Aneurysmal subarachnoid hemorrhage (aSAH) is a highly fatal and morbid type of hemorrhagic strokes. Intracranial aneurysms (ICAs) rupture cause subarachnoid hemorrhage. ICAs formation, growth and rupture involves cellular and molecular inflammation. Macrophages orchestrate inflammation in the wall of ICAs. Macrophages generally polarize either into classical inflammatory (M1) or alternatively-activated anti-inflammatory (M2)-phenotype. Macrophage infiltration and polarization toward M1-phenotype increases the risk of aneurysm rupture. Strategies that deplete, inhibit infiltration, ameliorate macrophage inflammation or polarize to M2-type protect against ICAs rupture. However, clinical translational data is still lacking. This review summarizes the contribution of macrophage led inflammation in the aneurysm wall and discuss pharmacological strategies to modulate the macrophageal response during ICAs formation and rupture.

Keywords: intracranial aneurysms, monocytes, macrophages, inflammation, subarachnoid hemorrhage, stroke, macrophage polarization

INTRODUCTION

Aneurysmal subarachnoid hemorrhage (aSAH) is a devastating subtype of hemorrhagic strokes and it accounts for 5% of all strokes. The worldwide incidence of aSAH is approximately 700000 person-years; the mortality of aSAH is approximately 40% despite appropriate surgical and medical care (1, 2). aSAH has a poor prognosis with significant lifelong morbidity and cognitive deficits for those who survive. Moreover, aSAH has a significant impact on society, as it often affects young people at the peak of their productive life (1, 2). This highly fatal and morbid type of intracranial hemorrhage is due to intracranial aneurysm (ICA) rupture in nearly 85% of SAH cases (3).

ICAs are weak ballooning, bulging, or abnormal dilatations that tend to form at arterial bifurcations due to chronic hemodynamic stress and inflammation (4). Intracranial aneurysms are usually found in 3% to 5% of the population and are slightly more prevalent among females (5).
The risk factors for aneurysm development are arterial hypertension, smoking, chronic alcohol consumption, aging, female gender, and family history of aSAH in first-degree relatives (6). Some genetic disorders such as autosomal dominant polycystic kidney disease, Marfan syndrome, Ehlers-Danlos syndrome type IV, neurofibromatosis type I, and fibromuscular dysplasia are associated with ICA formation (6). Moreover, single nucleotide gene polymorphisms (SNPs) in or near the genes CDKN2B-AS1, SOX17 transcription regulator gene, endothelin receptor gene, HDAC9, and the gene encoding elastin have been revealed in genome-wide association studies (GWAS). Linkage analysis suggests that these genes are strongly associated with intracranial aneurysms (5). An exome-wide association study identified a SNP of the collagen type XVII chain to be significantly associated with aSAH (7). Most ICAs are found incidentally and need preventive care to prevent enlargement and rupture. Prevention of growth and rupture is necessary, as the current treatment modalities, such as surgical clipping and endovascular modalities (coiling, with or without stent and flow diverter placement) are associated with some risks.

Patient factors (age, sex, comorbidities, family history, previous history of SAH, hypertension and smoking) and aneurysm characteristics (size, location, wall irregularity, presence of secondary pouches) are key factors that aid in deciding upon treatment for an unruptured ICA. It is challenging to predict exactly the rupture risk based on aneurysm characteristics and patient risk factors. It is thus, unclear which ICAs require active treatment.

A better understanding of the pathobiology of ICA is important to clarify when active treatment is needed and may facilitate development of pharmacological treatments with no or minimal risk.

Recent evidence from human and animal studies revealed that macrophage-mediated cellular and molecular inflammation is the key player in aneurysm formation and rupture. Here, we briefly review the current knowledge on the role of macrophages in aneurysm formation and their rupture.

INFLAMMATION IN INTRACRANIAL ANEURYSMS

The hallmarks of ICAs include endothelial cell dysfunction, smooth muscle cell phenotypic switch, matrix metalloproteinase secretion, and innate immune cell activation leading to vascular remodeling and vessel wall weakening (8–10). Histopathological analysis of aneurysm wall biopsies has revealed an upregulation of inflammatory mediators, disruption of lamina elastic interna, and thinning of media including mural cell death (11). Both cellular and molecular inflammation are crucial in aneurysm formation and rupture. Infiltration of inflammatory cells (especially macrophages) has been observed in the biopsies of ICAs, which shows a possible involvement of macrophages in aneurysm formation. NF-κB is a key transcription factor and is a major known regulator of important pro-inflammatory genes, including TNF, IL-1β, and COX-2. A genetic deletion of NF-κB has been shown to reduce ICA formation and growth (12). Moreover, pro-inflammatory genes regulated by NF-κB, including IL-1β (13), COX-2 (14), iNOS (15), and matrix metalloproteinase-9 (16) contribute to ICA formation. Furthermore, macrophage-specific deletion of the prostaglandin E (PGE) receptor subtype 2 (EP2) (Ptger2), an upstream signaling receptor for NF-κB activation, significantly suppresses the development of ICAs in mice, indicating that prostaglandin E2-EP2-NF-κB signaling in macrophages plays a crucial role in ICA development (12). Intriguingly, macrophage-specific expression of a variant of IkBα, which abrogates the translocation of NF-κB, prevents ICA formation (17).

Transcriptomic analysis of ICAs revealed upregulation of pro-inflammatory cytokine genes associated with leukocyte infiltration (18–23). For instance, Nakaoka, Tajima (19) have shown an upregulation of genes related to inflammation, immune response and phagocytosis, whereas anti-inflammatory genes were downregulated. Similarly, upregulation of TNF-α and pro-apoptotic gene expression was shown along with suppressed IL-10 expression in ruptured ICAs. Moreover, SNPs in the IL-10 gene are associated with formation of ICAs (24, 25). Similar, transcriptomic and bioinformatic analyses of ruptured and unruptured ICAs have revealed enhanced expression and upregulation of inflammatory pathways such as TLR signaling, cytokine-cytokine receptor interaction, leukocyte trans-endothelial migration, NF-κB signaling, and many other inflammation-related gene ontology categories (18). Activation and involvement of the complement system has also been observed in ICAs and suggests that chronic inflammation underlies the pathogenesis of ICAs (10, 26). Further, shear stress due to disturbed blood flow at arterial branching points (which contributes to ICA development) upregulates inflammatory pathways such as NF-κB, promotes monocyte recruitment, and triggers sterile inflammation (27, 28). Inflammation in ICA walls is characterized by immune cell infiltration and altered composition of the immune cell populations such as natural killer cells, mast cells, lymphocytes, and importantly macrophages (29).

MONOCYTES/MACROPHAGES IN INTRACRANIAL ANEURYSMS

Monocytes/macrophages are among the main components of innate immunity and represent important members of the mononuclear phagocyte system comprised of myeloid-derived cells (30). Data from human and animal studies has revealed an increased infiltration of immune cells in the aneurysm wall (24, 25, 31, 32). Several lines of evidence have shown increased infiltration of T and B lymphocytes and macrophages along with increased pro-inflammatory molecular expression in clinical resections of ICAs (24, 31, 32).

Studies have clearly demonstrated that monocyte/macrophage infiltration in the wall of ruptured aneurysms is not only found
after aneurysmal rupture, but contributes to aneurysm formation and rupture (33). Increased monocyte/macrophage marker CD68 expression has been observed in mice carrying negative mutations of PPARγ in smooth muscle cells of cerebral arteries along with CXCL1, MCP-1, TNF-α expression upregulation. These mice have an increased incidence of aneurysm formation and rupture (34). Aoki, Frøsen (12) demonstrated that macrophage infiltration driven by MCP-1 and activation of NF-κB involving PGE2-PGEP2 (PGE receptor subtype 2) signaling in the macrophages of arterial wall leads to aneurysm formation, suggesting that inflammation is not only present after aneurysm rupture, but also drives aneurysm formation. As intracranial arteries lack vasa vasorum in the arterial wall, the macrophages may infiltrate through endothelial cell junctions. Sphingosine-1-phosphate (S1P) receptor type 1 signaling activation strengthens the endothelial barrier. Interestingly, activation of S1P receptor type 1 reduced the number of infiltrated macrophages and enlargement of ICAs (35).

MACROPHAGE POLARIZATION AND INTRACRANIAL ANEURYSMS

Mills, Kincaid (36) described for the first time the M1/M2 paradigm, where M1 represents classically activated pro-inflammatory monocytes/macrophages, whereas M2 represents alternatively activated anti-inflammatory monocytes/macrophages. A very brief and simplistic overview of M1/M2 biology is represented in Figure 1. However, there is a considerable heterogeneity in macrophage phenotypes and several subtypes have been described such as M1, M2a, M2b, M2c, M2d, Mhem, Mox, M4 (37–40). This over simplistic representation of M1 as pro-inflammatory and M2 as anti-inflammatory macrophages is considered here to recognize different functional states of these polarized phenotypes to assign pro-inflammatory and anti-inflammatory role. Macrophage polarization has implications in aneurysm formation and rupture (Figure 2). Aortic aneurysms formation has been shown to be promoted by inflammatory M1

![FIGURE 1](image-url)
macrophages, whereas reparative M2 polarization prevents the formation, development and progression of aortic aneurysms (38, 41). It has been shown that GM-CSF contributes toward M1 polarization and M-CSF favors an M2 response (42). Intriguingly, GM-CSF has been shown to promote aortic aneurysm formation (43) and the levels of GM-CSF measured in plasma and lumen of the intracranial aneurysms have also shown a direct correlation with the size of intracranial aneurysms, highlighting a common inflammatory process upregulated by M1 macrophages underlie the development of both aortic and intracranial aneurysms (44). Consequently, immunohistochemical analysis of intracranial aneurysms have also shown a direct correlation with the size of intracranial aneurysms, highlighting a common inflammatory process upregulated by M1 macrophages underlie the development of both aortic and intracranial aneurysms (44). Previously, Froesen and colleagues demonstrated differences in CD68+ and CD163+ macrophages in human ruptured and unruptured ICAs (29). Intriguingly, CD68+ and CD163+ (hemoglobin-haptoglobin scavenger receptor) macrophages, mostly HLA-DR+, co-localize with glycophorin A (a component of the erythrocyte membrane) and infiltrate ICAs as a response to a luminal thrombus trapped and lysed erythrocytes, and may promote degenerative arterial wall remodeling (46). In a mouse model of ICAs, M1 (F4/80+ iNOS+) dominate over M2 (F4/80+ Arg1+) during aneurysm development (47). Interestingly, M1 dominance leading to aneurysm development is dependent on neutrophil infiltration, which when blocked led to an increased M2 polarization with reduced aneurysm formation (47). Shimada, Furukawa (48) employed different macrophage markers to assess the polarization of macrophages in ICAs. The authors employed CD68 as a macrophage marker and IL-12p40 and CD206 as M1 and M2 markers, respectively. They observed significant impairment in the M1/M2 ratio in ICAs associated with upregulation of M1-related gene expression (48).

**MACROPHAGE MODULATION AS A TREATMENT STRATEGY FOR INTRACRANIAL ANEURYSMS**

Recent case-control studies have shown that the use of statins and non-steroidal anti-inflammatory drugs (NSAIDs) is

---

**Figure 2** | Representation of the M1 role in the formation and rupture of intracranial aneurysm and therapeutic strategies to modulate the macrophage mediated inflammation during aneurysm formation and rupture. (MCA, Middle cerebral artery; M1, M1 – Classically activated macrophages, MCP-1, Monocyte chemoattractant protein-1; COX-2, Cyclooxygenase-2, PGE2: Prostaglandin E2, EP2: Prostaglandin E2 receptor, NF-κB: nuclear factor-kappa B; TNFα, Tumor necrosis factor alpha).
inversely associated with SAH by affecting rupture of ICAs (49–52), supporting the notion that rupture of ICAs can be prevented by pharmacological therapy.

Aspirin protects against ICA rupture through modulation of inflammatory pathways (COX-2 and microsomal PGE2 synthase-1 inhibition) and macrophage burden in ICAs (53–55). A prospective cohort study revealed that usage of atorvastatin in secondary prevention for ischemic stroke increases the incidence of hemorrhagic stroke (hazard ratio 1.66) (29). Therefore, statin usage to prevent aneurysm rupture should be approached with caution. Due to hemorrhagic diathesis by the antiplatelet effect, the use of NSAIDs as a pre-emptive medication to prevent SAH also requires caution. Thus, drugs with highly specific targets with minimal or no side effects should be explored for long-term prophylaxis.

Given the fact that macrophages are key players in orchestrating the inflammatory response during ICA formation and rupture, they may represent vital therapeutic targets to modulate and inhibit inflammation (48). Multiple targets at the level of macrophages and macrophage-mediated inflammation have been explored recently (Figure 2). Inhibition of a key chemokine receptor molecule, monocyte chemotactic protein-1 (MCP-1) and depletion of macrophages are associated with reduced ICAs in animal models (8, 33) demonstrating that reducing macrophage burden with both strategies effectively prevented aneurysm formation and rupture. In contrast, CXCL1 (neutrophil chemokine receptor) blockade reduced neutrophil infiltration and prevented aneurysm formation without modifying the macrophage burden in a mouse model of ICAs (47), which suggests that other molecular and cellular mechanisms may be involved. Interestingly, inhibition of neutrophil infiltration with CXCL1 inhibition is associated with a shift toward M2 macrophages from a M1 phenotype (47). Activation of PPARγ by Pioglitazone has also been shown to effectively reduce the rupture of ICAs through a reduction in infiltrating macrophages and the M1/M2 ratio (48). Clodronate liposome-mediated depletion of macrophages also reduced the rupture of ICAs similar to that shown with pioglitazone, which was associated with a decrease in M1-phenotype related gene expression (48).

In addition to cellular targets, molecular targets have also been successful in experimental models. Anagliptin, a dipetidyl peptidase-4 inhibitor, suppresses ICA growth through inhibition of macrophage infiltration and activation via ERK-5-mediated suppression of NF-κB (56). Moreover, Eplerenone, a mineralocorticoid receptor blocker, has been shown to reduce ICA formation, in part via reduction in MCP-1, MMP-9 expression and CD68+ macrophage infiltration in a rat model of ICAs (57). A pilot clinical study showed the beneficial effects of Eplerenone in preventing growth and rupture of ICAs (58). Employment of NF-κB p50 decoy oligodeoxynucleotide (ODN) has been shown to downregulate the expression of macrophage related inflammatory genes and reduced macrophage infiltration with a decline in ICAs growth in a rat model (59). Nifedipine, the drug known to be associated with better outcomes after aSAH, has been shown to prevent the enlargement and degenerative ICAs wall changes through reduced macrophage infiltration, MCP-1, and MMP-2 expression probably by modulating the DNA binding capacity of NF-κB (60).

Macrophage polarization as a therapeutic venture has been studied across various disease models. For instance, tumor associated macrophages (TAMs) represent primarily M2 like macrophages promoting tumors and their polarization toward M1 phenotype through the application of various agents such as CSF-1R inhibitor BLZ945, anti-CSF-1 mAb, Zoledronic acid, Histidine-rich glycoprotein, Hyaluronic curcumin, vandimezan (5,6-dimethoxynaphthalene-4-acetic acid; DMXAA), flavone glycoside Baicalin, IL10 mAb, CD40 mAb, corosolic acid, N-(2-hydroxy acetonaphene) glycinate (CuNG), imiquimod, etc. have been investigated as potential tumoricidal drugs (61, 62). Interestingly, certain pieces of evidence support the antagonism of M-CSF as a beneficial tumor therapy leading to M1 polarization of macrophages from M2 tumor associated macrophage phenotype (42). Similarly, in rheumatoid arthritis with a predominance of M1 response, an opposite approach polarizing macrophages from M1 to M2 type has been shown to reduce inflammation and disease severity (63). Several M1 to M2 polarizing agents such as gene therapy by using IL-10 DNA plasmid incorporated in nanoparticles carrying tuftsin protein to target synovial tissue macrophages, Withaferin-A incorporated in manosylated liposomes, paenofinorin-6’-O-benzene sulfonate (CP-25), sSiglec-9, fucose/galactose analog 2-D-gal and JWH133 have been shown to reduce disease severity in experimental arthritis models and polarize macrophages to anti-inflammatory M2 type (63). Similar, approaches to modulate macrophage polarization from M1 to M2 may prevent the rupture of ICAs. For instance, molecular genetic approaches leading to polarization toward M2 macrophages using miRNAs such as miRNA-181a (64) could be of great potential. Aptamer based enrichment of M2 polarized macrophages in ICAs may also be developed (65). Epigenetic control of macrophage polarization could also be exploited to abrogate the chronic inflammation leading to ICAs formation (66). Egress of macrophages may also be promoted to decrease macrophage burden (67). Berberine, an alkaloid from Coptis chinensis, has been shown to inhibit macrophage activation and infiltration in ICAs by modulation of the phospho-focal adhesion kinase (pFAK)/Grp78/unfolded protein response signaling pathway and reduced the elaboration of inflammatory factors from macrophages such as MCP-1, IL-1β, IL-6, TNF-α, and MMPs (68). Intriguingly, cutaneous non-invasive vagus nerve stimulation has been shown to reduce aneurysm rupture rates and improve outcomes after aneurysm rupture, and may implicate reduced MMP-9 expression as a potential mechanism of action (69). Suppression of MMP-9 expression in macrophages and polarization of macrophages/microglia to the M2 phenotype has already been shown to stem from vagus nerve stimulation-mediated modulation of inflammatory pathways (69, 70). Taken together, there are multiple strategies at the level of inflammation and macrophage modulation that have translational potential in human disease. However, the heterogeneity and the complexity of macrophageal response...

(Continued)
should be cautiously considered in future studies aiming at characterizing the role of these main sentinel cells of ICAs inflammation (39, 40). A recent study revealed that during Ang-II induced inflammation of the aorta, primarily adventitial macrophage population expanded due to the infiltration of the bone marrow derived macrophages, whereas the residential embryonic macrophages do show local proliferation, but retain their homeostatic roles (40). Similar, studies utilizing fate mapping, mass cytometry, single cell transcriptomics and proteomics may be required to unveil the complexity and heterogeneity of ICAs macrophages, which may be helpful to design better therapeutic strategies. A summary of various clinical and preclinical observations and interventions aiming to prevent macrophage mediated inflammation in ICAs is represented in Table 1. Clinical trials are needed to confirm the efficacy observed in animal studies.

**CONCLUSION**

Inflammation and macrophages represent the cornerstone of ICAs development and rupture. Macrophage modulation seems to represent an important therapeutic target and may lead to treatments against ICAs growth and rupture.
