Objective: Evaluate the relationship between the incidence of different types of degenerative diseases of the spine and lumbo pelvic biomechanics, according to the types of lordosis of Roussouly’s classification. Methods: Retrospective study of medical records and results of imaging exams of patients seen at a private hospital in São Paulo. The sagittal alignment of these patients was evaluated by classifying them according to Roussouly into 4 types, based on panoramic radiographs of the spine. These results were correlated with the patient’s degenerative diagnosis (Herniated disc, Canal stenosis, Spondylolisthesis, degenerative discopathy and Facet arthrosis). Statistical tests were performed comparing the types of curvature and diagnoses identified. Results: 418 patients were evaluated, 51.4% male and 49.6% female. The vast majority of patients, about 54%, had a diagnosis of herniated lumbar disc. There was a statistically significant difference that showed a predilection for surgical treatment in cases classified as Type I and Type II in the Roussouly classification. There was no statistically significant difference that correlated the type of lumbar lordosis with the diagnosis presented by the patients. Conclusion: There is no statistically significant difference that correlates the type of lumbar lordosis according to Roussouly with lumbar degenerative diseases. In contrast, patients classified as Type 1 and Type 2 by Roussouly underwent a greater number of surgical treatments compared to patients type 3 and 4, with statistical relevance. Level of evidence 2; Retrospective prognostic study.

INTRODUCTION

Lumbar arthrodesis is a widely-used surgical technique for treatment of various spinal pathologies, including degenerative diseases, traumas, and deformities. The initial objective of the procedure is to obtain fusion between vertebral segments to promote the reestablishment of stability and alignment lost due to pathologies that affect the spine. Although spinal arthrodesis is often effective in relieving pain and providing some degree of functional recovery, the procedure is not without potential issues. Spinal mobility is an integral component of the activities of daily life and the stiffness associated with arthrodesis can lead to limitations on individual functional capacity. Thus, the lumbar stiffness disability index questionnaire was developed in order to better understand the limitations on activities of daily life resulting from stiffness secondary to lumbar spine arthrodesis.

The objective of the present study was to evaluate the impact of stiffness associated with lumbar arthrodesis on functional capacity and the quality of life in order to gain a better understanding of the functional limitations that arthrodesis at different levels of the lumbar spine can cause.

METHODS

Type of study and population

This is a retrospective study evaluating 40 patients who underwent spinal arthrodesis surgery, including the lumbar segment. The study was approved by the institutional review board (CAAE: 82012017.6.0000.5463) and all patients signed the informed consent form. Patients who underwent spine surgery with arthrodesis, the extent of which included at least one lumbar segment (from L1-L2 to L5-S1), for the treatment of degenerative diseases, traumas, or deformities of the spine, with minimum postoperative follow-up of 24 months were included. Patients whose arthrodesis extended only as far as T12-L1 were not included, since we consider said segment to be the transition between the thoracic and lumbar spines and without the same biomechanics as the lumbar spine.

Patients who had undergone surgical procedures to treat oncologic conditions were excluded because systemic compromise from the disease can interfere with the functional capacity assessment. Patients with other associated orthopedic diseases such as sacroiliitis, coxarthrosis, gonarthrosis, and pseudarthrosis in bones of the lower limb were also excluded. Another exclusion factor was the occurrence of complications associated with the spine surgery, such as loosening of the implants, pseudarthrosis, or adjacent level disease, which were limiting the postoperative functional assessment.

Data collection

All the patients who met the inclusion and exclusion criteria were invited to participate in the study. Those who accepted moved on to the data collection phase. Demographic data, including sex, age, age at the time of surgery, and duration of follow-up, were considered, in addition to information about the surgical procedure, especially the extent of the arthrodesis. The version of the LSDI questionnaire translated and adapted for Brazilian Portuguese was applied to evaluate limitations on the activities of daily life due to stiffness secondary to lumbar spine arthrodesis. The higher the LSDI score, the greater the functional limitation indicated by the patient.

To quantify clinical postoperative lumbar stiffness/mobility, the modified-modified Schöber test (MMST) was administered to the patients. With the patient in orthostatism, the evaluator locates and demarcates the posterior superior iliac spine, also making a corresponding mark in the midline of the spine. Then, a point is drawn 15 centimeters above this caudal mark. Finally, the patient flexes the trunk with the knees in extension and the new distance between the points is calculated. The MMST value is indicated by the difference obtained between the two measurements. The lower the MMST value, the greater the lumbar stiffness.

The statistical analysis was conducted using SPSS v.20 software (IBM Corp., Armonk, NY, USA). The normality of the distribution of the samples was analyzed using the Shapiro-Wilk test. The linear correlation between the LSDI score and the number of arthrodesed levels, as well as between the LSDI score and the MMST measurement, were analyzed using the Spearman rank correlation test.

RESULTS

Sample

Eighteen patients (45%) were male and 22 (55%) were female. The age of the patients ranged from 18 to 79, with a mean of 57.7 years of age (standard deviation [SD]: 16.2). The minimum postoperative follow-up time was 2 years, and the maximum was 19 years (mean 7.5 years, SD: 4.2). The mean body mass index (BMI) of the sample was 28 (SD: 4.6).

Correlation between lumbar stiffness and functional limitation

The mean MMST value was 3.75 cm (SD: 1.5 cm), ranging from 0 to 7 cm. (Table 1) The mean LSDI score was 41.7 (SD: 20.6), ranging from 0 to 75. (Table 1, Figure 1) There was a moderate negative (r = -0.320) but statistically significant (p = 0.04) correlation between the MMST value and the LSDI score. (Figure 2)

Table 1. Total sample modified-modified Schöber test and Lumbar Stiffness Disability Index questionnaire score values.

|                | MMST (cm) | LSDI    |
|----------------|-----------|---------|
| Mean (SD)      | 3.75 (1.5) | 41.7 (20.6) |
| Median         | 4.0       | 42.0    |
| Minimum        | 0         | 0       |
| Maximum        | 7.0       | 75      |

MMST: modified-modified Schöber test; LSDI: Lumbar Stiffness Disability Index questionnaire; SD: standard deviation.

Figure 1. Graph illustrating the distribution of Lumbar Stiffness Disability Index questionnaire scores among the patients of the sample.
Arthrodesis levels and functional limitation

Regarding the levels of the lumbar spine arthrodesis, only one level was involved in most patients (18, 45%) (Table 2). Eleven (27.5%) patients had arthrodesis in two levels, five (12.5%) in three levels, five (12.5%) in four levels, and only one patient (2.5%) with all five lumbar levels involved in the arthrodesis. There was no correlation between the number of levels involved in the lumbar arthrodesis and the LSDI score (p = 0.160).

Influence of the extension of the arthrodesis to the sacrum on functional limitation

In the sample, 22 (55%) of the patients had arthrodesis extending to the sacrum. (Table 3) The mean LSDI score of the patients with extension of arthrodesis to the sacrum was statistically higher than that of patients with arthrodesis that did not extend to the sacrum (p = 0.002), (Table 3, Figure 3) indicating greater functional limitation in those with extension to the sacrum.

DISCUSSION

The present study demonstrates the impact of stiffness secondary to lumbar spine arthrodesis on the limitation of daily activities in 40 patients with a minimum postoperative follow-up of two years. The treatment of various pathological conditions of the spine through solid intervertebral arthrodesis is widely supported in the literature, despite the knowledge that the loss of segmental mobility associated with arthrodesis can impair, at least to some degree, the functional capacity for different activities. However, a relationship is not yet fully established between the number of levels included in the arthrodesis and either the degree of rigidity or the degree of limitation of functional capacity, especially when the inclusion or not of the sacrum in the arthrodesed levels are compared.

Extension of the arthrodesis to the sacrum has always been viewed as a challenge, both because of considerable levels of fusion failure when compared to arthrodesis without extension to the sacrum and due to a fear of limitation of functional capacity resulting from stiffness in the region of the lumbosacral transition. In the present study, the patients with lumbar arthrodesis without extension to the sacrum had significantly better LSDI scores than the patients with the sacrum included in the arthrodesis, i.e., the addition of the sacrum was associated with greater functional limitation related to stiffness.

In a literature review article, Bridwell et al. observed that the extension of the arthrodesis to the sacrum, in addition to increasing the risk of pseudarthrosis, compromised mobility in the lumbosacral junction, which can change the Mechanics of gait due to rigidity of the sacroiliac joints. On the other hand, Edwards et al. observed that the extension of arthrodesis to the sacrum in long fusions did not alter the functional outcome as evaluated by the Scoliosis Research Society-24 questionnaire, as compared to patients with arthrodesis extending to L5.

The LSDI questionnaire was developed to assess the limitation of daily activities specifically related to lumbar spinal stiffness after arthrodesis surgery, in order to facilitate understanding of the impact of arthrodesis. It is an easy to apply and easy to understand tool that has proven to be valid for quantifying functional capacity limitations in these patients. Recently, the LSDI questionnaire was translated into Portuguese and adapted for use in the Brazilian population.

In the present study, it was observed that less lumbar mobility, identified by lower MMST values, was indicative of worse functional capacity in the patients, as represented by higher LSDI scores. This is the first study to show a significant, albeit moderate, correlation between LSDI scores and clinical stiffness identified by the MMST value. Other studies have demonstrated a correlation between the LSDI score and lumbar stiffness evaluated by the range of motion in dynamic lateral radiographs (flexion and extension) of the lumbar spine. However, this examination cannot be considered the gold standard for evaluating lumbar mobility because of technical limitations, such as being dependent on the way it is executed (operator-dependent), in addition to exposure to radiation and the costs involved in performing it.

In terms of the number of lumbar levels included in the arthrodesis, the data from this series showed that the functional capacity as measured by the LSDI had no relationship with the number of levels, i.e., worsening of functional capacity was not proportional to the number of arthrodesed levels. This finding is in line with other published

Figure 2. Comparison of the Lumbar Stiffness Disability Index scores between patients with and without extension of the arthrodesis to the sacrum.

Figure 3. Comparison of the Lumbar Stiffness Disability Index scores between patients with and without extension of the arthrodesis to the sacrum.
CORRELATION BETWEEN DEGENERATIVE DISEASES OF THE LUMBAR SPINE AND TYPES OF LUMBAR LORDOSIS

studies. Gotfryd et al. observed no difference between the quality of life indicators of patients who underwent single-level arthrodesis and those with arthrodesis in two or more levels.19 Hart et al. observed that patients submitted to pan-lumbar arthrodesis, involving all lumbar levels, did not present a worsening of functional capacity related to lumbar stiffness during a minimum of two years of follow-up.20 Limitations can be identified in the present study. As it is a retrospective analysis, the preoperative functional capacity data could not be evaluated. Thus, the statement that lumbar arthrodesis causes functional limitations cannot be made. Although the study included 40 patients, considered a robust number compared to other published series,7 this number would limit more complex analyses considering specific subgroups.

CONCLUSIONS

Functional capacity related to lumbar stiffness, measured by the LSDI score in patients who underwent spinal arthrodesis, was shown to be causally related to clinical lumbar stiffness, measured by the modified-modified Schöber test. Inclusion of the sacrum in the arthrodesis was associated with greater impairment of functional capacity related to lumbar stiffness than arthrodesis without extension to the sacrum.

INTRODUCTION

Low back pain is a significant social and economic problem that leads to the loss of billions of dollars a year worldwide.\(^1\)\(^2\) The etiology is multifactorial, but degenerative changes in the lumbar spine are closely associated with this problem\(^7\) and are frequent causes of a reduction in the quality of life in the active population and especially among the elderly.\(^4\) The most common degenerative lumbar spine conditions involve the degeneration of the intervertebral disc, facet joints, capsule, and vertebral ligaments, which leads to diseases such as disc herniation, spondylolisthesis, and spinal stenosis.\(^5\) Although degenerative conditions are part of the natural progression of aging, it is suspected that in the spine these are related to the load that the vertebrae bear over time. Load distribution in the lumbar region would be directly linked to the anatomy and design of the physiological curves of the spine (lordosis and kyphosis), as well as to the positioning of the pelvis in relation to the vertebral axis.\(^6\)

In 2005, Roussouly et al.\(^7\) created a classification that addresses the normal variation in the sagittal alignment of the human lumbar spine and pelvis in the orthostatic position in order to quantify and classify common variations in the sagittal alignment of the spine, the sacrum, and the pelvis. While developing their classification, Roussouly et al.\(^7\) observed that the types of lordosis could be related to some of the most common degenerative lumbar spine diseases, suggesting that patients with symptomatic disc herniation fit into types 1 and 2 while stenoses were most often seen in cases classified as type 4. Patients classified as type 3 rarely had significant complaints. However, there was no evidence or statistical analysis of this observation. Given this gap in the literature, the objective of this study was to evaluate the relationship between the incidence of the different types of degenerative spine disease and lumbar pelvic biomechanics, according to the types of lordosis as classified by Roussouly and their correlation with the treatment performed in these patients.

METHODS

This study was approved by the Institutional Review Board. A retrospective search was conducted of the medical records of patients treated at a private hospital in the city of São Paulo, during the period from 2012 to 2017, who were diagnosed with degenerative lumbar spine disease and had previously received a surgical indication for this reason, but who did not necessarily undergo surgery. The diagnostic and treatment information of these patients was reviewed and the imaging examinations (radiographs and magnetic resonance imaging of the lumbosacral spine) were analyzed to confirm the lumbar lordosis diagnosis and classification. Extraction of patient imaging examinations was performed from the PACS Platform (Carestream Health, Rochester, New York, USA) at the hospital. The radiographs were imported to Surgimap\(^*\) software (version 2.2.15.1) (Nemaris Inc., Audubon, Pennsylvania, USA) for verification of the angles and classification of the lumbar curvature. They were assigned to one of Roussouly’s four lordosis curve types according to the radiographic analysis of the lumbar spine. These steps will be described in detail later. Magnetic resonance images of the lumbar spine, together with the medical history on record, were used to define the patient’s diagnosis of degeneration. In the presence of two concomitant diseases observed in the magnetic resonance images, the diagnosis of greater clinical severity, which in these patients was the cause of seeking treatment was considered. As such, diagnoses of degenerative discopathy, lumbar disc herniation, spinal canal stenosis, degenerative spondylolisthesis, and facet arthropathy were considered. These data were cross-referenced to correlate the pattern of the curve with the type of lumbar degeneration.

Patients between the ages of 18 and 75 with a diagnosis of degenerative lumbar spine disease who had radiographic and magnetic resonance examinations and complete medical records were included. Patients with prior spine surgery, pediatric spinal deformity, a history of infection or active infection, oncolgic diseases or spinal fracture were excluded from the study. In order to divide the groups by the types of lordosis according to the classification of Roussouly et al.,\(^7\) four types of lordosis were defined below and shown in Figure 1. In type 1 the inflection point (the point where there is a change in the orientation of the vertebral bodies) is L3/L4, sacral inclination is less than 35º, the pelvic incidence is small, and long kyphotic and short lordotic curves are present in an 80:20 ratio of the length of the thoracolumbar spine. In type 2, which has more vertebral bodies, the inflection point is above level L1/L2, sacral inclination is less than 35º, pelvic incidence is small, short kyphotic and long lordotic curves are present. They are in a proportion of 60:40 of the total length of the thoracolumbar spine. In type 3, the inflection point is in T12/L4, the sacral inclination is between 35º and 45º, pelvic incidence is high, and the kyphotic and lordotic curves are almost equal in a ratio of 50:50 of the total length of the thoracolumbar spine, and the spine is balanced. In type 4, the inflection point is in T9/T10, the sacral inclination is greater than 45º, pelvic incidence is high, and the lordotic curve is longer than the kyphotic curve in an inverse ratio of 20:80 of the total length of the thoracolumbar spine.

Magnetic resonances of the lumbar spine were used to define the patients’ diagnoses. Patients were classified as having disc herniation/ degenerative discopathy, spondylolisthesis, spinal canal stenosis, or facet arthropathy. The disc degeneration diagnosis was considered in patients with any degree of degenerative disc changes in the magnetic resonance, without other major changes, complaining of axial pain, especially with trunk flexion. Disc herniation was considered in patients who presented this condition in the magnetic resonance examination, with lumbosciatalgia, paresthesia and/or the loss of strength in the lower limbs. Spinal canal stenosis was considered when viewed in the examination and presenting with neurologic claudication. Degenerative spondylolisthesis was considered in patients with vertebral slippage of any degree in the examination, with possible symptoms of axial or root pain. Facet arthropathy was considered in those patients with joint changes without any other findings in the magnetic resonance and with complaints of axial pain.

**Figure 1.** Types of lumbar lordosis, according to Roussouly.
Two observers conducted the analysis of the radiographic and magnetic resonance images of the patients included in the study to define the diagnosis and classify the type of lordosis. A reliability analysis was conducted between the observers resulting in concordance greater than 90%, which was considered acceptable.

General data, such as age, sex, and treatment received were collected from the medical records and analyzed. For the statistical data analysis, the quantitative variables were described as mean, standard deviation, minimum and maximum values and the qualitative variables as absolute and relative frequencies.

Comparisons between the Roussouly classifications by sex, diagnosis, and type of treatment were verified via the chi-squared test and multinomial logistic regression.

The analyses were conducted using the Statistical Package for the Social Sciences – SPSS, v26.0 software (IBM – Armonk – New York – USA) and the level of significance considered was 5%.

RESULTS

The sample consisted of 418 patients with radiographs and magnetic resonance images of the lumbar spine, 203 of whom were women and 215 of whom were men, the equivalent of 48.6% and 51.4%, respectively.

As regards the Roussouly classification, 47 (11.2%) patients were classified as type 1 lordosis, 159 (38%) as type 2, 168 (40.2%) as type 3, and 44 (10.5%) as type 4.

The type of treatment performed was proportional, with 50% (209) of the sample undergoing surgical treatment and 50% (209) conservative treatment. Diagnoses of the type of degenerative lumbar spine disease were distributed as follows: 23 (5.5%) patients with facet arthritis, 92 (22.7%) with degenerative discopathy, 31 (7.4%) with spondylolisthesis, 41 (9.8%) patients with spinal canal stenosis, 219 (52.4%) disc herniation, and 9 (2.2%) patients with no changes in the imaging examinations. Patient characteristics are presented in Table 1.

One of the study objectives was to check possible associations between the type of lordosis, according to the Roussouly classification, and the sex of the patients, the diagnosis, and the type of treatment performed.

We found no evidence of significant association with sex (p value = 0.632). As for the type of treatment performed, patients with type 1 and type 2 lordosis had a higher predominance of surgical treatment (63.8% vs. 36.2%) and type 3 and type 4 lordosis had a higher predominance of conservative treatment (59.1% vs. 40.9%), as observed in Figure 2, representing a significant difference (p value = 0.008). For the purpose of comparison, we grouped diagnoses of degenerative discopathy and disc herniation together, since they are both considered intervertebral disc diseases, and we disregarded the nine cases of patients with normal examinations. Additionally, due to the low contingency table frequencies, we opted for the likelihood ratio test obtained through the multinomial regression model. However, we found no evidence of significant associations (p value = 0.246). The results are shown in Table 2.

We also compared each of the diagnoses with the Roussouly classifications individually. The comparisons were verified using the chi-squared test and we used the Benjamini-Hochberg correction to control type 1 errors, but none of the comparisons were significant (p value > 0.05). The results are presented in Table 3.

Finally, we compared the patients’ type of treatment and diagnosis and found evidence of significant association (p value < 0.001). For patients with facet arthritis and degenerative discopathy, conservative treatment was the most prevalent at 73.9% and 94.7%, respectively. In patients diagnosed with spondylolisthesis, canal stenosis, and disc herniations, surgical treatment was more prevalent, at 64.5%, 58.5%, and 70.3%, respectively. The results are presented in Table 4.

DISCUSSION

Around 50-70% of the population will experience low back pain symptoms for various reasons at least once in their life. One of the factors that leads to low back pain is degenerative changes that are more common with the increasing life expectancy of the population. In 2005, Roussouly et al. proposed a system to classify types of lumbar lordosis and demonstrated that most asymptomatic individuals were classified as type 3, as was observed in symptomatic individuals in our study. They hypothesized that different types of lordosis could be related to certain pathologies, for example, that patients with type 1 and 2 were liable to present disc herniation. In the present study, no statistically significant result was obtained to confirm this hypothesis.

In 2017, Roussouly conducted a new study of the types of lumbar lordosis, but for patients with degenerative changes, in addition to the 4 already established types, he included type 3 anteverted and type 4 anteverted, which present the same characteristics as the original

2. Likelihood ratio test.
Most patients with canal stenosis, spondylolisthesis, and disc degeneration were classified statistically significant results. These patients normally have reduced lumbar pelvic incidence and inclination values who tend towards greater pathologies, as in patients with low sacral inclination and increased pressure on the anterior spine, i.e., on the intervertebral disc leading to flat back syndrome, which we can assume causes increased load and early degeneration.

Regarding the type of treatment in these individuals, we confirmed a statistically significant result in which individuals classified as type 1 and type 2 had a propensity for surgical treatment and type 3 and type 4 for conservative treatment. A comparison of types of treatment and diagnoses yielded statistical significance. Most patients with canal stenosis, spondylolisthesis, and disc herniation underwent surgical treatment, while most patients with facet arthrosis and degenerative discopathy received conservative treatment, in agreement with Lindsey T,14 who in 2020 demonstrated that conservative treatment of facet arthrosis and degenerative discopathy should be the initial treatment for patients with low back pain.

The retrospective design of the study itself is one of its limitations. There are others, such as the distribution of the patients into groups where there was a much higher number of individuals with disc herniation than those with other diagnoses. Also, patients were included in the study who had previously been indicated for surgery at another institution, creating a much higher possibility of a real surgical outcome.

Understanding the etiology of lumbar spine degeneration and diseases is of utmost importance in today’s world, as these diagnoses contribute to high healthcare costs and a decrease in the productivity of the population. Given the study limitations presented, it was not possible to confirm a relationship between patient diagnosis and lumbar lordosis type. A study with a greater number of individuals is essential such that, if there were a statistically significant difference in the relationship between the diagnosis and the lumbar curvature, specific preventative methods could be established for each type of population to prevent spine diseases.

CONCLUSIONS

We can conclude that the patients classified as Roussouly type 1 and type 2 underwent surgical treatment in higher numbers than type 3 and type 4 patients. We did not observe any statistical correlation between the type of lumbar lordosis and the type of diagnosis presented.
