Abstract

At a distance of about 4.22 ly, it would take about 100,000 years for humans to visit our closest stellar neighbor Proxima Centauri using modern chemical thrusters. New technologies are now being developed that involve high-power lasers firing at 1 gram solar sails in near-Earth orbits, accelerating them to 20% the speed of light ($c$) within minutes. Although such an interstellar probe could reach Proxima 20 years after launch, without propellant to slow it down it would traverse the system within hours. Here we demonstrate how the stellar photon pressures of the stellar triple $\alpha$ Cen A, B, and C (Proxima) can be used together with gravity assists to decelerate incoming solar sails from Earth. The maximum injection speed at $\alpha$ Cen A to park a sail with a mass-to-surface ratio ($\sigma$) similar to graphene ($7.6 \times 10^{-8}$ gram m$^{-2}$) in orbit around Proxima is about 13,800 km s$^{-1}$ ($4.6\%$ c), implying travel times from Earth to $\alpha$ Cen A and B of about 95 years and another 46 years (with a residual velocity of 1280 km s$^{-1}$) to Proxima. The size of such a low-$\sigma$ sail required to carry a payload of 10 grams is about 10$^7$ m$^2$ = (316 m)$^2$. Such a sail could use solar photons instead of an expensive laser system to gain interstellar velocities at departure. Photogravitational assists allow visits of three stellar systems and an Earth-sized potentially habitable planet in one shot, promising extremely high scientific yields.

Key words: radiation mechanisms: general – solar neighborhood – space vehicles – stars: individual (Alpha centauri, Proxima Centauri) – stars: kinematics and dynamics

Supporting material: animation

1. Introduction

The discovery of Proxima b, a roughly Earth-mass planet (Anglada-Escudé et al. 2016) in the stellar habitable zone (Kasting et al. 1993; Barnes et al. 2016; Meadows et al. 2016; Ribas et al. 2016; Turbet et al. 2016) around our closest stellar neighbor, has recently excited humanity’s vision of interstellar travel to Proxima Centauri ($\alpha$ Cen C, or Proxima). The Voyager 2 space probe, launched in 1977 using chemical thrusters, required about 12 years to reach Neptune and about 35 years to reach the boundary of the solar system (Stone et al. 2013) at a speed of 17 km s$^{-1}$ relative to the Sun. At that speed, this 800 kg spacecraft would take about 75,000 years to reach Proxima b.

Advances in the design of light, extremely thin and highly reflective solar sails (Schefer 2015) and the development of ultracompact electronic devices could soon allow the construction of extremely light high-tech solar sails that could be sent to Proxima. While earlier studies of laser-pushed light sails toward $\alpha$ Cen involved sail masses of the order of tons and sail areas of the order of square kilometers (Marx 1966; Redding 1967; Forward 1984), ultrathin, highly reflective 1 gram photon sails (Macchi et al. 2010) are now being investigated for interstellar travel to $\alpha$ Cen (Lubin 2016; Manchester & Loeb 2016). With an intended interstellar speed of 0.2 c, however, they would traverse a distance equivalent to the Moon’s orbit around the Earth in just about six seconds, with little time left for high-quality close-up exploration and posing huge demands to the imaging system.

To maximize the scientific yield of such a mission, we here explore the new possibility of using Proxima’s companion stars $\alpha$ Cen A and B as photogravitational swings to decelerate an incoming light sail and deflect it into a bound orbit around Proxima, and possibly Proxima b. Using two astrophysical effects, the photon pressures and the gravitational tugs of $\alpha$ Cen A, B, and C, such a sail could be maneuvered through the system without the need for onboard fuel.

2. Methods

Our aim is to find the maximum possible injection speed ($v_{\text{inj}}$) of a sail coming from Earth to perform a sequence of at least one fly-by at $\alpha$ Cen A, B, and C. We studied all permutations of stellar encounters and found that the optimal sequence starts with a photogravitational assist at $\alpha$ Cen A at the time when stars A, B, and C are all in the same plane with the incoming sail. This configuration minimizes the deflection angle ($\delta$) required by the sail to reach the next star (B in this case) to $\delta \approx 10^\circ$, and it maximizes the injection speed for the first encounter, thereby minimizing the travel time from Earth. Proxima is not located in the orbital plane of the AB binary, but for a distant observer all three stars align about every 79.91 years (the orbital period of the AB binary). From the perspective of an incoming probe from Earth, the alignment occurs near the time of the AB periastron, the next of which will take place on 2035 June 24 (Beech 2015).

2.1. Photogravitational Assists

We consider a solar sail of mass $M$ and reflective surface area $A$ approaching a star at an instantaneous distance $r$ and with an instantaneous velocity $v$ in an $x$–$y$ plane (Figure 1). Its injection speed is $v_{\text{inj}}$. The sail is subject to both the gravitational attractive force between it and the star and subject to the stellar radiation pressure, which, assuming a radially oriented sail and a uniformly bright, finite angular-sized stellar
and the radius vector to the star (r) determines the stellar photon force \( F(\alpha, r) \) on the sail.

As an example, for an \( M = 1 \) gram sail with an area of \( A = 10 \text{ m}^2 \) that passes \( \alpha \text{ Cen A} \) at \( r_{\text{min}} = 5 R_* \) (assuming \( R_* = 1.224 \) solar radii and \( L_* = 1.522 L_\odot \); \( L_\odot \) being the solar luminosity), we obtain \( v_{\text{red}} \approx 1200 \text{ km s}^{-1} \), which corresponds almost precisely to the value of \( v_{\text{c,max}} \), achievable via a full stop trajectory as we found using our modified photogravitational trajectory code (see Section 2.3). The total maximum deceleration during a fly-by is slightly higher because the sail must climb out of the star’s gravitational well after its passage, and therefore it slows down further.

2.3. Numerical Integrations of Sail Trajectories

We use a modified N-body code to model the gravitational pull by the stars under the additional effects of the stellar photon pressure onto the sail. As a key feature of our simulations, we solve the problem of continuously adjusting the sail’s orientation to maximize the deceleration due to the photon pressure.\(^3\) Such an adaptive orientation could be achieved if the sail were able to modify its reflectivity across its surface, e.g., using technologies akin to the nanocrystal-inslass approach (Lluch et al. 2013; Ma et al. 2016). An asymmetric reflectivity distribution would induce a torque on the sail, which would start to rotate it (Kislov 2004; Hu et al. 2016).

The \((x, y)\) components of the photon force are calculated per

\[
F(\alpha, r) = F(\alpha, r)(\cos(\alpha + \varphi), \sin(\alpha + \varphi)),
\]

where \( \varphi = \arctan(y/x) \) (see Figure 1). The maximum deceleration of the sail is achieved if the force component

\[
F_\nu = F(\alpha, r)\cos(\nu)
\]

acting into the opposite direction of the sail’s velocity is maximized, where

\[
\nu = \arccos\left(\frac{F_x v_x + F_y v_y}{\sqrt{F_x^2 + F_y^2} \sqrt{v_x^2 + v_y^2}}\right)
\]

is the angle enclosed by \( F \) and \( v \). We enter Equation (7) into Equation (6) and numerically determine the value of \( \alpha \) that yields maximum deceleration. The resulting trajectory is here referred to as a photogravitational assist, along which the photon pressure is used to reduce speed while both the photon pressure and the gravitational tug from the star determine the sail’s deflection angle.

The orbits of the \( \alpha \text{ Cen} \) stellar system are non-coplanar, so we simulate each fly-by in a new \( x-y \) plane. For a broad range of \( v_{\text{c}} \), we numerically integrate hundreds of sail trajectories, each of which has a slightly different horizontal offset (in steps of \( 0.1 R_* \)) in the \( x-y \) plane.

Figure 2(a) illustrates an example of such a trajectory iteration for an \( M = 1 \) gram, \( A = 10 \text{ m}^2 \) sail approaching \( \alpha \text{ Cen A} \) with \( v_{\text{c}} = 1270 \text{ km s}^{-1} \). All trajectories with an initial \( x \)-offset \( \lesssim 3 R_* \) lead to a physical encounter of the sail with the star, i.e., the sail is lost (type I trajectory). For values of \( v_{\text{c}} \lesssim 1200 \text{ km s}^{-1} \), the stellar photon pressure can stop the sail beyond \( 5 R_* \), a distance that we use as a fiducial value to prevent the sail from destruction (see Section 4). We refer to such a trajectory as a full stop (type II). A full stop route allows the sail to reorient itself at \( r_{\text{min}} \) to then leave the stellar system.

\(^5\) Cassenti (1997) used a similar method to optimize the acceleration of possible solar sails leaving the solar system.
against gravity into arbitrary directions by means of the photon pressure. A type III trajectory leads the sail into a bound elliptical orbit around the star, from where it could then depart in an arbitrary direction. Type IV trajectories are what we refer to as photogravitational fly-bys. Figure 2(b) shows a detailed example of the optimum photogravitational assist around α Cen A toward α Cen B with $v_{\infty} = 1270 \text{ km s}^{-1}$, with the instantaneous speed of the sail shown along its trajectory and the instantaneous acceleration shown in the color bar at the right.

An important feature of this trajectory, note that the photon pressure acts to initially accelerate the sail toward positive $x$ values, that is, in the direction opposite to the intended deflection. The additional effect due to the gravitational force, however, can ultimately deflect the sail into very different directions. Somewhat larger deflection angles via photogravitational assists could be achieved if the trajectory were not determined according to the maximization of the instantaneous deceleration as per Equation (6). Although this would come at the price of less efficient deceleration, future simulations could show if such a trade-off could effectively increase the maximum possible injection speed.

### 3. Results

The maximum injection speed at α Cen A for a photogravitational assist to α Cen B and Proxima is strongly dependent on the sail’s mass-to-surface ratio ($\sigma$): the lower the $\sigma$ (for a given $M$) the stronger the photon force on the sail, and hence, the stronger the deceleration. We examined a range of plausible values of $\sigma$ and found that the lightest and most tensile materials known from laboratory experiments, such as graphene ($\sigma = 7.6 \times 10^{-4} \text{ gram m}^{-2}$; Peigney et al. 2001), allow injection speeds of several percents of the speed of light. In order for such a sail to carry a payload (science, navigation, and communication instruments, reflective coating, etc.) of about 10 grams, the sail area must be on the order of $10^5 \text{ m}^2$.

One key issue for a high-velocity interstellar sail is the extreme accelerations, which occur either during the departure from the solar system, or as in our case, during the arrival at the target star. Figure 3(a) shows the contributions from the gravitational and photonic forces (left ordinate) or decelerations (right ordinate, in units of the Earth’s surface acceleration $g = 9.81 \text{ m s}^{-2}$) on our $\sigma = 8.6 \times 10^{-4} \text{ gram m}^{-2}$ sail during its photogravitational assist at α Cen A. We find that the maximum forces are about 1400 N and the maximum accelerations are roughly 1600 g. Figure 3(b) visualizes the continuous adjustment of $\alpha$ as a function of distance to α Cen A.

Figure 4 illustrates the reduction of an initial speed of 13,800 km s$^{-1}$ for our fiducial sail into a parking orbit around Proxima after successive photogravitational fly-bys at α Cen A and B. Each assist has been constrained to $r_{\min} > 5 R_\odot$, where a sail with 99.999% (99.99%) reflectivity (Lubin 2016) absorbs about 24 W m$^{-2}$ (242 W m$^{-2}$), corresponding to an effective temperature of about 144 K (256 K).

One of the most critical aspects of a possible interstellar mission is flight duration. Figure 5 shows the dependence of $v_{\infty, \text{max}}$ (left ordinate) and the corresponding travel time (right ordinate) on the sail mass $M$, with the additional effect due to the gravitational and photonic forces on the sail. The total time required by the sail to traverse this panel is 48 hr. The sail’s deflection angle, mass-per-area ratio, and injection speed for this example are shown in the top left corner. The instantaneous acceleration of the sail is shown in the color bar at the right, using units of the Earth’s surface acceleration $g = 9.81 \text{ m s}^{-2}$.

(Ant animation of this figure is available.)
with the stellar photons. At this point, the total force becomes equal to the gravitational force and decelerates the sail. The probe, whereas gravity is attractive and therefore accelerates it. After the encounter, the sail is rotated and aligned with the stellar radiation to avoid re-acceleration during approach.

The injection speeds of up to 1280 km s\(^{-1}\) suggests that proposed ship designs are indicated at the bottom of the figure, deriving energy that can be absorbed using photogravitational forces.

The旅行 between

\[ r_{\min} = \frac{v_{\infty}}{v_{\text{c},\max}} = 13,800 \text{ km s}^{-1} \] 1.00522 = \frac{v_{\infty}}{v_{\text{c},\max}} = 13,800 \text{ km s}^{-1} \]

\[ v_{\text{c},\max} = 13,800 \text{ km s}^{-1} \]

Forces

\[ r_{\min} = 5 R_\odot \text{ and red lines assume } r_{\min} = 10 R_\odot \text{.} \]

We validated these values using our numerical N-body integrator and found that the analytical solution agrees with the numerical fly-bys within \(<1\%\). Reference values of \(\sigma\) for available materials or proposed ship designs are indicated at the bottom of the figure, suggesting that \(v_{\text{c},\max} = 13,000 \text{ km s}^{-1}\) (travel times of 100 years from Earth) could be achievable via photogravitational assists at \(r_{\min} = 5 R_\odot\) of our fiducial sail. After only a few days of travel between \(\alpha\) Cen A and B, such a sail could have maximum injection speeds of up to 1280 km s\(^{-1}\) at Proxima to perform a transfer into a bound orbit via a full stop trajectory with \(r_{\min} > 5 R_\odot\). This means that the sail would take about 46 years to traverse the \(\approx12,500\) AU between the AB binary and Proxima (Kervella et al. 2016), which is very short compared to the travel time from Earth of about 1000 years at 1280 km s\(^{-1}\).

Figure 5(b) shows the travel times from Earth to \(\alpha\) Cen A derived from more than a million computations of \(v_{\text{c},\max}\) per Equation (4) and using numerical integrations of Equation (3). An interstellar sail with a mass-to-surface ratio between graphite and an aluminum lattice ship (Drexler 1979) could arrive at \(\alpha\) Cen A within a few hundred years even if its closest approach to the star were restricted to \(r_{\min} > 10 R_\odot\).

4. Discussion

4.1. Limitations of the Model and Technical Challenges

Close stellar encounters necessarily invite the risk of impacts of high-energy particles and of thermal overheating. On the one hand, impacts of high-energy particles could damage the physical structure of the sail, its science instruments, its communication systems, or its navigational capacities. On the other hand, if those impacts could be effectively absorbed by the sail, they could even help to decelerate it. As shown in Section (3), heating from the stellar thermal radiation will not have a major effect on a highly reflective sail. However, the electron temperature of the solar corona is \(>100,000\) K at a distance of five solar radii. The Solar Probe Plus (planned to launch in mid-2018) is expected to withstand these conditions for tens of hours (Fox et al. 2015), although the shielding technology for an interstellar sail would need to be entirely different (Hoang et al. 2016), possibly integrated into the highly reflective surface covering.

The effects of special relativity can be neglected in our calculations, with the Lorentz factor being \(1 < \gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1/2} < 1.005\) for \(v < 10\% \text{ } c\). We also assumed that the stars are perfectly spherically symmetric. In reality, however, the acceleration of the probe will depend on the non-uniform mass distribution within the rotating star and possibly on effects from General Relativity (Kezerashvili & Vázquez-Poritz 2010). Stellar oblateness and limb darkening affect the photon pressure by \(<1\%\) at distances \(>5 R_\odot\) (McInnes & Brown 1990), so these effects do not change the results of this study significantly. Yet, they must be considered for the planning of real missions.

Regarding the nautical issues of an A-B-C trajectory, communication among sails within a fleet could support their navigation during stellar approach, as it will be challenging for an individual sail to perform parallel observations of both the approaching star and its subsequent target star or of other background stars. Course corrections will need to be calculated live on board. In particular, the location of \(r_{\min}\) will need to be determined on-the-fly because it will depend on the actual velocity and approach trajectory, and hence on the local stellar
Its initial speed of 13,800 km $s^{-1}$ allows for multiple assists to work, however, the stars need to be aligned within a few tens of degrees along the incoming sail trajectory of the sail. Such a successive braking is particularly interesting for multi-stellar systems, where bright stars can be used as photon bumpers to decelerate the sail into an orbit around a low-luminosity star, such as Proxima ($0.0017L_\odot$) in the $\alpha$ Cen system or the white dwarf Sirius B ($0.056L_\odot$) around Sirius A.

## 5. Conclusions

We present a new method of decelerating interstellar light sails from Earth at the $\alpha$ Cen system using a combination of the stars’ gravitational pulls and their photon pressures. This sailing technique, which we refer to as a photogravitational assist, allows multiple stellar fly-bys in the $\alpha$ Cen stellar triple system and deceleration of a sail into a bound orbit. In principle, photogravitational assists could also allow sample return missions to Earth. The maximum injection speed to deflect an incoming, extremely light and tensile sail (with properties akin to graphene) carrying a payload of 10 grams into a bound orbit around Proxima is about 4.6% $c$, corresponding to travel times of 95 years from Earth. After initial fly-bys at $\alpha$ Cen A and B, the sail could absorb another 1280 km $s^{-1}$ upon the arrival at Proxima, implying an additional travel time between $\alpha$ Cen AB and Proxima of 46 years.

Arrival at Proxima with maximum velocity could result in a highly elliptical orbit around the star, which could be circularized into a habitable zone orbit using the photon pressure near periastron. The time required for such an orbit transfer is small (years) compared to the total travel time. Once parked in orbit around Proxima, a sail could eventually use the stellar photon pressure to transfer into a planetary orbit around Proxima b.

In a more general context, photogravitational assists of a large, roughly $10^5 m^2 = (316 m)^2$-sized graphene sail could (1)
decelerate a small probe into orbit around a nearby exoplanet and therefore substantially reduce the technical demands on the onboard imaging systems; (2) in principle allow sample return missions from distant stellar systems; (3) avoid the necessity of a large-scale Earth-based laser launch system by instead using the Sun’s radiation at the departure from the solar system; (4) limit accelerations to about 1000 m/s²; and (5) leave of the order of 10 grams for the sail’s reflective coating and equipment. These benefits come at the price of a yet to be developed large graphene sail, which needs to be assembled or unfold in near-Earth space and which needs to withstand the harsh radiation environment within ≥ 5 Rₜ of the target star for several hours. This technical challenge, however, could be easier to tackle than the construction of a high-power ground-based laser system shooting laser sails in near-Earth orbits.

We thank the anonymous referee for a thoughtful report, and we thank Colin McInnes for his critical review of this manuscript prior to submission. This work has made use of NASA’s Astrophysics Data System Bibliographic Services.

Software: photograv (Heller & Hippke 2017). The software to create photogravitational trajectories is released¹, commit #727e77a under the free MIT license and can be used to reproduce the figures in this manuscript.
