INTRODUCTION

The Coronavirus (COVID-19) is a pandemic, which was generally evolved in Wuhan, China. The initial case was presented as pneumonia which eventually turned into a severe acute respiratory syndrome (SARS-CoV). The diagnosis of COVID 19 at the early stages is necessary to prevent the virus from dispersing from one person to another. It usually has four stages, namely imported cases, local transmission, community transmission, epidemic. Although this pandemic has reached stage four, hence early detection and appropriate treatment become mandatory.

The name Coronavirinae (CoVs) is derived from a Latin word corona means crown. The family Coronaviridae has a sub-family CoVs. These are further divided into four genera, namely alphacoronavirus, betacoronavirus, gamma coronavirus, and delta coronavirus. These zoonotic viruses that are regularly transmitted from animal species to humans.¹ Among this alpha- or the beta- CoV is known to cause the disease among humans. The seven types of CoVs ² known to infect humans are illustrated in Figure 1.

Figure 1: Types of Coronavirinae (CoVs).

The crown-shaped COVID-19 has an approximate diameter between 6 and 140 nm and is capped by 9 to 12 nm lengthened typical spikes.³ The virus is known to enter the human cell and binds with the angiotensin-converting enzyme (ACE) 2 protein. This protein is usually found to be present in the epithelial cells of the lungs and other tissues. Patients with diabetes mellitus and hypertension are found to have increased expression of ACE-2 protein.⁴

Transmission of the virus as postulated can be through contaminated dry surfaces or self-inoculation of mucous membranes of the nose, eyes, or mouth.⁵ The survival of viruses in the environment depends upon the temperature, nature of the surface, and relative humidity. It can survive more than...
24 hours on cardboard and multiple days on plastic and other surfaces. In today’s scenario, research in the field of coronavirus is at a higher pace. There are various methods to detect COVID 19 which majorly includes risk stratification, radiological techniques, however, there are many asymptomatic individuals.

This study aims to understand the ocular symptoms of COVID 19 amidst the eye professionals and propose the ocular manifestation in the retina as the pandemic’s growth occurs. Initially, this new disease was reported by an ophthalmologist who observed various ocular secretions resulting in conjunctivitis or conjunctival congestion in such patients. The need for face-to-face proximity to examine the COVID-19 patient through slit lamps and ophthalmoscope may increase the chances of spreading the disease among eye care professionals or ophthalmologists. Several safety measures for ophthalmologists are taken to prevent transmission. As per the report, installing a protective shield on slit lamps was implemented to prevent transmitting the disease along with a surgical mask.

There are various preventive measures for ophthalmologists that should be taken care of during diagnosing such patients. The precautions include patient isolation, sanitization, wearing a mask, gloves, goggles, shield, gowns, silence, fast track, outdoor clothes, etc. However, the correlation of COVID 19 with any of the ocular manifestations is still in its onset, to uncover the disease’s suspicion. In this paper, the ocular manifestations and corona virus-induced retinal changes are being reviewed.

**CLINICAL SIGNS AND SYMPTOMS**

The nature of COVID 19 patients can be symptomatic as well as asymptomatic. The various features observed in symptomatic COVID 19 patients can be respiratory or marginal. The common respiratory features include fever, headache, diarrhea, fatigue, cough, sputum production, and myalgia. The marginal symptoms include gastrointestinal inflammation, ocular congestion, skin rashes, headache, and loss of taste or smell, whereas shortness of breath, chest pain, loss of speech or movement are some of the serious symptoms. Although there are various symptoms for the detection of COVID-19, the precise diagnosis of the disease is still elusive.

**OCULAR TRANSMISSION AND PATHOGENESIS**

The only source of transmission of the disease through the eyes is the tears, therefore it is alarming for ophthalmologists to diagnose COVID 19 in the eyes as well. However, the researchers explain its transmission and pathogenesis through ACE 2 protein as well. The presence of ACE-2 is also seen in the anterior segment of the eye, which is similar to receptors of avian influenza species and the human influenza virus. These are extensively present in the corneal and conjunctival epithelium, similar to the nasal and tracheal mucosal lining. Hence it can be proposed that the transmission of this virus can occur through the tears in the ocular surface to the nasal cavity and tracheal tissues. However, the tears get renewed constantly by the lacrimal glands in the eye, and it can be speculated that the virus enters the tears in the form of droplets, which might be then transferred to the nasal and tracheal tissues.

Choudhary et al. in 2017 postulated that the ACE-2 protein is majorly expressed in the posterior segment of the eye and can be commonly seen in the retinal pigment epithelium. A few studies suggest that COVID-19 is proficient in producing a wide spectrum of ocular manifestations including sight-threatening conditions such as retinitis and optic neuritis. The virus may develop in-vivo mutations that can transform the manifestations of the disease. At present, there is limited literature supporting the COVID-19 infection through ACE-2 and its adverse effects in the eye. As this pandemic continues, a better understanding of the virus is required to understand its pathogenesis in the eye.

**OCULAR MANIFESTATIONS OF COVID 19**

Studies report that 30%-40% of the patients presenting with positive COVID-19 manifest ocular findings which are consistent with conjunctivitis. This may also be accompanied by other ocular symptoms such as epiphora, conjunctival chemosis, and anterior uveitis. The potential sources of transmission are the mucous membrane of the eye. According to a recent update by the American Academy of Ophthalmologists (AAO), conjunctivitis can be one of the symptoms in patients having this disease. If left untreated, it can result in keratoconjunctivitis and ultimately lead to severe blindness. Studies suggested the presence of the virus on the ocular mucosa is 35% of the eye CoVs and 10% of the associated conjunctivitis cases. Tears contact may thus rapidly lead to the spread of the virus which is a contradictory.

**Can COVID-19 affect the Retina?**

The COVID-19 pandemic has a massive impact on the human biological system, the associated coronaviridae decreases the cell-mediated immunity and makes the person highly susceptible to opportunistic viral ocular infections as well. Retinal findings in COVID 19 patients are still a mystery. It can be hypothesized that the pathogenesis of conjunctival and retinal microvasculopathy is perhaps similar and might involve increased plasma viscosity, circulating immune centers, and
infectious injury of the vasculature. In the existing literature, there are many groups of viruses which have significant retinal manifestations such as the Paramyxoviridae family, Picornaviridae family and Herpesviridae family.

Typically, the major group of viral ocular manifestations includes: opportunistic infections, neoplasms, microvascularopathy, and neuro-ophthalmic disorders. However, if we understand the ocular manifestations by the more common RNA viruses which are known to cause a sequel of retinal changes and more commonly the retinitis. Komurasaki et al. reported the presence of vasculitis in the mice with the COVID 19.

The taxonomically diverse group of viruses may affect the eye as primary infection or reactivation. A recently published research by Marinha et.al. where eleven patients diagnosed with COVID -19. These patients were known to show hyper-reflective lesions at the ganglion cell and inner plexiform layers levels. It has been shown more prominently at the papillomacular bundle in both eyes. Hence it becomes potent to undergo a retinal exam for each symptomatic or asymptomatic patient with COVID-19. The associated reduction in the cell arbitrated immunity makes the individual highly vulnerable to opportunistic viral ocular infections. This can be further explored by the speedily developing field of molecular diagnostics.

**PERSEPTIVES**

The ocular diagnosis among COVID 19 patients is still in its infancy. The clinical diagnosis of the COVID 19 is done by assessing the body temperature, blood tests and RT PCR (reverse transcriptase-polymerase chain reaction) investigations. However, these diagnoses there still exist at risk and increase in the rate of transmission of the coronavirus.

There are many innovative kinds of research going on across the globe to cure this pandemic. As eye care professionals the knowledge and management strategies should be kept ready. A routine eye examination should be kept mandatory among such patients. The anterior segment evaluation with a slit lamp and a retinal eye exam using appropriate personal protective equipment is should be recommended. It can also be planned systematically to maintain proximity from patients and not to loosen up on the necessary investigations. Other than direct ophthalmoscopes, there are various other available tools that are quick in detecting the retinal findings and help to maintain proximity from the patient. Fundus imaging and the Optical Coherence Tomography (OCT) are a few procedures that can be done in a few clicks and are also non-contact. However, fundus fluorescence angiography (FFA) and indocyanine green (ICG) is the vasculature imaging techniques recommended if there are any signs of leakage in a fundus image or OCT.

Fundus images can capture the interior of the eye and remain an important imaging tool. This can be effectively achieved by digital fundus photography as well as confocal scanning laser ophthalmoscopy (cSLO). A fundus camera captures a definite one image of the fundus, on the other hand, cSLO uses a pinhole aperture through which laser light is projected and isolates only a single wavelength to capture an image. This may add false color to the images hence fundus photography through a camera captures the true color of the image. On the other hand, OCT has quickly become a mainstay for eye care professionals. OCT techniques are based on the principle of interferometry and are available in two different domains, namely, time-domain OCTs (TD-OCT), spectral-domain OCTs (SD-OCT), and recently developed frequency-domain OCTs (FD-OCT). Each of these domains is superior and differs from its predecessor in the net result as an enhancement in the resolution of images and wavelength-swept laser sources. Fundus imaging is a deep ocean for the eye care industry and innovation happens every now and then. There are various modalities and alternative techniques used for the diagnosis of retinal diseases and these have become a crucial part of an eye exam in today’s pandemic scenario.

**CONCLUSION**

Although existing knowledge about COVID-19 is rapidly growing. Evidence shows its transmission through tears; however, its risk may be truncated. This paper gives an insight into the ocular findings due to coronavirus. Also, it is proposed that retinal images may guide ophthalmologist to understand its effect on the retina. Imaging considering the anterior and posterior segment complications is possible, but the pathophysiology still remains unclear. This can be understood by extensive clinical research among COVID 19 patients. Further, these images along with artificial intelligence can provide a basis to automate the diagnosis of COVID 19. Eye care professionals should pool in resources and work together to understand these ocular manifestations and address the current pandemic in a scientific manner.
