a mechanical relaxation time. All the previous discussion is best summarized by introducing a “state variable” \( n(x, z) \) such that \( n = 0/1 \) identifies the elastic/plastic state:

\[
\dot{\varepsilon}^{pl}(\{x, z\}, t) = \frac{1}{2\mu \tau} n(\{x, z\}; t) \, \sigma(\{x, z\}, t) \quad n(\{x, z\}; t) = \begin{cases} \frac{\tau_{plast}}{\tau_{elast}} & \text{if } \sigma > \sigma_Y \\ 1 & \sigma < \sigma_Y \end{cases} \quad (3)
\]

Equations \( (3) \) and \( (2) \) constitutes our minimal starting point to describe the dynamics of yield stress materials under flow. Note that, as in the somewhat related analysis of Langer \[ \text{[13]} \], neither the stress nor the state variable are convected by the displacement field within the present simplified model.

Before turning to their resolution, eqs \( (2) \) are made dimensionless using \( \sigma_Y \) and \( \tau \) as stress and time units. An important point emerging from this procedure is that the shear rate only appears in the form of the ratio \( \dot{\gamma} / \dot{\gamma}_c \), with \( \dot{\gamma}_c = \sigma_Y / \mu \tau \). In this dimensionless form, our model therefore points out to a very general scenario, in which specific microscopic details are embedded in the precise values of \( \sigma_Y \) and \( \dot{\gamma}_c \), as already suggested by some experiments \[ \text{[3, 21]} \].

The dynamical equations in this dimensionless form have been solved numerically, by discretizing the material into blocks of elementary size \( a \). A pseudospectral method is used, which allows us to express easily the stress increments in reciprocal space at each timestep. On the other hand, the state variable \( n(i, a, j a) \) in the block \( \{i, j\} \) evolves in real space according to the stochastic laws enounced above. We have focused on two geometries of \( N = (L/a)^2 \) blocks: a biperiodic geometry and a confined one where the system is bounded by two rigid parallel walls. Practically we have chosen \( \tau_{plast} = \tau_{elast} = \tau \) for the results reported here.

We first quote the results for the biperiodic system. In Fig. \[ \text{[1]} \] we plot the results for the macroscopic flow curve, which displays the essential features observed in experiments. First a plateau is found at small shear rate, defining a macroscopic yield stress at vanishing shear rates. The latter is found to be lower than the microscopic yield stress \( \sigma_Y \), and also lower than the related peak value of the stress versus time at small shear rates (see inset in Fig. \[ \text{[1]} \]). A different regime is found at large shear rates, where a Newtonian behaviour is recovered. The dynamics of the time dependent shear stress is also quite different in these two regimes. In particular, relative stress fluctuations around the mean value increase as the shear rate decreases (not shown), in agreement with observations in experiments and simulations \[ \text{[7, 8]} \].
To get more insight into this aspect, a possible route is to develop a shear rate dependent length scale in direction.

Interestingly, the transition between the intermediate to knowledge absent in previous studies of yield stress fluids. Verifying length scale at small shear rates, a feature to our development of a shear rate dependent correlation length, the correlation spatial effect observed above. Assuming the existence of a shear rate dependent correlation length $\xi(\dot{\gamma})$ in the system, a saturation effect is expected for the mean stress drop when $\xi(\dot{\gamma})$ reaches the system size, $N^{1/2}a$. The rescaled graph indicates that such a saturation occurs for a fixed value of $N\dot{\gamma}/\dot{\gamma}_c$ which suggests $\xi(\dot{\gamma}) \sim \dot{\gamma}^{-\alpha}$, with $\alpha \approx 1/2$ from these data. Our model therefore explicitly yields indication of (at least) one diverging length scale at small shear rates, a feature to our knowledge absent in previous studies of yield stress fluids. Interestingly, the transition between the intermediate to development of a shear rate dependent length scale in the system, which grows at small shear rates. In order to get more insight into this aspect, a possible route is to measure the length via measurements of correlation function. This is however a difficult task in general and we have followed a different strategy here, analogous to finite size scaling. Namely, since such a length is associated with the correlation of plastic events during a macroscopic stress drop, it should show up in the statistics of stress drops. To this end, we have computed the mean stress drop in plastic events, $\Delta\tilde{\sigma}$, as a function of shear rate. Results are shown in Fig. 3 for various system sizes. Let us first discuss the inset which exhibits the bare results for the average stress drop normalized by the average stress, $\Delta\tilde{\sigma} = \Delta\sigma(\dot{\gamma})/\sigma(\dot{\gamma})$. Three different regimes can be identified for all system sizes: two plateaus at large and small shear rates and an intermediate regime relating these two. We remark that the transition between the intermediate and “saturation” regime at low $\dot{\gamma}$ shifts to lower shear rates when the size of the system is increased.

The system size dependence of this transition at low shear rate is best evidenced using a rescaling procedure, in which all different curves are found to coincide in the variables $\{N\dot{\gamma}/\dot{\gamma}_c, \Delta\tilde{\sigma}(\dot{\gamma})/\Delta\tilde{\sigma}(0)\}$. This rescaling in the $\dot{\gamma}$ variable actually allows us to quantify the correlation spatial effect observed above. Assuming the existence of a shear rate dependent correlation length $\xi(\dot{\gamma})$ in the system, a saturation effect is expected for the mean stress drop when $\xi(\dot{\gamma})$ reaches the system size, $N^{1/2}a$. The rescaled graph indicates that such a saturation occurs for a fixed value of $N\dot{\gamma}/\dot{\gamma}_c$ which suggests $\xi(\dot{\gamma}) \sim \dot{\gamma}^{-\alpha}$, with $\alpha \approx 1/2$ from these data. Our model therefore explicitly yields indication of (at least) one diverging length scale at small shear rates, a feature to our knowledge absent in previous studies of yield stress fluids.
the inset) occurs roughly at the characteristic shear rate \( \dot{\gamma}_c \), independent of system size, as for the macroscopic flow curve in Fig. 1. From these first results, our model yields a flow behaviour with three different regimes as sketched on Fig. 4: (i) for \( \dot{\gamma} > \dot{\gamma}_c \) (or \( \sigma > \sigma_Y \)), the blocks uncorrelated in their dynamics and the flow is homogeneous; (ii) for \( \dot{\gamma} < \dot{\gamma}_c \), correlations increase up to a correlation length \( \xi(\dot{\gamma}) \) which diverges algebraically at small shear rates; (iii) at very low shear rates, the correlation length saturates at the size of the system, leading to a quasi-static dynamical behaviour.

FIG. 4: Sketch of the emerging flow scenario in the \( (\dot{\gamma}/\dot{\gamma}_c,1/N) \) plane. Successive transitions from a homogeneous flow to an organized and a finite size regime occur as the correlation length \( \xi \) grows from the block size to the system size, as the shear rate decreases.

We have also studied a confined geometry where two rigid walls bound the system in the \( z \) direction. A delicate technical point is then the calculation of the Green function, which shows that shear stress perturbation is amplified close to the walls. Essentially, the picture in the confined geometry is very similar to that of the biperiodic system described above (Figs 1, 3, 4). One important specific feature however concerns the localization of the flow: while at high shear rate the flow is homogeneous, at low shear rates the plastic bursts occur preferentially close to the walls. In this last regime, the average flow corresponds to an increased shear rate close to the walls, but this "localization on average" of the flow is only part of a complex spatio-temporal pattern. A more detailed analysis of this regime is left for a future publication.

To sum up, we have proposed an athermal elastoplastic model for the flow of yield stress systems, constructed on the basis of two generic ingredients: localized plastic events, occurring above a microscopic yield stress with a finite duration, and an otherwise elastic behaviour of the material (including redistribution of stress during the events). These two ingredients lead to a complex spatio-temporal behaviour of the system at small shear rates. More precisely a correlation length is exhibited which diverges at small shear rates, corresponding to intermittent collective events (correlated bursts of plastic events), leading to the creation of (long live) fragile zones where the deformation of the system takes place. These bursts take place preferentially close to the walls. At high shear rates, this correlation length is comparable to the size of the individual elements which flow independently from one another. These features are essentially compatible with recent observations in experimental or numerical systems: localization of the time-averaged deformation, intermittency at low shear rate, a diverging length scale at small shear rate in granular systems. Moreover numerical simulation of glassy systems show that flow heterogeneities occur for global shear rates such that \( \sigma < \sigma_Y \), a conclusion which is recovered within our minimal model. Although our model should be refined to take into account convection and the full tensorial nature of the problem, the present early results suggest that the generic behaviours observed in the experiments and molecular simulations originate in a minimal number of ingredients. This opens the possibility for a coherent and robust scenario for the slow flow behaviour of disordered materials.

Stress drops can be identified using a simple criterion, checking that the stress at a time \( t + \delta t \) is larger than the stress at time \( t \). We chose \( \delta t = 0.01 \tau \) and checked that results are robust with respect to variations of \( \delta t \).
