Decoherence in quantum searches and in Grover search in particular has already been extensively studied, leading very quickly to the loss of the quadratic speedup over the classical case, when searching for some target (marked) element within a set of size $N$. The noise models used were, however, global. In this paper we study Grover search under the influence of localized partially dephasing noise of rate $p$. We find, that in the case when the size $k$ of the affected subspace is much smaller than $N$, and the target is unaffected by the noise, namely when $kp \ll \sqrt{N}$, the quadratic speedup is retained. Once these restrictions are not met, the quadratic speedup is lost. In particular, if the target is affected by the noise, the noise rate needs to scale as $1/\sqrt{N}$ in order to keep the speedup. We observe also an intermediate region, where if $k \sim N^{\mu}$ and the target is unaffected, the speedup seems to obey $N^{\mu}$, which for $\mu > 0.5$ is worse than the quantum, but better than the classical case. We put obtained results for quantum searches also into perspective of quantum walks and searches on graphs.

I. INTRODUCTION

Grover search \cite{1} is one of several quantum algorithms that provide us with speedups when compared with classical counterparts. Its basic function is searching over a database of $N$ elements in which no prior structure between the database elements is known. In this setting quantum mechanics offers quadratic speedup over classical (blind) search; Grover search finds marked element in $O(\sqrt{N})$ steps, while in the classical case we need $O(N)$ steps. It has been proven, that the quadratic speedup is optimal under assumption of unitary evolution \cite{2-4} with Grover algorithm reaching optimal scaling — we will call this specific transformation Grover evolution.

Since the unitarity is only an idealized situation, quantum searches have been studied also under various models of decoherence to determine their functionality under these more realistic conditions. A recurring observation is that the quadratic speedup is quickly lost; the decoherence rate for which this happens is usually of order $1/\sqrt{N}$. Getting such bound is typically difficult, because when studying decoherence one has to overcome the difficulties arising from the departure from pure states. In particular, the usual approach in the unitary case — identification of invariant subspaces — is no longer applicable and different methods have to be employed.

The rapid loss of efficiency is observed not only for Grover search under various types of decoherence \cite{5-12} but also in more general quantum search scenarios where the Grover evolution is not set and for purpose of the search any evolution with an arbitrarily large ancillary system that undergoes some decoherence is considered \cite{13-15}. The works studying the noisy quantum searches typically apply the decoherence on the whole Hilbert space where evolution happens. This includes noisy oracle \cite{9} \cite{13} \cite{14} or global qubit register decoherences \cite{7} \cite{8} \cite{12} in various forms, such as depolarization, dephasing or some deviations from unitary Grover evolution.

In this work we are motivated by a situation in which only a subspace of the Hilbert space is affected — this might happen e.g. if the database is encoded as a (multiple-)qubit system, where only one qubit (or a few) undergo decoherence. Such a model was outlined in Refs. \cite{7} \cite{8} \cite{12}. There the authors studied situation where the search is performed on a system encoded in qubits and these undergo decoherence individually. However, in all these works the locally applied noise was added to all the qubits and so the localization of it was not studied.

In this paper we present a novel approach to the problem of localized decoherence in the Grover evolution. We focus on the question, whether the limited influence of the decoherence can loosen the strict bounds on the speedup. We will make use of a method, which is based on identifying invariant subspaces in which evolution takes place. Whereas in the unitary evolution these subspaces had an operational meaning of state subspaces through which the evolution was defined, in our case the invariant subspace is only an abstract mathematical construct where the usual interpretation no longer holds. Nevertheless, the approach we use in the end provides tangible results.

The paper is organized as follows. In the next section we provide Grover algorithm for reference. In Section II we define the noise model and provide technical details on how it affects density matrices. In Section III we define the method of invariant subspaces on density matrices fit to the problem of Grover evolution. Results are presented in the following Section IV for several scenarios. As in the recent years quantum searches have also been heavily studied in quantum walks setups, in Section V we alter the methodology to suit the framework of quantum walks which we also introduce in that section. The conclusions of the paper are provided in Section VI.
A. Invariant subspace in the Grover search

Formally, the Grover algorithm allows for searches on Hilbert space \( \mathcal{H} \) of dimension \( N \) for an element marked by a (quantum) oracle, which is represented by a unitary operation

\[
O_f : |x⟩ \otimes |m⟩ \mapsto |x⟩ \otimes |m ⊕ f(x)⟩,
\]

defined on elements of the canonical basis \( |x⟩ \in \mathcal{H}, |m⟩ \in \mathbb{C}^2 \) and \( ⊕ \) is addition modulo 2. Boolean function \( f \) is the classical oracle associated with \( O_f \) — in a sense in the quantum oracle there is only as much information as in the classical oracle with the difference being that the quantum oracle can get also non-classical state on input. As such oracle provides no further information about the structure of the marked element(s), it is called unstructured. In this paper we will use only such oracle.

The Grover algorithm makes use of two operators. One is derived from the oracle \( O_f \) — by observing that states \( |s⟩ \otimes |−⟩ \) with \( |x⟩ \) from the canonical basis are eigenstates of \( O_f \) we define new oracle \( R_f \) as the action of oracle \( O_f \) on mentioned state. This allows us to drop the second part of the state and write the action of the oracle simply without the ancillary system as

\[
R_f : |x⟩ \mapsto (-1)^{f(x)} |x⟩.
\]

Second operator used in the Grover search is the inver-

\[
G = 2|s⟩⟨s| - I,
\]

where

\[
|s⟩ = \frac{1}{\sqrt{N}} \sum_x |x⟩.
\]

Note that if we define \( t = 2/N \) and \( r = 1 - t \), for each canonical state \( |x⟩ \) we have \( G |x⟩ = -r |x⟩ + t \sum_{y ≠ x} |y⟩ \).

As we will not deal with more than one marked element in this paper, we suppose now that the oracle marks only a single element. Then the result of \( U \) is, that by defining \( U = GR_f \) one can express the success probability after \( m \) steps of evolution by formula

\[
p_{\text{succ}}(m) = \sin^2 \left( \frac{(2m + 1)θ}{2} \right),
\]

where \( \cos θ = \frac{1}{\sqrt{2}} \). This probability is maximized when \( (2m_0 + 1)θ = π \), which gives the optimal number of steps

\[
m_0 \simeq \frac{π}{4} \sqrt{N}
\]

valid for large number of elements \( N \); this further means that one needs only \( m_0 \sim O(\sqrt{N}) \) repetitions of \( U \), i.e. calls to the oracle \( R_f \), in order to transform the initial state \( |s⟩ \) into the state

\[
|e⟩ = |f^{-1}(1)⟩.
\]

which is the marked element, or the target. This means that the quantum search is quadratically faster than the best classical search which requires \( N/2 \) queries to the oracle \( f \) on average.

The states \( |e⟩ \) and \( |s⟩ \) define an invariant subspace in which the evolution happens. Specifically, defining \( S = \text{span} \{|s⟩, |e⟩\} \), for any \( |ψ⟩ \in S \) also \( U |ψ⟩ \in S \). This method is employed also in more involved cases, commonly in quantum walks, where a precise identification of invariant subspaces is essential and leads to similar speedups; see e.g. [16, 17] for graph-specific definition (see also Section V of this paper).

As a side note, let us mention that for the purpose of estimating the efficiency of the search the requirement on the oracle is just its computational complexity being low. For example in the classical case of an unstructured search one can think of a search for a name belonging to a known number. The phone book works as an oracle — it takes \( O(\log N) \) steps to find whether a queried person belongs to the particular number if the phone book has \( N \) entries). Similarly, in quantum case the oracle may be just a subroutine of a more complex algorithm, such as in the case of the algorithm for element distinctness in [15].

II. NOISE MODEL

Global noise in Grover search, and in quantum searches in general, has a strong degrading effect on the efficiency of the algorithm. Typically already with noise rates stronger than \( 1/\sqrt{N} \) the quadratic speedup is already lost and quantum searches offer only linear speedup at best. The question stands whether this undesirable property can be lifted if we consider only localized noise as it seems unrealistic for a noise to be dependent (in this way) on the number of the database elements.

A consequence of the fact that the noise destroys coherence in the system is that we neet to switch from the pure state formalism to the density matrix formalism, in which the state is described by a trace-one operator, usually labelled \( ϱ \). The unitary evolution described in the previous section now reads \( \hat{U}(g) = U ϱ U^† \). The noise \( D_p \) is parametrized by its strength \( p \in [0;1] \) and will affect the state between any two applications of the unitary. The evolution of the state \( ϱ \) under decoherence will now be described as

\[
g(m) = (U \circ D_p)^m(ϱ),
\]

where \( m \) is the number of performed steps of the evolution and the “exponentiation” is in the sense of concatenation of the operations. This type of evolution is standard in the literature. Here, however, the noise \( D_p \) will not affect the whole Hilbert space \( \mathcal{H} \), but rather only a small subset of it.

For such a noise model we consider partially dephasing localized noise, where the dephasing is defined via partial
projection into a subspace of a Hilbert space. More concre-

tely, let us consider a Hilbert space \( \mathcal{H} \) of dimension \( N \) and suppose we can split it into two subspaces \( \mathcal{H}_0 \) and \( \mathcal{H}_1 \) such that \( \mathcal{H} = \mathcal{H}_0 \oplus \mathcal{H}_1 \) with the dephasing acting on the whole subspace \( \mathcal{H}_0 \). Denoting the projection onto \( \mathcal{H}_0 \) as \( \Pi_0 \) and the projection onto the orthogonal complement as \( \Pi_0^\perp = 1 - \Pi_0 \), the partial dephasing with rate \( p \) has the form

\[
\mathcal{D}_p(g) = p\Pi_0 g \Pi_0 + p\Pi_0^\perp \Pi_0^\perp + (1 - p)g.
\]

Note that since \( \Pi_0^\perp = \Pi_1 \) is a projection onto \( \mathcal{H}_1 \), the previous equation treats the two subspaces symmetrically. This noise thus performs dephasing between the two subspaces, while keeping the coherence within them intact. We will consider only noise where the dephasing is in the canonical basis with a specific focus on two cases of this type of noise.

### A. Coupled noise

In the first case, which we shall call **coupled noise** the \( \mathcal{H}_0 = \text{span} \{ |A_0| \} \) is some subset of canonical basis states. This is for example the case of a register consisting of qubits, when one of the qubits is affected by the dephasing — let \( j \) be the qubit that undergoes decoherence, then \( A_0 \) is the set of all canonical states that have in their binary notation the same value 0 (or 1) on \( j \)th position. Considering more general case of multiple dephasing qubits is beyond the scope of this paper and studies cases will not cover it; some results for globally (on all qubits) applied noise on qubit registers can be found in [7, 8, 12].

Mathematically, applying Eq. (9), the dephased matrix splits the density matrix for a system state into four blocks with the split corresponding to the two subspaces, and affecting only the non diagonal blocks

\[
\mathcal{D}_p(g) = \mathcal{D}_p \left( \begin{bmatrix} \hat{\varrho}_{00} & \hat{\varrho}_{01} \\ \hat{\varrho}_{10} & \hat{\varrho}_{11} \end{bmatrix} \right) = \begin{bmatrix} \hat{\varrho}_{00} & (1 - p)\hat{\varrho}_{01} \\ (1 - p)\hat{\varrho}_{10} & \hat{\varrho}_{11} \end{bmatrix}.
\]

Here the \( \hat{\varrho}_{ij} \) are submatrices of the original state on respective subspaces \( \mathcal{H}_0 \) and \( \mathcal{H}_1 \). The effect of \( \mathcal{D}_p \) can be written for density matrix elements \( \langle j | k \rangle \) as well as

\[
\mathcal{D}_p(\langle j | k \rangle) = \begin{cases} 
\langle j | k \rangle & \text{if } | j \rangle, | k \rangle \in \mathcal{H}_0 \\
(1 - p) \langle j | k \rangle & \text{otherwise}.
\end{cases}
\]

### B. Decoupled noise

In the second case the dephasing within the set of elements from the canonical base \( A_0 = \{ |j\rangle \} \) will be decoupled (we shall denote \( [A_0] = \{ j : |j\rangle \in A_0 \} \) and similarly \( [A_1] \)). Unlike in the previous case, for each canonical state of \( A_0 \) the dephasing acts independently, while

subspace determined by \( A_1 \) stays unaffected (resp. has a coupled decoherence with \( \mathcal{H}_0 \)). This removes the symmetrical treatment of \( \mathcal{H}_0 \) and \( \mathcal{H}_1 \) from the previous case. The decoherence on \( \mathcal{H}_0 \) is here separated into the canonical decoherences on each vector of \( A_0 \). In particular, for each \( j \in [A_0] \) we define local dephasing \( \mathcal{D}^{(j)}_p \) as given by Eq. (11) with \( \Pi_0 = \langle j | j \rangle \). From now on we suppose the same noise rate \( p \) for all \( j \)’s.

Important property is that the canonical dephasings with respect to different \( j \)’s commute,

\[
\mathcal{D}^{(j)}_p \circ \mathcal{D}^{(k)}_p = \mathcal{D}^{(k)}_p \circ \mathcal{D}^{(j)}_p
\]

for \( j, k \in [A_0], j \neq k \). This can be confirmed by a simple calculation. The overall (but localized to \( \mathcal{H}_0 \)) dephasing is defined as composition of all the canonical dephasings,

\[
\mathcal{D}_p = \bigcirc_{j \in [A_0]} \mathcal{D}^{(j)}_p.
\]

Invoking Eq. (11) we can now describe action of decoupled noise \( \mathcal{D}_p \) for all density matrix elements \( \langle j | k \rangle \).

If \( j = k \) or \( j, k \in A_1 \), then

\[
\mathcal{D}_p(\langle j | k \rangle) = \langle j | k \rangle.
\]

If \( j \in A_0, k \in A_1 \) or \( j \in A_1, k \in A_0 \), then

\[
\mathcal{D}_p(\langle j | k \rangle) = (1 - p) \langle j | k \rangle.
\]

And, finally, if \( j, k \in A_0 \) and \( j \neq k \),

\[
\mathcal{D}_p(\langle j | k \rangle) = (1 - p)^2 \langle j | k \rangle.
\]

The density matrix is then affected in the following way:

\[
\mathcal{D}_p(g) = \mathcal{D}_p \left( \begin{bmatrix} \hat{\varrho}_{00} & \hat{\varrho}_{01} \\ \hat{\varrho}_{10} & \hat{\varrho}_{11} \end{bmatrix} \right) = \begin{bmatrix} \hat{\varrho}_{00} & (1 - p)\hat{\varrho}_{01} \\ (1 - p)\hat{\varrho}_{10} & \hat{\varrho}_{11} \end{bmatrix},
\]

where

\[
\hat{\varrho}_{00} = (1 - p)^2 \hat{\varrho}_{00} + p(2 - p) \text{ diag}[\hat{\varrho}_{00}],
\]

which is \( \hat{\varrho}_{00} \) with unchanged diagonal elements and off-diagonal elements scaled by factor of \( (1 - p)^2 \).

Practically this type of noise can be present when performing e.g. a quantum-walk search where some of the corresponding vertices might be “damaged.” In Ref. [25] an interferometric interpretation of quantum walks is presented and this view can have a literal meaning in realization, where noises affecting laterally close states (vertices) might be present (see also Fig. 5).

### III. GROVER SEARCH WITH DEPHASING

In this section we shall expand the model presented in Section I A by introducing the noise into the pure unitary search. In our studied case the oracle \( f \) marks only a single element to which we refer to as the target. Without
loss of generality this element will be the very first one. The rest of the elements will be called normal(s). Some of these elements will be affected by noise; these will be numbered from 2 to \( k + 1 \), so there will be \( k \) such elements. The target element might, or might not be affected by the noise and we will consider both possibilities. The rest \( M = N - k - 1 \) elements will be normal ones that are unaffected by the noise.

Furthermore, we consider the dephasing rate to be uniform (either it describes the case of larger affected subspace with coupled noise or, if it is decoupled, the rate is the same for all elements). We will, however, set different rates on the target and on noisy normal (non-targeted) states in our computations in order to be able to distinguish between different cases of target either being or not being affected by the dephasing.

As noted, the invariant subspace formalism (see \[16, 17\]) cannot be used directly, as the dephasing not only takes the system out of the subspace, but even more, it destroys the purity of the state. In what we shall present, we identify an invariant subspace \( S \) within the density matrix formalism. The subspace will be defined as a span of a specific set of operators that will no longer have a clear physical interpretation. They will, however, still define a linear space invariant under both the unitary evolution \( U \) and the dephasing \( D \). As the usual initial state \( |1\rangle \rangle \) is from the subspace \( S \), also any subsequent state within the evolution will lie in this subspace \( S \).

In the generality needed for the full analysis within the questions addressed by this paper, the subspace \( S \) will be seven-dimensional, \( S = \text{span} \{ \sigma_j : j = 1, 2, \ldots, 7 \} \), where

\[
\sigma_1 = |1\rangle \langle 1|,
\]

\[
\sigma_2 = \frac{1}{\sqrt{k(k-1)}} \sum_{j=2}^{k+1} \sum_{m=2}^{k+1} |k\rangle \langle m|,
\]

\[
\sigma_3 = \frac{1}{M} \sum_{j=k+2}^{M} \sum_{m=k+2}^{N} |k\rangle \langle m|,
\]

\[
\sigma_4 = \frac{1}{\sqrt{2k}} \sum_{j=2}^{k+1} (|j\rangle \langle j| + |j\rangle \langle 1|),
\]

\[
\sigma_5 = \frac{1}{\sqrt{2kM}} \sum_{j=2}^{k+1} \sum_{m=k+2}^{N} (|j\rangle \langle m| + |m\rangle \langle j|),
\]

\[
\sigma_6 = \frac{1}{\sqrt{2M}} \sum_{j=k+2}^{N} (|1\rangle \langle j| + |j\rangle \langle 1|),
\]

\[
\sigma_7 = \frac{1}{\sqrt{k}} \sum_{j=2}^{k+1} |j\rangle \langle j|.
\]

We will call this also a \( \sigma \)-base. The operators \( \sigma_j \) are depicted in Fig. 1 as different renormalized sub-parts of a uniform operator \( \sum_{j,k} |j\rangle \langle k| \). This splitting recognizes the differences between the various parts of states (target/normals and noise-affected/not-affected) and it still allows to define the unitary evolution \( U \) on this subspace. Similarly as in the Introduction, we use

\[
t = \frac{2}{N}, \quad r = 1 - t = \frac{N - 2}{N}.
\]

The unitary evolution \( U \) is described by transformation rules within the subspace \( S \):

\[
U(\sigma_1) = r^2 \sigma_1 + t^2 \sqrt{k(k-1)} \sigma_2 + t^2 M \sigma_3 - rt \sqrt{2k} \sigma_4
\]

\[
+ t^2 \sqrt{2M} \sigma_5 - rt \sqrt{k} \sigma_6 + t^2 \sqrt{k} \sigma_7,
\]

\[
U(\sigma_2) = t^2 \sqrt{k(k-1)} \sigma_1 + [1 + t(k-1)(tk-2)] \sigma_2
\]

\[
+ t^2 M \sqrt{k(k-1)} \sigma_3 + t(k-1)(2(k-1)) \sigma_4
\]

\[
+ t(k-1) \sqrt{2M(k-1)} \sigma_5
\]

\[
+ t^2 \sqrt{2M} \sqrt{k(k-1)} \sigma_6 + t(tk-2) \sqrt{k-1} \sigma_7,
\]

\[
U(\sigma_3) = t^2 M(\sigma_1 + \sqrt{k(k-1)} \sigma_2 + \sqrt{2k} \sigma_4 + \sqrt{k} \sigma_7)
\]

\[
+ (1 - tM)^2 \sigma_3 - (\sqrt{k} \sigma_5 + \sqrt{k} \sigma_6) t(1 - tM) \sqrt{2M},
\]

\[
U(\sigma_4) = tr \sqrt{2k} \sigma_1 + \sqrt{2t(1 - tk)}(\sqrt{k - 1} \sigma_2 + \sigma_7)
\]

\[
- t^2 M \sqrt{2k} \sigma_3 - [r - tk(1 - 2t)] \sigma_4
\]

\[
+ t(1 - 2tk) \sqrt{M} \sigma_5 + (1 - 2t) \sqrt{M} \sigma_6,
\]

\[
U(\sigma_5) = t^2 \sqrt{2M} \sqrt{k} \sigma_1 + t(k - 1) \sqrt{2M} \sqrt{k - 1} \sigma_2 + \sigma_7
\]

\[
+ t(M - 1) \sqrt{2M} \sigma_3 + t(2tk - 1) \sqrt{M} \sigma_4
\]

\[
+ (2t^2 k - r) \sigma_5 + t(2M - 1) \sqrt{k} \sigma_6,
\]

\[
U(\sigma_6) = tr \sqrt{2M} \sigma_1 - t^2 \sqrt{2M} \sqrt{k - 1} \sigma_2 + \sigma_7
\]

\[
- t(M - 1) \sqrt{2M} \sigma_3 + t(1 - 2t) \sqrt{M} \sigma_4
\]

\[
+ t(1 - 2tM) \sqrt{k} \sigma_5 + (1 - tk - 2t^2 M) \sigma_6,
\]

\[
U(\sigma_7) = t^2 \sqrt{k} \sigma_1 - t(2 - tk) \sqrt{k - 1} \sigma_2 + t^2 M \sqrt{k} \sigma_3
\]

\[
+ \sqrt{2t} (tk - 1)(\sigma_1 + \sqrt{M} \sigma_5) + t^2 \sqrt{2M} \sigma_6
\]

\[
+ (1 - 2t + t^2) \sigma_7.
\]

This means that the Grover evolution is restricted to the subspace \( S \) and the evolution in this subspace can be represented by a 7-dimensional unitary matrix \( U \).
In general we can obtain coefficients $a_j$ from any state $\varrho_a$ as presented in Eq. (24) by defining inner product via the usual formula
\[(\varrho_a, \varrho_b) = \text{Tr} [\varrho_a^* \varrho_b] = \sum_{j=1}^7 a_j^* b_j. \quad (26)\]

The coefficients are extracted by the formula
\[a_j = \frac{(\sigma_j, \varrho_a)}{(\sigma_j, \sigma_j)} = (\sigma_j, \varrho_a). \quad (27)\]

The last equality holds due to orthonormality of $\sigma_j$’s under the inner product (26).

Success probability we are interested in is given by the projection to the state $\sigma_1$ and so $p_{\text{succ}} = a_1$. Finally, the trace in the $\sigma$-base is given as
\[\text{Tr} \varrho = a_1 + a_4 + \sqrt{k} a_7, \quad (28)\]

since only $\sigma_1$, $\sigma_3$ and $\sigma_4$ are not traceless.

As the presented formulation in the 7-dimensional subspace $S$ is still very demanding and to make an example of using presented identification of invariant subspaces, we look at the specific cases of the general evolution with the decoherence, starting from the simplest.

\section{Results}

\subsection{Normal elements treated equally}

In this case we will restrict ourselves to the case when all the normal elements of the database are the same — either not affected by the decoherence, or all under the influence of decoherence. Roughly speaking we consider here the situation when $k \to N - 1$ in which case the matrices $\sigma_3$, $\sigma_5$ and $\sigma_6$ are ill-defined and we do not include them in the computation any more. The unitary evolution is now described by transformation rules
\[
\begin{align*}
U(\sigma_1) &= r^2 \sigma_1 + t \sqrt{2r(1+r)} \sigma_2 \\
&\quad - r \sqrt{2(1+r)} \sigma_4 + t \sqrt{(1+r)} \sigma_7, \\
U(\sigma_2) &= t \sqrt{2r(1+r)} \sigma_1 - (1 - 2rt) \sigma_2 \\
&\quad + 2r \sqrt{r} \sigma_4 - t \sqrt{2r} \sigma_7, \\
U(\sigma_4) &= r \sqrt{2l(1+r)} \sigma_1 - 2r \sqrt{l} \sigma_2 \\
&\quad + (2r^2 - 1) \sigma_4 - 2r \sqrt{l} \sigma_7, \\
U(\sigma_7) &= t \sqrt{(1+r)} \sigma_1 - t \sqrt{(1+r)} \sigma_2 \\
&\quad + \sqrt{2r} \sigma_4 + r(1 + t) \sigma_7. \quad (29)
\end{align*}
\]

The dephasing obeys
\[
\begin{align*}
D(\sigma_1) &= \sigma_1, \\
D(\sigma_2) &= (1 - p)^2 \sigma_2, \\
D(\sigma_4) &= (1 - p)(1 - q) \sigma_4, \\
D(\sigma_7) &= \sigma_7. \quad (30)
\end{align*}
\]
We have therefore set $1 - w = (1 - p)^2$ and $1 - s = (1 - p)(1 - q)$. This allows us to study three different scenarios: (A) broken target ($p = 0$, $q \neq 0$), (B) global decoupled dephasing ($p = q$), and (C) noisy normals and unaffected target ($p \neq 0$, $q = 0$). While both cases (A) and (C) treat the target in a different way than the normals, the case (C) seems to be rather unreasonable, as it would indicate, that while all elements undergo dephasing, the oracle does not. The case (A) is in this respect more reasonable, as it defines a system that evolves unitarily.

The important eigenvectors are those having large value of $\omega_j := |(\nu_j, \varrho_{\text{init}})(\nu_j)|$. In this specific example eigenvector $\nu_1$ has overlap of $\omega_1 \sim O(1/N)$, while all other eigenvectors have overlap $\omega_j \sim 1/2$. The evolution can be after some manipulation expressed by Eq. (5).

2. Including the noise

Now let us include also dephasing into our discussion. With respect to the definition of trace in Eq. (28), only eigenvalue $\nu_1$ has a non-zero trace. Since both the unitary $U$ and the dephasing $D$ are trace preserving, $\nu_1$ has to be the eigenvalue of $D$ with the eigenvalue 1 as well. This reduces the analysis to the three remaining eigenvalues — eigenvalue 1 corresponding to the vector $\nu_2$ and eigenvalues $e^{\pm 2i\theta}$.

Already in this simple case the analysis under full evolution is difficult and therefore we will restrict ourselves to the case of small values of $p$ and $q$ and use perturbation theory to find the corrections to the eigenvalues. As the overlaps of these eigenvectors with the initial state are of $O(1)$, under supposition of first-order terms of $p$ and $q$ these overlaps do not change significantly and we will treat them as constants as over the studied time of evolution they remain unchanged and do not change the success probability.

Note also, that (even in the full problem) if we have no noise on normal elements ($p = 0$), the 1-eigenvectors of $U$ are also eigenvectors of $D$, i.e. the corrections to the 1-eigenvalue terms will depend only on $p$ — the noise rate on the normal elements, while the dependence on $q$ in the first order approximation shall be absent.

The characteristic polynomial $P(\lambda) = \epsilon$ as defined in (23) is of fourth order with one solution 1. The other eigenvalue 1 of the matrix $U$ is perturbed — setting $\lambda = 1 + \delta p$ we find that

$$P(1 + \delta p) = 16p[N + (N - 1)\delta] + R_2,$$

where $R_2$ represents terms of higher order; these are of order $p^2/N$ and so are small for all considered $p$'s. Setting $\Delta P(1)$ being the first order variation to $P$ at value 1 we solve for $\Delta P(1) = 0$ and get

$$\delta = -\frac{N}{N - 1}, \quad \lambda = 1 - \frac{N - N - 1}{N - 1},$$

where we marked the approximated eigenvalue by tilde.

For the conjugated eigenvalues we let $\lambda_\pm = e^{\pm 2i\theta}(1 + \delta \pm p + \gamma \pm q)$ and solving for $\Delta P(\lambda_\pm) = 0$ we get

$$\lambda_\pm = e^{\pm 2i\theta} \left[ 1 - \frac{2N - 3}{2(N - 1)} p - q \right].$$
The higher order terms are smaller than the leading terms if $p,q \ll 1/\sqrt{N}$. The full evolution is obtained from formula similar to Eq. (35),

$$\rho(m) = \mathcal{E}^m \left[ \sum_j (\nu_j, \varphi_{\text{init}}) \varphi_j \right] \simeq \sum_j (\nu_j, \varphi_{\text{init}}) \mathcal{E}^m \varphi_j,$$

which to the first order of approximation gives

$$p_{\text{suc}}(m) \simeq \frac{1}{N} + \frac{N-2}{2N} \left( 1 - \frac{N}{N-1} p \right)^m - \frac{1}{2} \cos([2m+1] \theta) \left[ 1 - \frac{2N-3}{2(N-1)} p - \frac{q}{2} \right]^m \simeq \frac{1}{2} \left( 1 - p \right)^m - \cos([2m+1] \theta) \left( 1 - p - \frac{q}{2} \right)^m. \quad (40)$$

The second approximation is for $N \to \infty$. We note that this result is consistent with the noisless case of the Grover search, as for $p = q = 0$ it gives Eq. (5).

Taking now $p = 0$, $q \neq 0$, i.e. with just the target dephasing (case A, see Fig. 2(b)(i)), the success probability has a stationary point $1/2$. The limiting state in this case is

$$\mu_0 = \frac{1}{2\sqrt{1+r}} (\sqrt{1+r}, \sqrt{2r}, 0, \sqrt{7}), \quad (41)$$

which, with probability $1/2$ gives the target element and with probability $1/2$ projects into the normal subspace with equal probability to be located in any normal state.

After $n_0$ steps given by [5], when the cosine term becomes positive we have the success probability $p_{\text{suc}} \geq 1/2$ which means, that the number of oracle calls by Eq. (A6) is still of order $\sqrt{N}$ and we do not lose the quadratic speedup. However, this works only under given approximation ($q \ll 1/\sqrt{N}$) — outside this bound the higher order terms will lead to the change of the frequency of oscillations and prolong the computation in a way that might eventually lead to the loss of quadratic speedup. This is indeed the case, as can be observed in Fig. 6.

On the other hand, additional dephasing $p \neq 0$ destroys the success probability quickly and the limiting state is the completely mixed state that gives probability of success only of order $1/N$. In this setting the only physically relevant situation is a global decoupled dephasing with $p = q$ (case B, see Fig. 2(b)(ii)). Invoking the results of [15] we find out, that in this case the quadratic speed-up is lost as well and the number of oracle calls is of order $pN$, unless $p,q \ll 1/\sqrt{N}$. The same analysis holds also for case C.

In this simplest example the parameter regions for applicability were small and, in turn uninteresting, recovering only previous results. In the next section we shall extend the model and show that in some particular cases the parameters regions can be extended beyond $1/\sqrt{N}$ bound and provide interesting results. As the computations get more involved, we remove lengthy expositions and present only results.

FIG. 2: Evolutions of the success probability (with $N = 500$) under (a) coupled noise — when the target element is part of the (much) larger subset (i), the periodic oscillations are pronounced ($p = 0.1$, $k = 10$, $q = 0$) and the approximation is well-fitting. When the size of the set where target belongs shrinks (case (ii), $k$ increases to $N/2$), the fit becomes worse and the probability grows slower, in the limit of large times approaching $1/3$. When the number of noisy elements in the normal set drops to $k = 0$, we have only noisy target, which is the same case in the decoupled noise scenario (b)(i), with $p = 0$, $q = 0.05$. In this case the limiting probability is $1/2$ and not $1/3$, as it is described by Eq. (42). More general case is (ii), where $k = 10$ but without the noise affecting the target, which still offers quadratic speedup. Again, the more elements are affected by noise, the easier it is to destroy the speedup; it gets even faster, when noise affects the target (iii), where we show the limiting case of all elements under delocalized dephasing with $p = q = 0.05$.

B. Coupled noise on any subset of elements

Splitting the set of normal elements into those affected by noise and those that are not increases the dimensionality of the problem. Considering only coupled noise does, on the other hand, allow the dimensionality to be only six, as the diagonal matrix $\sigma_7$ can be merged with the off-diagonal matrix $\sigma_2$ of affected normals into one,

$$\bar{\sigma}_2 = \frac{1}{k} \sum_{j=2}^{k+1} \sum_{m=2}^{k+1} (j) \langle m \rangle. \quad (42)$$
This state change affects several definitions from the introduction. Firstly, the unitary transformation rules (21) will be different; under action of \( \mathcal{U} \) the matrix \( \tilde{\sigma}_2 \) evolves as

\[
\mathcal{U}(\tilde{\sigma}_2) = t^2 k \sigma_1 + (1 - t k)^2 \tilde{\sigma}_2 + t^2 k M \sigma_3 - t \sqrt{2 k M} (1 - t k) \sigma_3 - t \sqrt{2 k M} (1 - t k) \sigma_5 + t^2 k \sqrt{2 M} \sigma_6.
\]

(43)

All other transformation rules \( \mathcal{U}(\sigma_j) \) from (21) change only in the \( \sigma_2 \) terms. These changes can be described by exchange rule

\[
\sigma_2 \rightarrow \sqrt{\frac{k}{k-1}} \tilde{\sigma}_2.
\]

(44)

The initial state is

\[
g_{\text{init}} = \frac{t}{2} (1, k, M, \sqrt{2 k}, \sqrt{2 k M}, \sqrt{2 M})
\]

(45)

and the trace (28) is now

\[
\text{Tr} g = a_1 + \tilde{a}_2 + a_3,
\]

(46)

where \( \tilde{a}_2 \) is the coefficient by \( \tilde{\sigma}_2 \). The dephasing noise is acting according to the rules (displaying only those, that do not act as identity):

\[
\mathcal{D}(\sigma_4) = (1 - s) \sigma_4,
\]

\[
\mathcal{D}(\sigma_5) = (1 - p) \sigma_5,
\]

\[
\mathcal{D}(\sigma_6) = (1 - q) \sigma_6.
\]

(47)

This parametrization allows us to discern three particular physically interesting cases in this discussion: in the coupled noise scenario (A) noise-unaffected target for which \( q = 0 \) and \( s = p \), (B) noise-affected target when \( s = 0 \) and \( q = p \), and (C) a specific case of decoupled noise when \( k = 1 \) that can be obtained by setting \( q = p \) and \( s = 2 p - p^2 \). These cases will be analyzed below in separate subsections. As the difficulty of solving the problem grows beyond the point when displaying of the intermediate calculations would be useful, we present only a simplified analysis.

The unperturbed problem now contains two pairs of complex-conjugate eigenvalues and a double-degenerate eigenvalue one. One pair of complex-conjugate eigenvalues gives the usual periodic behavior. The second pair would introduce a different period to the evolution, but the two corresponding eigenvectors have zero overlap with our initial state and are, hence, unimportant in the analysis. In the eigenvalue one subspace we can find a base of two eigenvectors, one of which has trace zero. The other eigenvector is the only eigenvector with non zero trace and, thus, is also an eigenvector for the dephasing \( \mathcal{D} \). Success probability coming from this vector is \( 1/3 \). The problem is now solved by perturbing the remaining eigenvector for the eigenvalue one and the relevant periodic part.

1. **Coupled noise**

A situation (case A), when we have target that is unaffected by the noise, is obtained by taking \( q = 0 \) and \( s = p \). In this case the success probability is

\[
p_{\text{succ}}(m) \lesssim \frac{1}{3} + \frac{1}{6} \left[ 1 - \frac{3 k M}{(N-1)^2} \right]^m
\]

\[
- \frac{1}{2} \cos[(2 m + 1) \theta] \left[ 1 - \frac{k (2 N - k - 2)}{2 (N-1)^2} \right]^m.
\]

(48)

The approximations for the 1-eigenvalue are appropriate for both \( p \ll 1 \) and \( k \ll N \) and for the periodic term the applicability of the approximation is for \( k p \ll \sqrt{N} \). However, in this case, the former restriction on the 1-eigenvalue term does not affect the complexity of the search, as with the constant term, this part of probability will always be \( O(1) \); we are, hence, limited only by constraint \( kp \ll \sqrt{N} \). This is confirmed also numerically, see Fig. 3.

Within given constraints, after \( m_0 \) steps given by (6) the periodic term is positive as well and the whole probability is of order one — the quadratic speedup is retained. This situation is depicted in Fig. 3 (i). However, if we, e.g. set \( k = N/2 \) (Fig. 3 (ii)), which will take us outside the validity of the approximation, we are not guaranteed to have quadratic speedup any more.

Interestingly, we can look also at intermediate cases, when \( k \sim N^\mu, \mu > 0.5 \), where the numerical simulations show (see Fig. 4) that although the quadratic speedup is lost, the search can be still faster than the (linear) classical one, as the efficiency seems to scale as \( N^\mu \).

Note that taking \( k \rightarrow 0 \) recovers the Grover search (5) and taking \( k \rightarrow N - 1 \) (which requires \( p \ll 1/\sqrt{N} \)) recovers Eq. (40) in which the \( p \) and \( q \) have inverted roles, i.e. \( p := 0 \) and \( q := p \) Furthermore, comparing to the previous section we see the extension of validity of our approximations for small \( k \lesssim \sqrt{N} \), for which we require only \( p \ll 1 \). That is, the approximation does not require the noise parameter to scale with the size of the system whenever \( k \) is small.

Due to the symmetry of the coupled noise the interpretation is that the quadratic speedup is retained for small noises whenever the target is in the larger noise-affected set. This symmetry also offers solution to the case B, which is simply case A with \( k \rightarrow N - k - 1 \) and, hence, it does not require further comment.

In both previous cases the limiting state is the same, the single eigenvector with eigenvalue one of both \( \mathcal{U} \) and \( \mathcal{D} \),

\[
\mu_0 = \frac{1}{3} (\sigma_1 + \tilde{\sigma}_2 + \sigma_3),
\]

(49)

which has the same probability to be found in either of the three types of elements — target, noisy normal and unaffected normal element.
in the previous section, we reduce the number of noise given by (25). As we have already treated coupled noise obeys the rules presented in (21) and the initial state is only at rate $p/N$ is the most difficult to treat. The unitary evolution $U$ elements under decoupled dephasing.

now, but becomes valuable for general number of normal noises $q$, which has a quadratic speedup; dashed black line corresponds to the classical search. Cases having target noises $q \ll 1/\sqrt{N}$ and for normals $kp \ll \sqrt{N}$, are retaining quadratic speedup (shaded region). Any deviation from these bounds leads to the loss of the speedup. Linear scaling is obtained whenever $q$ is constant (dot-dashed line); this loss is further pronounced when some noisy normals are added (dotted line). Dashed gray line, when $k \simeq N^{0.7}$, diverges from quadratic speedup, but within the studied range it does not lead to linear scaling.

2. Decoupled dephasing on a target and single normal element

The case (C) is obtained by setting $q = p$ and $s = 2p - p^2$ with $k = 1$. Here we observe that the success probability is

$$p_{\text{suc}}(m) \simeq \frac{1}{3} + \frac{1}{6} \left[ 1 - \frac{3(N-2)}{(N-1)^2 p} \right]^m - \frac{1}{2} \cos(2m + 1)\theta \left[ 1 - \frac{N^2 - 2}{2(N-1)^2 p} \right]^m,$$  \hspace{1cm} (50)

where the periodic term is a good approximation only for $p \ll 1/\sqrt{N}$ valid for the periodic term. More interestingly, the middle term is no longer damped at rate $p$, but only at rate $p/N$, which does not have high importance now, but becomes valuable for general number of normal elements under decoupled dephasing.

C. Decoupled noise on any subset of elements

The most general case, as introduced in Section III is the most difficult to treat. The unitary evolution $U$ obeys the rules presented in (21) and the initial state is given by (25). As we have already treated coupled noise in the previous section, we reduce the number of noise parameters by setting the $D$ as follows:

$$D(\sigma_2) = (1 - p)^2 \sigma_2,$$

$$D(\sigma_4) = (1 - p)(1 - q) \sigma_4,$$

$$D(\sigma_5) = (1 - p) \sigma_5,$$

$$D(\sigma_6) = (1 - q) \sigma_6.$$  \hspace{1cm} (51)

All other rules act as identities. This parametrization allows us to discern two cases — either target being affected by the noise ($p = q$ is assumed due to the symmetry considerations) or not affected ($q = 0$ which is interesting for the case of small $k$'s in particular).

The solution of the unperturbed problem has, in comparison to the cases mentioned in Section IV B, a three-fold degeneracy of eigenvalue one, where we can find a third eigenvector for which the eigenvector has a zero overlap with the initial state and is not eigenvector for the dephasing $D$. Interestingly, all three eigenvectors are for $p = 0$ eigenvectors of the dephasing $D$; the first order dependence of the eigenvectors is thus independent of $q$.

With the analysis of the eigenvectors and known limit for $k = 1$ (Section IV B 2) we can obtain the first order approximation to the success probability in the form

$$p_{\text{suc}}(m) \simeq \frac{1}{k + 2} + \frac{k}{2(k + 2)} \left[ 1 - \frac{(N - 2)(k + 2)}{(N - 1)^2 p} \right]^m - \frac{1}{2} \cos(2m + 1)\theta \left[ 1 - \frac{k(2N - 3)}{2(N - 1)^2 p - q/2} \right]^m.$$  \hspace{1cm} (52)

The strongest restriction on validity comes from the periodic term approximation, namely, $kp \ll \sqrt{N}$ and $q \ll 1/\sqrt{N}$. This shows that whenever the target is affected by noise ($q > 0$), the quadratic speedup is quickly lost as the threshold scaling as $1/\sqrt{N}$ is very restrictive; this uncovers the destructiveness of the noise usually observed in the literature on the topic.

Interesting situation appears when $q = 0$, i.e. when the target is in the noise-affected subspace. If the affected subspace is small ($k < \sqrt{N}$) the approximation to the success probability is valid even for larger noise rates $p$. In other words, when the previous conditions are met, the search is robust towards the noise. The evolution in this case is depicted in Fig. 2b(ii).

We can observe that the first static term decreases with growing $k$, but for small enough $k$’s still provides a quadratic speedup with scaling $k\sqrt{N}$ as after $m_0$ steps the periodic term becomes positive; see Appendix for explanation. For larger $k$’s approaching $\sqrt{N}$ the first term becomes small and does not allow quadratic speedup anymore. On the other hand the second term is damped only at a rate proportional to $kp/N$, which still provides a quadratic speedup by Eq. (51). For larger $k$’s, especially when approaching $N$, we lose the speedup and the number of oracle calls grows towards $pN$; the solution approaches Eq. (40). In addition, Eq. (50) can be recovered from (52) by taking $k = 1$ and $p = q$. 

FIG. 3: Scaling properties of different situations in log-log scale; these situations are displayed for coupled noise, however, qualitatively the same discussion holds also for decoupled noise. Black solid line depicts Grover search without noise, which has a quadratic speedup; dashed black line corresponds to the classical search. Cases having target noises $q \ll 1/\sqrt{N}$ and for normals $kp \ll \sqrt{N}$, are retaining quadratic speedup (shaded region). Any deviation from these bounds leads to the loss of the speedup. Linear scaling is obtained whenever $q$ is constant (dot-dashed line); this loss is further pronounced when some noisy normals are added (dotted line). Dashed gray line, when $k \simeq N^{0.7}$, diverges from quadratic speedup, but within the studied range it does not lead to linear scaling.
Summing up the previous results, we can observe that the quadratic speedup of the quantum search can be retained when the noise affects a small number of normal elements, but not the target. In fact, our numerical simulations in Fig. 3 show that the bound for the noise rate on the target, $q \ll 1/\sqrt{N}$ and the bound for the noise on normals, $kp \ll \sqrt{N}$ is a rather strict one. Any deviation seems to lead to the loss of quadratic speedup if not any speedup. Probably the most disastrous is noise on the target, which very quickly leads to linear scaling. Having noise on the normals then only intensifies the loss of the speedup.

If, however, the target is unaffected by the noise, the quadratic speedup is retained even for large noises $p$ and number of affected normals up to $k \simeq N^{\mu}$. Any larger scaling of $k \simeq N^{\mu}$ with $\mu > 0.5$ seems to lead to the loss of the quadratic speedup. As seen in Fig. 4 the efficiency slowly deteriorates roughly as $N^{\mu}$. The convergence seems to be robust as seen in the inset of the Figure. Interestingly, these qualitative results hold irrespective of what type of dephasing we use, whether it is coupled, or decoupled noise.

In the following section we shall make some parallels with quantum walks, where this method might be applicable as well.

V. APPLICATIONS TO QUANTUM WALKS

The possibility of applying quantum searches within quantum walks does not provide additional results but the different point of view might be useful. Quantum walks gained recently a lot of attention, as they are relatively easy to experimentally realize and, hence, may pose as a good testing ground for quantum algorithms that are applicable to them. One of the more prominent applications of algorithms to quantum walks are searches that have been described on various forms of graphs [27, 22, 23]. Yet again, their results suffer from the problem of being proven to work only for the ideal unitary evolutions. The role of noise, which is important in experimental realizations, is only sparsely studied beyond observation of general properties on lattices. Especially in the mentioned results, the theory of invariant subspaces, presented in [24] in great depth, plays a deep role and in fact, was the original inspiration for this paper. For these reasons, the paper should not only offer results for the general quantum searches, but also more specifically for the community of quantum walks.

Quantum walks are quantum evolutions defined on graphs of specific structure. Following the interferometric interpretation of discrete-time quantum walks introduced in [25], the quantum walk is defined on a graph $G = (V, E)$, where $V = \{1, 2, \ldots, N\}$ is the set of vertices and $E$ is the set of edges, i.e. pairs of vertices. The graph is considered to be undirected, meaning, that if $(x, y) \in E$, then also $(y, x) \in E$. Quantum walk is then defined on a Hilbert space $\mathcal{H} = \text{span}\{\ket{x,y} : (x, y) \in E\}$. The walker in these types of quantum walks can thus be interpreted as a particle travelling on edge $(x,y)$ from vertex $x$ to vertex $y$. The evolution $U$ on such graph is defined via local evolutions on all vertices $x, U_x : \Omega_x \rightarrow A_x$, where

$$ \Omega_x := \text{span}\{\ket{x,y} : y \in V, (y, x) \in E\} \quad (53) $$

is the subspace of $\mathcal{H}$ where the walker is travelling towards vertex $x$ and

$$ A_x := \text{span}\{\ket{x,y} : y \in V, (x, y) \in E\} \quad (54) $$

is the subspace of $\mathcal{H}$ where the walker is travelling away from vertex $x$. The overall evolution $U$ is then a direct sum of all these sub-evolutions, $U = \oplus_{x \in V} U_x$. 

![FIG. 4: Dependence of efficiency exponent $\beta$ in dependence of exponent $\mu$ for the size of affected subspace, $k \simeq N^{\mu}$ for coupled dephasing (dot-dashed) and decoupled dephasing (dashed) is roughly linear. Inset shows the convergence of $\beta$ for various choices of $\mu = 0.5, 0.6, 0.7, 0.8, 0.9$ from bottom to top.](image)

![FIG. 5: Star graph with central vertex 0, spokes' end-vertices 1 through $N$. Vertex 1 is marked by the oracle and vertices 2 through $k+1$ are undergoing decoherence. When $k$ is small, the search by quantum walks can still be quadratically faster than in the classical case.](image)
Quantum walks provide a playground for many quantum algorithms and quantum searches in particular. When performing a search with quantum walks, a usual assumption is homogenity of a graph (high symmetry) and also high homogeneity of the quantum evolution. In particular, in connection to the oracle \( f \) it is usually assumed that \( U_x = (-1)^{f(x)} U_0 \) where \( U_0 \) is chosen to be the inversion about average operator \( G \), or the identity \( I \) (depending on the setup). In these cases, the theory of superposition of outgoing walkers, additional phase, vertex 1 reflects the particle back as well, but with an f[24] can be used to show quadratic speedups in localization of elements (vertices) for which \( f \) gives one.

As an example, let us consider a quantum-walk based search on a star graph (see Fig. 5) having one central vertex (labelled 0) and \( N \) vertices at the ends of the spokes (numbered from 1 to \( N \)) that are connected to the central vertex. Let the oracle \( f \) select one of the outer vertices, which we can set to be 1 without loss of generality. In ideal case the evolution on this graph is described by three different local unitaries. The central vertex acts as the inverse about average \[3\], i.e. \( U_0 = G \). The unmarked (normal) outer vertices simply reflect the walker back, i.e. \( U_j = I \) for \( j = 2, 3, \ldots, N \). The target vertex 1 reflects the particle back as well, but with an additional phase, \( U_1 = -\frac{1}{2}I \). Let us again use the notation \( U(\phi) = U \rho U^\dagger \), and let the initial state be the equal superposition of outgoing walkers, 

\[
|\psi_{\text{init}} \rangle = \frac{1}{\sqrt{N}} \sum_{j=1}^{N} |0,j \rangle.
\] (55)

What we shall show is that this problem can be mapped to our previous results for noisy quantum search.

Defined unitary evolution is an ideal situation, which in real experiment might be disturbed by noise that will be again labelled as \( \mathcal{D} \). Suppose, some subset of vertices, from 2 through \( k + 1 \), is faulty and acts similarly as in Ref. [29]. In particular (e.g. due to thermal fluctuations) a random phase-shift \([0, x] \mapsto e^{i\phi} |0, x \rangle\) is introduced to each of the faulty vertices, where \( \phi \) is sampled from a pdf \( \pi \) that is symmetric around 0 and on interval \([-a, a]\). This phase-shift is considered to be dynamic, i.e. randomly sampled at each step. This situation is also depicted in Fig. 5.

We can simplify the problem by considering two steps of evolution. Due to the nature of the initial state [55] and the noise not affecting states of form \( |j, 0 \rangle \), the application of the noise after every use of the unitary \( U \), the dephasing \( \mathcal{D} \) will have no effect half of the time. In particular, when the state \( \rho \) is described as a particle leaving vertex 0, then we have identity

\[
(U \circ \mathcal{D})^2 (\rho) = (U^2 \circ \mathcal{D}) (\rho).
\] (56)

Furthermore, as we are unaware what the actual phase-shift is, to our best knowledge the state changes under channel that is the average over all phase shifts

\[
\mathcal{D} (\rho) = \int_{-a}^{a} \pi(\phi) \mathcal{D} (\rho) d\phi.
\] (57)

So in the end, what we are interested in is evolution described at every step by \( \mathcal{E} = U^2 \circ \mathcal{D} \). Let us now have a closer look at the introduced noise \( \mathcal{D} \) in this averaged image.

If we describe the quantum walker state by the density matrix, then we have three types of coefficients \( g_{j,m} \). First are those where both \( j, m \) are not from the noise-affected subspace, or when \( j = m \). In this case the corresponding density matrix coefficients do not change under dephasing. If one of \( j, m \) belongs to the affected subspace, but the other does not, the coefficient after the application of dephasing \( \mathcal{D} \) acquires a phase \(-\phi_j - \phi_m \). In both cases the averaging gives a multiplicative factor to the coefficient

\[
0 \leq 1 - p \equiv \int_{-a}^{a} \pi(\phi) e^{i\phi} d\phi = 2 \int_{0}^{a} \pi(\phi) \cos(\phi) d\phi \leq 1.
\] (58)

Finally, if both vertices \( j, m \) are from the affected subspace and \( j \neq m \), then the density matrix coefficient acquires a phase \( \phi_j - \phi_m \). Similarly as before, the averaging gives a prefactor to the coefficient of the form \((1 - p)^2\).

We can observe now, that this behavior of the dephasing \( \mathcal{E} \) is the same as the depolarizing noise used in [51]. Furthermore the unitary part of the evolution given by \( U^2 \) is described by transformation rules [21] where in the definition of the \( \sigma \) basis [19] we identify the edge states \( |0,j \rangle \) with states \( |j \rangle \). Hence, we have mapped the quantum-walk search problem with dynamical phase-shifting on some elements to the case of noisy quantum search from Section L.V.C. We can now use the results obtained there also in this case.

**VI. CONCLUSION**

We have studied Grover search under local partially dephasing channel using a novel method of invariant subspace in the density matrix formalism.

The analysis shows interesting behavior in several cases, that still allow for (the quadratic) speedup. The dephasing we considered was of two sorts. For the first kind of coupled noise we found out, that such a noise does not hinder the possibility of quadratic speedup when the number of affected elements is small \((k \leq \sqrt{N})\). In this case the periodic behavior might be dampened quite fast, however, the limiting state is, due to the damping, such that the probability of finding the target element is still high, 1/3. For \( k \) larger, the approximation does not hold anymore and the angle of rotation \( \theta \) decreases; this in turn increases the running time.

The case of decoupled noise is no less interesting. In this case the limiting state gives success probability of \( 1/(k + 2) \) and thus for small \( k \)'s still provides a quadratic speedup with the number of oracle calls scaling as \( k \sqrt{N} \), unless again as in the previous case the noise is strong and the cosine stays for a long time close to \(-1/2\) (as a combination of slow dampening and extreme slowing down.
of rotation) effectively decreasing the success probability. If, however the noise on the target is small, having $k \lesssim \sqrt{N}$ still allows quadratic speedup via the second non-oscillating term, whose damping is slow.

In both cases a general rule for quadratic speedup seems to be preserved whenever there is no noise on the target (or when it scales as $1/\sqrt{N}$) and when $kp \ll \sqrt{N}$, where $p$ is the noise rate on the normals. The speedup is lost, whenever the inequality is broken. However, from numerics we observed that when the number of noise-affected elements grows like $N^\mu$, the efficiency scaling is roughly like $N^\mu$. This has a consequence for a physically relevant case of a qubit register with one of the qubits decohering ($k = N/2$). In such case our results suggest that any speedup might already be lost unless the noises scale like $1/\sqrt{N}$.

Appendix A: Measuring the speed of the search

When trying to decide how fast a search is (measured in the number of oracle calls), in general the usual approach to wait until the probability hits one may not work as quite commonly, the success probability will be dampened fast enough not to get close to one. After an unsuccessful search one needs to try again, which prolongs the search. In such case one weighs different factors in — the smaller number of oracle calls one makes can lead to smaller success probability (at least right after the start of the search) but, on the other hand, the longer we let the system evolve, the higher contribution to the overall number of oracle calls it has in the end.

A good measure of how an algorithm can search for an element is then the compromise between the two drawbacks — the smallest average (expected) time to find searched item. If the success probability of finding the item in $k$ steps is $p(k)$, then the average number of steps

$$
\sqrt{N}$$
Once one needs to perform is
\[
m_\text{m}(k) = p(k)(k + 1) \sum_{r=1}^{\infty} [1 - p(k)]^{r-1} = \frac{k + 1}{p(k)} \quad \text{(A1)}
\]
where \( r \) counts the repetitions and we also account for an extra oracle call at the end checking whether we have the correct item. In proving this we used
\[
\frac{1}{(1-q)^2} = \frac{d}{dq} \left[ \sum_{k=0}^{\infty} q^k \right] = \sum_{k=1}^{\infty} kq^{k-1}. \quad \text{(A2)}
\]
The optimal number of steps is found in the global minimum of function \( m_\text{m} \), which in particular is easy to find in numerical simulations. To find the optimal number of steps analytically we could look at the maximum of \( m(k) \) when \( m'(k) = 0 \); this would give us condition
\[
k + 1 = \frac{p(k)}{p'(k)}. \quad \text{(A3)}
\]
This is usually hard to compute as it often leads to transcendental equations. However, in our cases when the success probability is given generally as
\[
p_{\text{suc}}(m) = \alpha + \beta(1-b)^m - \gamma(1-c)^m \cos[(2m+1)\theta], \quad \text{(A4)}
\]
\( \alpha, \beta, \gamma \geq 0 \), we can always choose \( m : = m_0 = \pi \sqrt{N}/8 \), which is a point when \( (2m + 1)\theta \) becomes closest to \( \pi/2 \) and the cosine term becomes positive. Thus our success probability is
\[
p_{\text{suc}}(m) \geq \alpha + \beta(1-b)^m. \quad \text{(A5)}
\]
When \( \alpha \) is \( O(1) \) we can immediately use Eq. (A1) to find
\[
m(m) \leq \frac{m + 1}{\alpha} = O(\sqrt{N}). \quad \text{(A6)}
\]
Once \( \alpha \) becomes too small, possibly scaling with \( N \), we reduce our interest to
\[
p_{\text{suc}}(m) \geq \beta(1-b)^m, \quad \text{(A7)}
\]
while we suppose that \( b = p/N^\kappa \) with \( p \in [0,1] \) and \( \kappa \geq 1/2 \). Under these restrictions the function
\[
\left(1 - \frac{p}{N^\kappa}\right)^{\sqrt{N}} \quad \text{(A8)}
\]
is increasing in \( N \) and so
\[
p_{\text{suc}}(m) \geq \beta \left(1 - \frac{p}{4^\kappa}\right)^{\sqrt{N}} \geq \frac{\beta}{3}. \quad \text{(A9)}
\]
Using Eq. (A1) we see that
\[
m(m) \leq \frac{3}{\beta}(m + 1) = O(\sqrt{N}), \quad \text{(A10)}
\]
where the last equality holds for \( \beta = o(1) \).

On the other hand, when we take \( b, p = O(1) \) (and when \( \alpha \) is small), which is the usual form of restriction in our paper, we simply have
\[
m(m) \geq \frac{m + 1}{2\beta(1-p)^{\sqrt{N}}} \geq \frac{m}{2\beta}(1 + \sqrt{Np}) = O(pN). \quad \text{(A11)}
\]
This means, that once \( b \) is large and does not change with \( N \), the search becomes inefficient and the number of oracle calls becomes linear in both \( N \) and \( p \) and the quadratic speedup is lost.
