Abstract. We provided separate bivariate log-normal distribution fits to the BATSE short and long burst samples using the durations and fluences. We show that these fits present an evidence for a power-law dependence between the fluence and the duration, with a statistically significant different index for the long and short groups. We argue that the effect is probably real, and the two subgroups are different physical phenomena. This may provide a potentially useful constraint for models of long and short bursts.

Key words: gamma rays: bursts

1. INTRODUCTION

The simplest grouping of gamma-ray bursts (GRBs) divides bursts into long ($T_{90} > 2\text{s}$) and short ($T_{90} < 2\text{s}$) duration groups. Here we analyze (see also Balázs et al. 2003) the distribution of the observed fluences and durations, and present arguments indicating that the intrinsic durations and fluences are well represented by log-normal distributions within these groups. We calculate the power-law exponent for the two types of bursts and the possible implications for GRB models are briefly discussed. A statistically significant difference between the two subgroups will be found.
2. ANALYSIS OF THE DURATION DISTRIBUTION

Our GRB sample is selected from the current BATSE Gamma-Ray Burst Catalog (Meegan et al. 2001). The bimodal distribution of the observed $T_{90}$ can be well fitted by means of two Gaussian distributions in the logarithmic durations (Horváth 1998). The $T_{90}$ observed duration of GRBs (which may be subject to cosmological time dilatation) relates to $t_{90}$ the duration which would be measured by a comoving observer by

$$T_{90} = t_{90} f(z),$$

where $z$ is the redshift, and $f(z)$ measures the time dilatation. Taking the logarithms of both sides of equation one obtains the logarithmic duration as a sum of two independent stochastic variables. According to a theorem of Cramer (Cramér 1937), if a variable $\zeta$ which has a Gaussian distribution is given by the sum of two independent variables, e.g. $\zeta = \xi + \eta$, then both $\xi$ and $\eta$ have Gaussian distributions. The Gaussian distribution of $\log T_{90}$ implies that the same type of distribution exists for the variables $\log t_{90}$ and $\log f(z)$. The distribution of $\log f(z)$ cannot be Gaussian which means that the Gaussian nature of the distribution of $\log T_{90}$ must be dominated by the distribution of $\log t_{90}$.

3. DISTRIBUTION OF THE ENERGY FLUENCES

The fluences are given in four different energy channels, $F_1$, $F_2$, $F_3$, $F_4$, whose energy bands correspond to $[25,50]$ keV, $[50,100]$ keV, $[100,300]$ keV and $> 300$ keV. The total fluence is defined as $F_{\text{tot}} = F_1 + F_2 + F_3 + F_4$. The observed total fluence $F_{\text{tot}}$ can be expressed as

$$F_{\text{tot}} = \frac{(1 + z)}{4\pi d_l^2(z)} E_{\text{tot}} = c(z) E_{\text{tot}}.$$

Here $E_{\text{tot}}$ is the total emitted energy of the GRB at the source in ergs, the total fluence has dimension of erg/cm$^2$, and $d_l(z)$ is the luminosity distance corresponding to redshift $z$. Accepting the hypothesis of a Gaussian distribution within the short and the long group, one can apply again Cramer’s theorem which leads to the conclusion that either both the distribution of $\log c(z)$ and the distribution of $\log E_{\text{tot}}$ are Gaussian, or else the variance of one of these quantities is negligible compared to the other, which then must be mainly responsible
for the Gaussian behavior. Calculating the variance of $\log c(z)$ for the GRBs with known redshifts one obtains $\sigma_{\log c(z)} = 0.43$. The total observed variance is $\sigma_{\log F_{\text{tot}}} = 0.66$. Hence, the variance of $c(z)$ gives roughly a $(0.43/0.66)^2 \approx 43\%$ contribution to the entire variance, so its significant fraction is also intrinsic.

4. RELATIONSHIP BETWEEN FLUENCE AND DURATION

We observe only those bursts which fulfil some triggering criteria and the observed quantities are suffering from some type of bias depending on the process of detection. The detection proceeds on three time scales: on 64, 256 and 1024 ms resolution. We shown in a previous paper (Bagoly et al. 1998) that the duration and the peak intensity are independent stochastic variables:

$$\log F_{\text{tot}} = a_1 \log T_{90} + a_2 \log P + \varepsilon,$$

where $a_1$ and $a_2$ are constants and $\varepsilon$ is some noise term. By fixing the $P$ peak intensity we get the relationship between the fluence and duration. To ensure the best time resolution we used $P_{64}$ in our calculations. In order to fit the $[\log T_{90}, \log F_{\text{tot}}]$ data pairs with the superposition of two two-dimensional Gaussian bivariate distributions we splitted the Catalog into subsamples with respect to 64 ms peak fluxes. The strata were obtained by taking 0.2 wide strips in the logarithmic peak fluxes in the $0.0 < \log P_{64} < 1.0$ range. With this choice we avoided the incompleteness among the faint bursts and get enough objects for statistics within the strips investigated. The calculated weighted mean of the slopes resulted in $a_1 = 0.81 \pm 0.06$ for the short bursts and $a_1 = 1.11 \pm 0.03$ for the long bursts. The difference is significant at the 99.998 % level. Fig. 1 shows the results obtained for the faintest and brightest subsample of our calculations.

5. CONCLUSIONS

We have presented evidence indicating that there is a power-law relationship between the logarithmic fluences and the $T_{90}$ durations. An intriguing corollary of these results is that the exponents in the power-law dependence between fluence and duration differ significantly for the two groups of short ($T_{90} < 2$s) and long ($T_{90} > 2$s) bursts. This also means that the same power law relations hold between the total energy emitted ($E_{\text{tot}}$) and the intrinsic durations ($t_{90}$).
of the two groups. In summary, we have presented quantitative arguments that there is a power law relation between the fluence and duration of GRBs and this relation is significantly different for the two groups of short and long bursts. This may indicate that two different types of central engines are at work, or perhaps two different types of progenitor systems are involved.
