Abstract

Steel slag is an industrial byproduct of steel manufacturing processes and has been widely used in countries like Japan, United States, and European Union nations. However, the current utilization of steel slag in Vietnam is very low mainly because of lack of quality control of slag treatment and chances for reuse of treated steel slag. This paper presents the current steel slag production status and its potential to use as road construction aggregates in consideration of environmental and quality control issues. The basic oxygen furnace (BOF) and electric arc furnace (EAF) slag samples were collected from the seven large steel making factories of Vietnam and brought back to evaluate leaching amount from the slags. The batch leaching test methods were performed at laboratory using the leaching test of steel slag roadbed material in Japan (JIS K 0058 – 1) and Toxicity Characteristic Leaching Procedure (EPA method 1311) widely adopted in Vietnam. The results show that pH level and parameters such as T-Cr, Ni, Cu, Pb, As, Mn differ from the two test methods. The EPA 1311 seems too harsh to evaluate the environmental impacts because in the operation condition of the road, acidic liquid is absent. It is concluded that JIS test, which uses fresh water with gentle mixing not to degradation in size while leaching, is suitable for the evaluation, for the environmental assessment in service of the slag aggregate for roadbed.

Introduction

Steel slag is an industrial byproduct of steel making processes and has been widely used in countries like Japan, United States, and European Union nations. Steel slag has been widely utilized as construction materials for road construction and environmental remediation because of its similarity in physical properties as natural materials such as gravel (Chen et al. 2020; Hainin et al. 2015; Horii et al. 2013; Liyun et al. 2017; Mombelli et al. 2016; Piatak et al. 2015).

According to the Steel Industry Report (2019), the steel making industry in Vietnam is the fast-growing industry with the growth rate of 17% per year from 2014 to 2018 and forecast a 9% growth from 2019 to 2023. Together with the increase of steel products, the amount of slag generated in 2018 is about 4.2 million tons. While there is increasing demand for utilizing steel slag for road construction in Vietnam, due to the lack of national regulations and guidelines, most of the slag remains unutilized and kept in the storage yard in the factory area. On the other hand, there is also the concern about bulk utilization of steel slag may post the significant impact to the environment due to leaching of hazardous substances from steel slag matrix, which may become mobile in ground water and soil environment (Chaurand et al. 2007; Riley and Mayes 2015; Spanka et al. 2018).

Because slag is widely re-used as construction materials and environmental application globally, the assessment of environmental aspects of slag would contribute to encourage the utilization of steel slag in Vietnam.

This paper presents the current steel slag production status and its potential to use as road construction aggregates in consideration of environmental and quality control issues. The BOF, EAF and IF slag samples were collected from the seven steel making factories in Vietnam with relatively high crude steel production to evaluate leaching amount from the slags. The leaching test methods were compared using the leaching test of steel slag roadbed material in Japan (JIS K 0058 – 1) and EPA method 1311 widely adopted in Vietnam.

According to statistics of the Vietnam Steel Association (VSA), in Vietnam, there are more than 70 factories producing crude and finished steel. In 2020, crude steel production is estimated at 18 million tons. Vietnam steel market will become one of the fastest growing markets in the world from 2020 to 2024. The slag volume of the iron and steel industry is expected to reach 7.1 million tons by 2020.

Steel slag is generated from the steel production process. Depending on the type of the furnace, the steel slag is characterized into two types: Basic Oxygen Furnace Slag – BOF and Electric Arc Furnace slag – EAF.

Basic Oxygen Furnace slag is generated during refining of hot metal produced at blast furnaces, into steel in BOF. While carbon in iron is eliminated as gaseous carbon monoxide by injected oxygen, the impurities like silicon, manganese phosphorus and iron are also oxidized to form liquid state slag with lime and dolomite; the mixture of these oxides phase are called slag. Due to the difference in density with molten steel, liquid slag will float to the top and be removed from the furnace to form the steel slag after cooling. BOF slag is slowly cooled by natural air, or sprays water at the cooling yard. The yield of BOF slag is about 100–150 kg per ton of molten steel.

Electric arc furnaces use graphite electrodes to increase the temperature to melt by arcing and refining raw materials (scrap steel, lump cast iron). Some other metals like ferro, alloys are added to balance the required chemical compositions of steel, and oxygen is also used for refining of molten steel. Oxidizing slag and Reducing slag (reduction process) are generated from each stage of the steel making process. The yield of Oxidizing slag and Reducing slag is 100 kg and 50 kg per ton of molten steel respectively. The manufacturing of steel slag was illustrated in Fig. 1. Most of the steel slag produced is then dumped in the steel plant areas while hot and cooled in the slag storage yards. In some factories, slag was processed by sieving and magnetic separation for metal recovery.

Materials And Methods

Steel slag collection and pre-treatment

The BOF and EAF slag samples were collected from seven dumping sites of the steel plants during May 2019. The slags were stored in plastic containers and transported back to the laboratory for analysis. At the laboratory, the coarse particles were crushed and sieved to meet TCVN...
Experimental procedure

To investigate the mobility of trace metals in steel slags, the two type of single batch test were performed according to the US-EPA 1311 which is an evaluation method of waste and JIS K 0058 – 1 which is a standard for evaluating the environmental safety quality of steelmaking slag road base material in Japan (Table 2 ). The EPA 1311 standard procedure uses dilute acidic leachant solutions (acetic acid or acetate buffer) with a contact time of 18 hours and continuous end-over-end rotation of 30 rpm. While the JIS K 0058 – 1 uses deionized water with a contact time of 6 hours and constant stirring frequency of 200 rpm. The pH and leached concentrations of trace element such as Pb, Hg, Se, As, Cd, T-Cr (Cr3+, Cr6+), Cr6 + F, B, Mn, Ni, Zn, Cu, F, B were measured by pH meter and ICP–OES. The detection limit of ICP-OES for Pb, Hg, Se, As, Cd, T-Cr(Cr3+, Cr6+), Cr6+, F, B, Mn, Ni, Zn, Cu was 0.005, 0.005, 0.002, 0.005, 0.001, 0.02, 0.08, 0.1, 0.01, 0.1, 0.1 mg/L respectively.

Results And Discussion

The pH level and element leachate concentration in steel slag sample were given in Table 3. It is noticed that the pH and alkalinity of the leachate from JIS K 0058 – 1 test were significantly higher than those from EPA 1311 test. The reason is that JIS standard uses deionized water while EPA test employ acetic acid for leachant. The leached pH in most samples is higher than the National Technical Regulation on Industrial Wastewater (QCVN 40:2011/BTNMT). The high alkaline level was also found in other studies, because of the dissolution of Ca silicates, oxides, and/or carbonates to form Ca2 + ion and hydroxyl OH- (Chand et al. 2019; Piatak et al. 2015).

The pH level is a major parameter controlling the leaching of many elements in slags and shown clearly from the results of the two different leaching procedures employed. The standard leaching tests EPA results shows that some hazardous element was leached from the samples with the amount may be harmful to the environment such as F, Pb, As, Hg, Cd, Mn, Ni, T. Cr and B. The release of trace metals was likely because of lower pH of the buffer solution and enhanced extraction by acetic acid (Ettril et al. 2009; Proctor et al. 2000). The concentration of the leached element from EPA 1311 procedure was significantly higher than that from JIS K 0058-1 procedure, especially for Mn, T. Cr and F (Table 3, Fig. 3). Most of the concentration of toxic elements in leachate results from JIS K 0058-1 method were lower than detection limit of the ICP-OES and far below the standard for industrial wastewater discharge (QCVN 40-2011/BTNMT). These results are identical to those of the studies by Liyun et al. (2017) and Oh et al. (2012). Cr(6+) was not detected by either method.
The particle size of slag and liquid to solid ratio also affect the leaching of metals during leaching tests (Chand et al. 2019; Liyun et al. 2017; Mizutani et al. 2006; Piatak et al. 2015; Riboldi et al. 2020). During the EPA 1311 test, the end-over-end rotation produces finer particles then compared to the agitation in the JIS K 0058 – 1 test which accelerate the release of toxic elements to the leachant. While the increasing of water or leachant volume may increase the amount of dissolved slag and increase the leached concentration of trace metals.

Conclusions

For a better understanding of the status quo of Vietnamese steelmaking slag when applied to road building material, several steelmaking slags were collected from seven steel making factories in the region of Ha Noi, Da Nang and Ho Chi Minh city. The steel slags were crushed and sieved to meet the size distribution for road aggregate. Two types of single batch leaching test were performed according to the US-EPA 1311 and JIS K 0058 – 1 to analyze the possible environmental impact of the leached elements from slag when applying as roadbed aggregates. Some remarks can be obtained from the results of leaching tests:

- The pH level is a major parameter controlling the leaching of many elements in slags and shown clearly from the results of the two different leaching procedures employed. The EPA 1311 seems too harsh to evaluate the environmental impacts when applied to slag aggregate because it is the method used for proper waste management;
- The concentration of the leached element from EPA 1311 procedure was significantly higher than that from JIS K 0058 – 1 procedure, especially for Mn, T-Cr and F. Most of the concentration of hazardous element in leachate result from JIS K 0058 – 1 method were lower than detection limit of the ICP-OES and far below the standard for industrial wastewater discharge (QCVN 40-2011/BTNMT). The results of the leaching test would suggest the possibility of safe utilizing slag for roadbed construction. Because of the correlation between chemical composition and leaching test results, it is suggested that to control a correct balance of chemical composition during the production of steel to generate stable and safe slag.
- The particle size of slag and liquid to solid ratio are among the fundamental factors influencing the leaching of metals during leaching tests. It is suggested that a non-acidic, neutral or possibly alkali water that imitates groundwater or rainwater, and a gentle agitation without reduction in particle sizes, are suitable for the assessment of slag aggregates when used for road building such as JIS K 0058 – 1 procedure.
- Some of Vietnamese steel making slag that meets the requirement of leached heavy metals is safely applicable to road aggregate for the conservation of natural resources. The criteria need to be promulgate by the Government such as the official guideline or standard to promote recursive use of by-product as long as it is safe in construction and in service; if not, those shall be disposed complying with the regulations of Vietnam.
