Using ultracold alkaline-earth atoms in optical lattices, we construct a quantum simulator for \( U(N) \) and \( SU(N) \) lattice gauge theories with fermionic matter based on quantum link models. These systems share qualitative features with QCD, including chiral symmetry breaking and restoration at non-zero temperature or baryon density. Unlike classical simulations, a quantum simulator does not suffer from sign problems and can address the corresponding chiral dynamics in real time.

Introduction. Non-Abelian gauge fields play a central role in the dynamics of the Standard Model of particle physics. In particular, the strong \( SU(3) \) gauge interactions between quarks and gluons in Quantum Chromodynamics (QCD) give rise to the spontaneous breakdown of the chiral symmetry of the light quarks. Heavy-ion collisions produce a high-temperature quark-gluon plasma in which chiral symmetry is restored. The deep interior of neutron stars contains high-density nuclear matter or even quark matter, which may be a baryonic superfluid or a color superconductor \([1]\). Unfortunately, due to severe sign problems, the real-time evolution of heavy-ion collisions or the phase structure of dense QCD matter is inaccessible to first principles classical simulation methods. In condensed matter physics strongly coupled gauge theories play a prominent role in strongly correlated systems. In particular, the non-Abelian \( SU(2) \) variant of quantum spin liquids has long been debated as a possible connection between the doped Mott insulator and the high-\( T_c \) superconducting phase in cuprates \([2]\). The challenge of solving such problems motivates the development of quantum simulators for non-Abelian lattice gauge theories. Recently, quantum simulators have been constructed for Abelian \( U(1) \) gauge theories with \([3,4]\) and without coupling to matter fields \([5,7]\). Here, we construct a quantum simulator of \( U(N) \) and \( SU(N) \) strongly coupled lattice gauge theories in \((1+1)\), \((2+1)\), and \((3+1)D\) using ultracold alkaline-earth (AE) atoms in an optical lattice. On the one hand, our approach is based on quantum link models (QLMs) \([8,10]\), which allow the exact embodiment of non-Abelian gauge interactions in ultracold matter. On the other hand, we utilize fundamental symmetries of matter, such as the \( SU(2N+1) \) invariance of interactions between fermionic AE isotopes such as \(^{87}\)Sr or \(^{173}\)Yb \([11,20]\). While still being far from a quantum simulator for full QCD, simpler model systems share several qualitative features, including confinement, chiral symmetry breaking (\(\chi\)SB), and its restoration (\(\chi\)SR) \([1]\). They provide a unique environment to investigate important dynamical questions which are out of reach for classical simulation.

The non-perturbative physics of non-Abelian gauge theories is traditionally addressed in the context of Wilson’s lattice gauge theory \([21]\), in which the gluon field is represented by parallel transporter matrices residing on the links connecting neighboring lattice points of a 4D space-time lattice. Since Wilson’s classical link variables take values in the continuous gauge group \(SU(N)\), the corresponding Hilbert space is infinite-dimensional even for a single link. The elements of a quantum link matrix are non-commuting operators, similar to the components of a quantum spin. As a result, QLMs have a finite-dimensional Hilbert space, and therefore provide an attractive framework for the construction of quantum simulators for dynamical Abelian and non-Abelian gauge theories. In the continuum limit of QLMs, which is naturally realized via dimensional reduction, one recovers QCD with chiral quarks as domain wall fermions.
while operators associated with different links commute. The resulting Hilbert space per link is then unavoidably infinite-dimensional. In order to represent the commutation relations of the gauge algebra of Eq. (2) in a finite-dimensional Hilbert space, QLMs give up the commutativity of the matrix elements $U^{ij}$ without compromising gauge invariance. The real and imaginary parts of the matrix elements $U^{ij}$ of the $N \times N$ quantum link matrix are represented by $2N^2$ Hermitian operators. Together with the electric field operators $L^a, R^a,$ and $E$ these are $2N^2 + 2(N^2 - 1) + 1 = (2N)^2 - 1$ generators which form the embedding algebra $SU(2N)$. While $U(1)$ quantum links can be represented by quantum spins embedded in an $SU(2)$ algebra, $U(N)$ or $SU(N)$ QLMs can be realized with different representations of $SU(2N)$. A useful representation is based on fermionic rishon constituents.

The hopping of a quark, which exchanges color with the gluon field, is then described by $\psi^\dagger_x U_{xy} \psi_y = \psi^\dagger_x \psi_y U^{ij}$. This term is invariant against gauge transformations, $\Omega \psi_x^\dagger = \Omega_x \psi_x^\dagger \Omega^\dagger = \Omega_x \Omega_y \psi_{xy}$ with $\Omega_x \in U(N)$. The $SU(N)$ gauge transformations and the additional $U(1)$ gauge transformation contained in $U(N)$ are generated by

$$G^a = \psi^\dagger_x \lambda^a \psi_x + \sum_k \left( L^a_{x,x+k} + R^a_{x,x-k} \right),$$

$$G_x = \psi^\dagger_x \psi_x - \sum_k \left( E_{x,x+k} - E_{x,x-k} \right),$$

where $\lambda^a (a \in \{1, 2, \ldots, N^2 - 1\})$ are the $SU(N)$ Gell-Mann matrices, and $f_{abc}$ are the $SU(N)$ structure constants, such that $[G^a_x, G^b_y] = 2i\delta_{xy} f_{abc} G^c_x$. The operators $L^a_{xy}$ and $R^a_{xy}$ represent $SU(N)$ electric field operators associated with the left and right end of a link $\langle xy \rangle$, while $E_{xy}$ represents the Abelian $U(1)$ electric field operator. Physical states $|\Psi\rangle$ obey the $SU(N)$ Gauss law $G^a_x |\Psi\rangle = 0$, while in a $U(N)$ gauge theory also $G_x |\Psi\rangle = 0$. The operators $L^a, R^a, E$, and $A$ associated with the same link obey

$$[L^a, L^b] = 2i f_{abc} L^c, \quad [R^a, R^b] = 2i f_{abc} R^c,$$

$$[L^a, R^b] = [E, L^a] = [E, R^a] = 0,$$

$$[L^a, U] = -\lambda^a U, \quad [R^a, U] = U \lambda^a, \quad [E, U] = U,$$

where $\lambda^a$ and $\lambda^a \pm k \pm l, \Omega \psi_x^\dagger \psi_y$ form a site-based $U(2d + 1)$ algebra. The rishon number is conserved locally on each link. The $U(N)$ model has no baryons, since the $U(1)$ baryon number symmetry is gauged. In order to obtain charge conjugation invariance $C$ and to reduce the gauge symmetry to $SU(N)$, one must work with $N_{xy} = N$ risbons per link. Adding the term $\sum_{\langle xy \rangle} (\text{det} U_{xy} + \text{h.c.})$ to the Hamiltonian, explicitly breaks the $U(N)$ gauge symmetry down to a local $SU(N)$ and a global $U(1)$ baryon number symmetry generated by $B = \sum_x \left( \psi^\dagger_x \psi_x - N \right) / 2$. The symmetries of various model systems are summarized in Table 1. All models have a $Z(2)$ chiral symmetry, which is
TABLE I. Symmetries and phenomena in some QLMs.

| dimension | group | C flavor | baryon | phenomena |
|-----------|-------|----------|--------|-----------|
| (1+1)D   | U(2)  | 1 no     | no     | no        |
| (2+1)D   | U(2)  | 2 yes    | Z(2)   | no        |
|          | SU(2) | 2 yes    | Z(2)   | U(1) boson |
|          | SU(3) | 3 yes    | Z(2)^2 | U(1) fermion |

spontaneously broken at a critical temperature T_c, and may get restored at non-zero baryon density n_B. It would be natural to add electric and magnetic field energy terms \( \frac{g^2}{2} \sum_{\langle xy \rangle} (L_{xy}^a I_{xy}^a + R_{xy}^a R_{xy}^a) \), \( \frac{g^2}{2} \sum_{\langle xy \rangle} E_{xy}^2 \), and \( \frac{1}{4g^2} \sum_{\langle wxyz \rangle} (U_{wx} U_{xy} U_{yz} U_{zw} + \text{h.c.}) \), where \( \langle wxyz \rangle \) denotes an elementary plaquette with \( g^2 \) and \( g^2 \) as the coupling constants. At strong coupling these terms are inessential for qualitative features of the dynamics at finite temperature or baryon density, and are thus not yet included in our implementation.

Atomic quantum simulation of \( U(N) \) QLMs. An illustration of the QLM and its rishon representation for \((1+1)D \) and \((2+1)D \) is provided in Fig.1a. Quark fields \( \psi_x^i \) reside on the lattice sites \( x \), while the rishons \( c_{x,\pm k}^i \) are on “link-sites” \( (x, \pm k) \) at the left (right) end of the links exiting (entering) the point \( x \) (c.f. Fig.1a, lower panel). The key step in our physical implementation is to interpret the lattice with quark and rishon sites in Fig.1a, b as a physical optical lattice for fermionic atoms. Hence, an atom on site \( x \) of the optical lattice represents a quark \( \psi_x^i \), while hopping of this atom to a link-site \( (x, \pm k) \) converts it to a rishon \( c_{x,\pm k}^i \). The color index \( i \) is encoded in internal atomic states.

The basic building blocks in our atomic setup are the tunnel-coupled triple-wells in \((1+1)D \) (Fig.1a) or the cross-shaped vertices in \((2+1)D \) (Fig.1b). The corresponding hopping dynamics of the atoms is described by the Hamiltonian \( h_{x,k} = i (s_x Q_{x,k} + Q_{x,-k} + \text{h.c.}) \). Physically, the overlap of the Wannier wave functions can be used to implement the usual tunneling [23]. In case different phases are needed to simulate staggered fermions in the lattice, Raman assisted tunneling [24] or shaken optical lattices [26, 27] can be applied. In order to obtain the desired quark-rishon dynamics, we introduce the microscopic atomic Hamiltonian

\[
\tilde{H} = U \sum_{\langle xy \rangle} (N_{xy} - n)^2 + \sum_x h_{x,k} + m \sum_x s_x M_x. \quad (5)
\]

The second term represents atomic hopping, while the last term realizes the staggered fermion mass with a superlattice. In second order perturbation theory in the tunnel-coupling, the above Hamiltonian induces the hopping term of Eq.(7) with \( t = t'/2 \). Fig.2a illustrates the matter-gauge interaction. We note that an additional term \( t \sum_{x,\pm k} Q_{x,\pm k} Q_{x,\pm k} \) is also generated. This is no problem, because this term is invariant under all relevant symmetries. It is also possible to add a 4-fermion term \( V \sum_i M_i^2 \).

With the Hamiltonian of Eq.(5) we have reduced the realization of \( U(N) \) QLMs to a lattice dynamics of interacting fermions. This is enabled by the factorization of the quantum link variables into rishons. We emphasize that the building blocks in \( \tilde{H} \) are gauge invariant “meson” and “constituent quark” operators, which allows a gauge invariant implementation of the dynamics. This is in contrast to previous work, where Gauss’ law was enforced by an energy constraint in the microscopic dynamics. The essential symmetries of \( \tilde{H} \) to be respected by the implementation are: (i) the color-independent hopping of fermions and rishons, and (ii) the color-independent interaction between rishons to ensure the local particle number conservation on each link. Indeed these symmetries are accurately respected in setups with AE atoms [11, 13, 20].

For a given nuclear spin \( I \), the electronic ground state \( ^1S_0 \) of fermionic AE atoms has \( 2I + 1 \) Zeeman levels \( m_I = -I, \ldots, +I \). We encode the color degrees of freedom for the even (odd) building blocks (triple-wells in \((1+1)D \) and cross-shaped vertices in \((2+1)D \)) represented by the light (dark) shading in Fig.1a in the \( N \) lowest (highest) \( m_I \) levels (c.f. Fig.1a). For example, to implement a \( U(2) \) QLM, we choose positive nuclear spin states \( m_I = 3/2, 1/2 \) on the even and negative nuclear spin states \( m_I = -3/2, -1/2 \) on the odd building blocks. The AE atoms have the unique property that their scattering is almost exactly \( SU(2I + 1) \)-symmetric, i.e., all pairs of states have the same scattering length [11, 13, 20]. This guarantees the symmetry of the \( U \) term in Eq.(6). The \( m_I \)-dependent hopping illustrated in Fig.1a can be realized in optical lattices with an appropriate choice of laser frequencies and polarizations [23, 29], or with optical potentials obtained by holographic techniques [30, 31]. Finally, the repulsion \( U \), which only affects the rishon- but not the quark-sites, can be realized with optical Feshbach resonances of AE atoms allowing spatially dependent on-site interactions [32, 33]. An alternative setup uses \( m_I \)-dependent optical lattices with overlapping sites for the interacting, and spatially separated sites for the non-interacting fermions (c.f. Fig.1a).
overlapping rishon-sites. As indicated in Fig. 2 a) we assume in our AE setup partially overlapping rishon-sites implying a different overlap of the Wannier functions. This generates a repulsive interaction energy, which differs by \(\Delta U\) between rishons on the same and on different link-sites, thus breaking the \(SU(2I + 1)\) symmetry. The two-particle transfer is now implemented as a Raman process with a Rabi frequency \(\Omega\) and some large de-tuning \(\delta\), so that single particle transitions are strongly suppressed, while a two-particle transfer can be an energy conserving process enabled by energy exchange between the atoms (see also Ref. [39]). The resulting coefficient of the \(\text{det}U_{xy}\) term is \(\gamma = 2\Omega^2\Delta U/\delta^2\), which should be larger than the typical temperature scale in cold atoms experiments.

Initial conditions and loading the optical lattice. We now discuss how to load the lattice with the gauge invariant state illustrated in Fig. 1. This state has local color-singlet pairs of atoms on alternating quark and rishon sites. It is an eigenstate of the Hamiltonian

\[
H_{\text{strong}} = m \sum_x s_x \psi_x^\dagger \psi_x^+ + \gamma \sum_{(xy)} (\text{det}U_{xy} + \text{h.c.}),
\]

which is induced by \(\bar{H}\) in the limit \(U \rightarrow \infty\). The \(\text{det}U_{xy}\) term favors the state \(|\uparrow\downarrow,0\rangle - |0,\uparrow\downarrow\rangle\) where \(|\uparrow\downarrow,0\rangle = e_{x,y}^\dagger c_{x,y}^\dagger |0,0\rangle\) and \(|0,\uparrow\downarrow\rangle = e_{x,y} c_{x,y}^\dagger |0,0\rangle\). The preparation of the initial state requires to adiabatically ramp up the optical lattice on an ultracold cloud of atoms which are internally in a 50% mixture of the states \(m_I = 3/2,1/2\). This leads to a band insulator with two atoms of positive nuclear spin on the dark-shaded sites in Fig. 1. Then, an on-site Raman two-body process will generate the desired state of Fig. 1 after a coherent transfer of the rishon population from the dark- to the light-shaded rishon-sites.

Imperfections and quality of gauge invariance. The emergence of gauge symmetry from the microscopic model of Eq. 5 and the effect of imperfections have been addressed on small system sizes by means of exact diagonalization in the \(U(2)\) case with \(N_{xy} = 2\). The \(U(1)\) symmetry generated by \(G_x\) has been verified by checking the condition \(\langle N_{xy} \rangle = 2 + \Delta_{\text{link}}(U/t,\ell/t)\), where \(\Delta_{\text{link}}\) has to be small in order to ensure gauge invariance. As in Ref. [3], we found that a relatively small \(U\) is sufficient to accurately realize gauge invariance [7? ]. The \(SU(2)\) gauge symmetry, on the other hand, is potentially vulnerable to imperfections in the engineering of the tunneling rate. Fortunately, symmetric interactions emerge naturally thanks to the fundamental \(SU(2I + 1)\) symmetry of AE atoms. Since the number of fermions per basic building block (including sites of the same shading in Fig. 1) is conserved in the experiment up to exponentially small long-range tunneling processes, \(G_x^2\) automatically commutes with \(\bar{H}\). One still needs to check whether the expectation values of the operators \(\langle G_x^2 \rangle^2, \langle G_y^2 \rangle^2\) vanish in the ground state. We have verified this numerically on up to 12 fermions (4 quark- and 8 rishon-sites) by introducing an imperfect color-dependent hopping rate \(\bar{\ell}_1 = (1-z)\bar{\ell}_2\). We observe that gauge invariance is very well preserved even for \(z \approx 0.1\) [7? ]. Moreover, we emphasize that the low-energy properties of the system are expected to be robust even in the presence of small gauge variant terms (see for instance [10]).

Exact diagonalization results. We have performed exact diagonalization studies of the \((1 + 1)D\) \(U(2)\) model with \(N = 1\) rishon per link. Figure 3a shows the splitting between two almost degenerate vacuum states, which decreases exponentially with the system size \(L\), thus indicating \(\mathbb{Z}(2)\) chSB. Figure 3b shows the real-time evolution of the chiral order parameter profile \(\langle \bar{\psi}\psi \rangle_x = s_x (\psi_x^\dagger \psi_x^+ - N/2)\), starting from an initial chirally restored “fireball” embedded in the chirally broken vacuum. This dynamics can be observed by initializing the system in a product state of Mott double wells, and subsequently lower the lattice potential. This mimics the expanding quark-gluon plasma generated in a heavy-ion collision, and can be probed in an experimental setup by just monitoring the time-dependence of the particle density, similarly to Ref. [11].

Conclusions. We have proposed an implementation of...
a quantum simulator for non-Abelian $U(N)$ and $SU(N)$
gequation theories for staggered fermions with ultracold
atoms. The proposal builds on the unique properties
of quantum link models with rishons representing the
gauge fields: this allows a formulation in terms of a
Fermi-Hubbard model, which can be realized with multi-
component alkaline-earth atoms in optical lattices, and
where atomic physics provides both the control fields and
measurement tools for studying the equilibrium and non-
equilibrium dynamics and spectroscopy. Extending such
investigations towards QCD requires the incorporation
of multi-component Dirac fermions with the appropriate
chiral symmetries, and of additional link and plaquette
terms for electric and magnetic field energies [42].

SUPPLEMENTARY MATERIAL I: \(U(N)\) AND \(SU(N)\) QUANTUM LINK MODELS WITH STAGGERED FERMIONS

Introduction

Non-Abelian gauge fields are the key to understanding the weak and strong interactions between leptons and quarks, mediated by W- or Z-bosons and gluons, respectively. The strong interactions are described by Quantum Chromodynamics (QCD), the relativistic quantum field theory of quarks and gluons with an \(SU(3)\) non-Abelian gauge symmetry. Due to asymptotic freedom, at very high energies quarks and gluons interact only weakly. At low energies, on the other hand, they interact so strongly that they do not appear as physical states in the spectrum. Instead quarks and gluons are permanently bound together and thus confined inside hadrons. Protons and neutrons mostly contain up and down quarks as well as gluons, while the heavier strange quarks are more suppressed. Since the mass difference between up and down quarks is small compared to the intrinsic energy scale of QCD, there is an approximate isospin flavor symmetry \(SU(2)_F\). Protons and neutrons form an isospin \(SU(2)_F\) doublet. In addition, the number of quarks is conserved which gives rise to a \(U(1)_B\) baryon number symmetry. There are different categories of hadrons. States with a non-vanishing baryon number, i.e. with a different number of quarks and anti-quarks, are known as baryons. In a simple-minded quark model, protons and neutrons are baryons consisting of three quarks of different \(SU(3)\) colors, while mesons are quark-anti-quark pairs. The lightest mesons of QCD are the three pions \(\pi^+, \pi^0, \text{and} \pi^-\), which form an isospin \(SU(2)_F\) triplet. The pions are the pseudo-Nambu-Goldstone bosons of the approximate \(SU(2)_L \times SU(2)_R\) chiral symmetry of two flavor QCD, which gets spontaneously broken down to the isospin symmetry \(SU(2)_F\) by the strong gauge interactions. Flavor singlet states with baryon number zero may be dominated by gluons and are then denoted as glueballs.

Since quarks and gluons are confined inside hadrons (i.e. baryons, mesons, or glueballs) their low-energy dynamics cannot be studied in perturbation theory. In order to define QCD beyond perturbation theory, Wilson has regularized the theory on a 4-dimensional space-time lattice \([21]\). The quark fields then reside on the lattice points, while the gluon fields are naturally associated with the links connecting neighboring points. In lattice QCD the gluon field is represented by \(SU(3)\) matrices, which act as parallel transporters. Due to its non-perturbative nature and great complexity, lattice QCD requires large-scale Monte Carlo simulations. In this way, during the past decade very impressive progress has been made in determining the hadron spectrum as well as numerous static properties of hadrons. Also the nature of the transition that separates the low-temperature chirally broken phase from the quark-gluon plasma at high temperatures has been understood in some detail. However, despite of these successes, there are also important problems in QCD that cannot be addressed with Monte Carlo methods. Such problems include QCD at large baryon density, which is relevant in nuclear and astrophysics, in particular, for understanding the state of matter inside neutron stars, as well as all problems concerning the real-time dynamics of strongly interacting matter, in particular, heavy-ion collisions. In these cases, severe sign problems prevent importance sampling which renders the Monte Carlo method inapplicable.

Similar problems arise in strongly correlated systems in condensed matter physics. In recent years, several such systems have been emulated with ultra-cold matter in optical lattices, thus realizing an analog quantum simulator. Since these systems realize quantum dynamics in their hardware, they do not suffer from the sign problem, and are thus ideally suited for investigating real-time dynamics. Recently, quantum simulator constructions have been proposed for Abelian \(U(1)\) gauge theories with and without fermionic matter. Some of these constructions take advantage of the quantum link formulation of lattice gauge theory, which has a finite-dimensional Hilbert space per link. In Wilson’s formulation, on the other hand, the Hilbert space is infinite-dimensional, and thus much harder to realize in ultra-cold matter. A non-Abelian quantum link model with gauge group \(SU(2)\) has been formulated in \([8,10]\). Subsequently, in \([22]\), quantum link models have been constructed for the non-Abelian gauge groups \(SU(N), U(N), SO(N),\) and \(Sp(N)\), as well as for the exceptional group \(G(2)\). In particular, lattice QCD has been formulated as an \(SU(3)\) quantum link model \([22]\). In order to reach the continuum limit, the model is formulated with an additional dimension of finite extent, which ultimately disappears via dimensional reduction. In this framework, quarks with a chiral symmetry emerge naturally as domain wall fermions. While it may take a long time until a quantum simulator will be realized for quantum link QCD in the continuum limit, it is timely to investigate simpler non-Abelian gauge theories in order to address non-perturbative questions that are inaccessible to classical simulation.

In this paper, we construct quantum simulators for \(U(N)\) and \(SU(N)\) lattice gauge theories in \((1 + 1)\) and \((2 + 1)\) space-time dimensions coupled to staggered fermions with a \(\mathbb{Z}(2)\) chiral symmetry. Being discrete, this chiral symmetry can break spontaneously in just one spatial dimension, at least at zero temperature. In two spatial dimensions it can break spontaneously even at finite temperature. In \((2 + 1)\) dimensions, staggered fermions have an additional discrete \(\mathbb{Z}(2)_F\) flavor symmetry, which allows us to distinguish “mesons” from “glueballs”. In a \(U(N)\) gauge theory, baryon number is part of the local symmetry. Hence, baryons violate Gauss’ law
and thus do not belong to the physical spectrum. In an $SU(N)$ gauge theory, on the other hand, there is a global $U(1)_B$ symmetry that distinguishes physical states with different baryon numbers. In an $SU(2)$ gauge theory two quarks are confined inside a baryon. Then, in contrast to the real world, baryons are bosons. Despite numerous differences with QCD, concerning the space-time dimension, the gauge group, and the nature of the chiral symmetry, $U(2)$ and $SU(2)$ lattice gauge theories in (1 + 1) and (2 + 1) space-time dimensions are still useful toy models for investigating interesting non-perturbative dynamics. For example, one can study the real-time dynamics of chiral symmetry breaking across a phase transition, the superfluidity of baryons resulting from the spontaneous breakdown of $U(1)_B$, and one can even mimic heavy ion collisions.

A distinguishing feature of quantum link models is that the gauge fields can be realized as fermion bilinears. The fermionic constituents of gauge fields are known as rishons. As we will see, the rishon formulation is crucial for our construction of a quantum simulator for non-Abelian gauge theories. In fact, both “quarks” and rishons are represented by the same fermionic atoms that hop between the sites of an optical lattice. From a theoretical perspective, the color indices of “quarks” and rishons can be contracted to form color-neutral “meson”, “glueball”, and “constituent quark” operators. It is remarkable that the theory can be formulated entirely in terms of these $U(N)$ or $SU(N)$ gauge invariant objects. Thanks to the explicit reduction to the gauge invariant sector, exact diagonalization studies are possible even on moderate size systems, which can be used to validate an experimentally realized quantum simulator. Since the number of rishons per link is conserved locally, in the $U(N)$ or $SU(N)$ gauge invariant formulation of the theory, an additional $U(1)$ link gauge invariant emerges. This ensures that the confining dynamics of “quarks” and “gluons” is still correctly represented by “mesons”, “glueballs”, and “constituent quarks”.

$U(N)$ and $SU(N)$ Quantum Link Models

Let us consider a system of staggered fermions on a $d$-dimensional spatial lattice coupled to a $U(N)$ gauge field. The corresponding Hamiltonian then takes the form

$$H = -t \sum_{\langle xy \rangle} (s_{xy} \psi^t_x U_{xy} \psi_y + \text{h.c.}) + m \sum_x s_x \psi^t_x \psi_x + \frac{g^2}{2} \sum_{\langle xy \rangle} (U^a_{xy} U^a_{xy} + R^a_{xy} R^a_{xy}) + \frac{g'^2}{2} \sum_{\langle xy \rangle} E^2_{xy} \tag{7}$$

Here $\psi^t_x$ and $\psi^t_x (i \in \{1, 2, \ldots, N\})$ are fermion creation and annihilation operators that obey standard anti-commutation relations, $t$ is a hopping parameter, and $s_x$, $s_y$ are sign-factors associated with the points $x$ and $y$, respectively. The site factor is given by $s_x = (-1)^{x_1 + \cdots + x_d}$. For the links in the 1-direction $s_{xy} = 1$, for those in the 2-direction $s_{xy} = (-1)^{x_1}$, and for the links in the $k$-direction $s_{xy} = (-1)^{x_1 + \cdots + x_k-1}$. $U_{xy}$ is an $N \times N$ matrix (with matrix elements $U^i_{xy}$) associated with the oriented link connecting the neighboring lattice points $x$ and $y$, respectively. The magnetic field energy is represented by the term associated with the elementary plaquettes $(w_{xy})$. Finally, the term proportional to $\gamma$ explicitly breaks a $U(N)$ gauge symmetry down to $SU(N)$.

The various operators obey the commutation relations

$$[L^a, L^b] = 2i f_{abc} L^c, \quad [R^a, R^b] = 2i f_{abc} R^c, \quad [L^a, R^b] = [E, L^a] = [E, R^a] = 0, \quad [L^a, U] = -\lambda^a U, \quad [R^a, U] = U \lambda^a, \quad [E, U] = U. \tag{8}$$

Here we have suppressed the link index $xy$. Operators associated with different links commute with each other. The Hermitian generators of $SU(N)$ obey the commutation relations

$$[\lambda^a, \lambda^b] = 2i f_{abc} \lambda^c, \quad \text{Tr} \lambda^a \lambda^b = 2 \delta^{ab}, \tag{9}$$

where $f_{abc}$ are the structure constants of the $SU(N)$ algebra. By construction, the Hamiltonian of Eq.(7) is gauge invariant, i.e. it commutes with the infinitesimal generators of $SU(N)$ gauge transformations

$$G^a_x = \psi^t_x \lambda^a_x \psi_x + \sum_{k} (L_{x,x+k} + R_{x-k,x}^a),$$

$$[G^a_x, G^b_y] = 2i \delta_{xy} f_{abc} G^c_x, \tag{10}$$

FIG. 4. Rishon dynamics: The trace part of the Hamiltonian induces a hopping of rishons of various colors around a plaquette. The determinant part shifts a color-neutral rishon baryon from one end of a link to the other.
where \( \hat{k} \) is a unit-vector in the \( k \)-direction. A general \( SU(N) \) gauge transformation is represented by the unitary transformation \( V = \prod_k \exp(i \alpha_k^a G^a_{xy} \), which acts as
\[
U'_{xy} = V^\dagger U_{xy} V = \exp(i \alpha_y^a \lambda^a) U_{xy} \exp(-i \alpha_y^a \lambda^a). \tag{11}
\]
For \( \gamma = 0 \) the Hamiltonian has an additional \( U(1) \) gauge symmetry which is generated by
\[
G_x = \psi^i_x \bar{\psi}^j_x - \sum_k \left( E_{x,x+k} - E_{x-k,x} \right), \quad [G_x, G^a_{xy}] = 0. \tag{12}
\]
A general \( U(1) \) gauge transformation, represented by the unitary transformation \( W = \prod_x \exp(i \alpha_x G_x) \), acts as
\[
U'_{xy} = W^\dagger U_{xy} W = \exp(i \alpha_x U_{xy} \exp(-i \alpha_y). \tag{13}
\]
In Wilson’s formulation of lattice gauge theory, the link matrices \( U_{xy} \) are parallel transporters that take values in the gauge group \( U(N) \) or \( SU(N) \), and \( E_{xy}, L_{xy} \), and \( R^a_{xy} \) are the corresponding canonically conjugate momentum operators, which take derivatives with respect to the matrix elements of \( U_{xy} \). In that case, the commutation relations of Eq.(8) are realized in an infinite-dimensional Hilbert space per link, which poses great challenges for the implementation in a quantum simulator. Quantum link models extend the theoretical framework of lattice gauge theories by realizing the algebra of Eq.(8) in a finite-dimensional Hilbert space per link. This is achieved by giving up the classical commutative nature of the matrix elements of \( U_{xy} \). In contrast to Wilson’s lattice gauge theory, in quantum link models the real and imaginary parts of \( U_{xy} \) are no longer represented by real numbers, but by non-commuting Hermitean operators. In this sense, quantum links are gauge covariant generalizations of quantum spins.

On each link the commutation relations of Eq.(8) can be realized by using the generators of an \( SU(2N) \) algebra. In particular, the real and imaginary parts of the \( N^2 \) matrix elements \( U_{ij}^{\alpha} \) are represented by \( 2N^2 \) Hermitean generators of the embedding algebra \( SU(2N) \). The \( 2(N^2-1) \) generators \( L^a \) and \( R^a \) of \( SU(N)_L \times SU(N)_R \) gauge transformations on the left and on the right end of the link also belong to the \( SU(2N) \) algebra. The Abelian \( U(1) \) gauge transformations do not distinguish between left and right and are represented by the additional generator \( E \). Altogether there are thus \( 2N^2 + 2(N^2-1) + 1 = 4N^2 - 1 \) generators, which form the algebra \( SU(2N) \). This requires that, unlike in Wilson’s lattice gauge theory, the elements of a link matrix, \( U_{ij} \), are non-commuting operators that obey the commutation relations
\[
[U_{ij}, U_{kl}] = 2(\delta_{ik} \sigma_{jl}^a R^a - \delta_{jk} \sigma_{il}^a L^a + 2 \delta_{ik} \delta_{jl} E),
\]
\[
[U_{ij}, U_{kl}] = [(U^\dagger)_{ij}, (U^\dagger)_{kl}] = 0. \tag{14}
\]
Again, we should emphasize that the commutation relations are local, namely all commutators between operators assigned to different links are zero.

Since all elements of \( U_{xy} \) commute with each other (although \( U_{xy} \) and \( U_{xy}^\dagger \) do not commute) the definition of \( \det U_{xy} \) does not suffer from operator ordering ambiguities. By construction, for \( \gamma \neq 0 \), the Hamiltonian of Eq.(7) is invariant only under \( SU(N) \) but not under additional \( U(1) \) gauge transformations. However, there is a subtlety that needs to be taken into account. In the fundamental representation of \( SU(2N) \), the operator that represents \( \det U_{xy} \) turns out to vanish. Hence, in that case even the Hamiltonian of Eq.(7) has a \( U(N) \) gauge invariance. On the other hand, since the above commutation relations can be realized with any representation of \( SU(2N) \), we can use higher representations in which the determinant in general does not vanish. The \( (2N)!/(N!)^2 \)-dimensional representation of \( SU(2N) \) is the smallest with a non-vanishing determinant. For an \( SU(2) \) gauge theory the Hilbert space of the corresponding quantum link model then has 6 states per link, while for \( SU(3) \) it has 20 states per link. In the standard Wilson formulation of lattice gauge theory, on the other hand, the single link Hilbert space is already infinite-dimensional.

**Global Symmetries of the \( U(N) \) and \( SU(N) \) Quantum Link Model**

Let us discuss the global symmetries of the Hamiltonian of Eq.(7). First, we consider the shift symmetry \( S_k \) by one lattice spacing in the \( k \)-direction
\[
S_k \psi^i_{xy} = (-1)^{x+y+k} \psi^i_{x+k,y+k}, 
S_k U_{ij}^{xy} = U_{ij}^{x+k,y+k}, 
S_k L^a_{xy} = L^a_{x+k,y+k}, 
S_k R^a_{xy} = R^a_{x+k,y+k}, 
S_k E^{a}_{xy} = E^{a}_{x+k,y+k}. \tag{15}
\]
Only the mass term breaks this symmetry explicitly. Shifts by an even number of lattice spacings in the \( k \)-direction play the role of ordinary translations. The associated conserved quantum number is the momentum \( p_k \in [-\frac{N-1}{2}, \frac{N-1}{2}] \). In the zero-momentum sector the different shifts \( S_k \) form the group \( Z(2)^d \). Simultaneous shifts by one lattice spacing in an even number of different directions play the role of flavor transformations, which form the subgroup \( Z(2)^{d-1} \). Simultaneous shifts by one lattice spacing in an odd number of different directions can be decomposed into a flavor transformation and a \( Z(2)^d \) chiral transformation, which is explicitly broken by the staggered fermion mass term. In one spatial dimension, the chiral transformation is simply the shift by one lattice spacing. In two dimensions, simultaneous shifts by one lattice spacing in both directions represent a \( Z(2) \) flavor transformation, while a shift in either the 1- or the 2-direction correspond to the \( Z(2) \) chiral symmetry.

In a \( U(N) \) gauge theory, there are no baryons because the \( U(1) \) symmetry contained in \( U(N) \) is gauged. Hence, baryons (which are “charged” under this \( U(1) \) symmetry)
violates the Gauss law and are thus excluded from the physical Hilbert space. In an SU(\(N\)) gauge theory, on the other hand, there is a global U(1)_{B} baryon number symmetry, i.e. \([H,B]=0\), which is generated by
\[
B = \sum_{x} \left( \psi_{x}^{\dagger} \psi_{x} - \frac{N}{2} \right).
\]
(16)

Note that baryon number is counted relative to a filled Dirac sea.

Another important symmetry is charge conjugation, which for staggered fermions also involves a shift by one lattice spacing. As for the chiral and flavor symmetries, there are separate symmetries \(C_{k}\) for the different directions.

\[
\begin{align*}
C_{k}\psi_{x}^{\dagger} & = (-1)^{x_{1}+\cdots+x_{N}} \psi_{x}^{\dagger}, \quad C_{k}U_{xy}^{ij} = \hat{U}_{x+k,y+k}^{ij}, \\
C_{k}L_{xy} & = -L_{x+k,y+k}^{a}, \quad C_{k}R_{xy}^{a} = -R_{x+k,y+k}^{a}, \\
C_{k}E_{xy} & = -E_{x+k,y+k}^{a}.
\end{align*}
\]
(17)

A combination of the two symmetries \(C_{k}\) and \(C_{l}\) acts as
\[
C_{k}C_{l}\psi_{x}^{\dagger} = -S_{S}S_{k}\psi_{x}^{\dagger}.
\]
(18)

This implies that, up to an overall minus-sign, the combination of \(C_{k}\) and \(C_{l}\) corresponds to a flavor transformation. A combination of an odd number of \(C_{k}\) operations, on the other hand, plays the role of a genuine charge conjugation. It should be noted that, strictly speaking, charge conjugation is a symmetry only if one chooses a non-chiral (i.e. real or pseudo-real) representation of the embedding algebra SU(2\(N\)). Finally, let us also list the parity symmetry \(P\), which acts as
\[
\begin{align*}
P\psi_{x}^{\dagger} & = \psi_{x}^{\dagger}, \quad PU_{xy}^{ij} = U_{-y,-x}^{ij}, \\
P\hat{L}_{xy}^{a} & = -\hat{L}_{-y,-x}^{a}, \quad PR_{xy}^{a} = R_{-y,-x}^{a}, \\
P\hat{E}_{xy} & = -E_{-y,-x}.
\end{align*}
\]
(19)

The Rishon Representation of Quantum Links

In this section we formulate quantum link models using anti-commuting operators describing fermionic constituents of the gluons. The algebraic structure of a quantum link model is determined by the commutation relations derived above. The Hilbert space is a direct product of representations of SU(2\(N\)) on each link, with the generators on different links commuting with each other. We can thus limit ourselves to a single link. The commutation relations can be realized in a representation using anti-commuting rishon operators \(c^{\dagger}_{x,\pm k}, c_{x,\pm k}\) with color index \(i \in \{1,\ldots,\hat{N}\}\). The rishon operators are associated with the left and right ends of a link and are characterized by a lattice point \(x\) and a link direction \(\pm k\). They obey canonical anti-commutation relations
\[
\begin{align*}
\{c^{\dagger}_{x,\pm k}, c_{y,\pm l}\} & = \delta_{x,y}\delta_{k,l}\delta_{i,j}, \\
\{c^{\dagger}_{x,\pm k}, c^{\dagger}_{y,\pm l}\} & = \{c_{x,\pm k}, c_{y,\pm l}\} = 0.
\end{align*}
\]
(20)

It should be noted that quark and rishon operators also anti-commute with each other. Under SU(\(N\)) gauge transformations the operators \(c\) and \(c^{\dagger}\) transform in the fundamental and anti-fundamental representation, respectively. It is straightforward to show that the commutation relations of Eq.(8) are satisfied when we write
\[
\begin{align*}
\hat{L}_{xy}^{a} & = c_{x,+}^{\dagger}a^{a}_{y}c_{x,+}^{l}+c_{x,-}^{\dagger}a^{a}_{y}c_{x,-}^{l}, \\
\hat{R}_{xy}^{a} & = c_{x,-}^{\dagger}a^{a}_{y}c_{x,+}^{l}+c_{x,+}^{\dagger}a^{a}_{y}c_{x,-}^{l}, \\
\hat{E}_{xy} & = \frac{1}{2}(c_{x,+}^{\dagger}c_{x,-}^{l}-c_{x,-}^{\dagger}c_{x,+}^{l}), \quad U_{xy}^{ij} = c_{x,+}^{ij}c_{x,-}^{lji}.
\end{align*}
\]
(21)

All operators introduced so far (including the Hamiltonian) commute with the rishon number operator
\[
\mathcal{N}_{xy} = c_{x,+,c_{x,+}^{l}}+c_{x,+,c_{x,+}^{l}}.
\]
(22)

on each individual link. Hence, we can limit ourselves to superselection sectors of fixed rishon number for each link. This is equivalent to working in a given irreducible representation of SU(2\(N\)). Let us use the rishon representation to take a closer look at the determinant operator that we used to break the \(U(\hat{N}\)) gauge symmetry down to SU(\(N\)). We have
\[
det U_{xy} = \frac{1}{N!}c_{i_{1}\cdots i_{2}}U_{xy}^{i_{1}i_{2}i_{3}}U_{xy}^{i_{3}i_{4}}\cdots U_{xy}^{i_{N-1}i_{N}},
\]
\[
= \frac{1}{N!}c_{i_{1}\cdots i_{2}}c_{x,+}^{i_{1}}c_{x,+}^{i_{1}^{\dagger}}c_{x,-}^{i_{2}}c_{x,-}^{i_{2}^{\dagger}}\cdots c_{x,+}^{i_{N}}c_{x,+}^{i_{N}^{\dagger}}c_{x,+}^{i_{N}^{\dagger}}c_{x,+}^{i_{N}^{\dagger}},
\]
\[
= N!c_{x,+}^{i_{1}}c_{x,+}^{i_{1}^{\dagger}}c_{x,-}^{i_{2}}c_{x,-}^{i_{2}^{\dagger}}\cdots c_{x,+}^{i_{N}}c_{x,+}^{i_{N}^{\dagger}}.
\]
(23)

Only when this operator acts on a state with exactly \(N\) rishons (all of a different color), it can give a non-zero contribution. In all other cases the determinant vanishes. This means that we can reduce the symmetry from \(U(\hat{N}\)) to SU(\(N\)) via the determinant only when we work with exactly \(N\) fermionic rishons on each link. The number of fermion states per link then is
\[
\binom{2\hat{N}}{N} = \frac{(2\hat{N})!}{(\hat{N})!^{2}}.
\]
(24)

This is the dimension of the SU(2\(N\)) representation with a totally antisymmetric Young tableau with \(N\) boxes (arranged in a single column).

The various symmetries act on the rishons as
\[
\begin{align*}
S_{k}^{i}c_{x,\pm k}^{i} & = c_{x,\pm k}^{i}, \quad S_{k}^{i}c_{x,\pm k}^{i} = c_{x,\pm k}^{i}, \\
C_{k}c_{x,\pm k}^{i} & = -c_{x,\pm k}^{i}, \quad P_{x,\pm k}^{i} = c_{x,\pm k}^{i}.
\end{align*}
\]
(25)

It is straightforward to show that these transformations induce the corresponding transformations of Eqs.[15], [17], and [19].
Glueballs, Mesons, and Constituent Quarks

In this section we express the Hamiltonian of the $U(N)$ quantum link model with quarks in terms of color neutral operators. Gauge invariance requires that these operators are local bilinear combinations of rishons and quarks, which we refer to as glueballs, mesons, and constituent quarks. All these objects — including the constituent quarks — are bosons. The determinant term in the $SU(N)$ quantum link Hamiltonian would give rise to an additional color-singlet rishon-baryon consisting of $N$ rishons. For odd $N$ this object would hence be a fermion. To avoid complications related to these objects we limit ourselves to $U(N)$ in this section.

By contracting the color indices of two rishons, we construct “glueball” operators

$$\Phi_{x,\pm k,\pm l} = c^\dagger_{x,\pm k} c^\dagger_{x,\mp l},$$

which satisfy the local commutation relations of $U(2d)$

$$[\Phi_{x,\pm k,\pm l}, \Phi_{y,\pm m,\pm n}] = -\delta_{xy} (\delta_{k,\pm m} \Phi_{x,\pm k,\pm n} - \delta_{k,\pm n} \Phi_{x,\pm k,\pm m}).$$

By contracting the color index of two quark fields, we construct a “meson” operator

$$M_x = \psi^\dagger_{x} \psi_{x},$$

which generates a $U(1)$ algebra. While glueballs and mesons are not related via their commutation relations, i.e. $[\Phi_{x,\pm k,\pm l}, M_y] = 0$, they are both related with the constituent quark operators that one obtains by contracting the color indices of a quark and a rishon

$$Q_{x,\pm k} = c^\dagger_{x,\pm k} \psi^\dagger_{x},$$

via the commutation relations

$$[\Phi_{x,\pm k,\pm l}, Q_{y,\pm m}] = \delta_{xy} \delta_{\pm k,\pm m} Q_{x,\pm k},$$

$$[M_x, Q_{x,\pm k}] = -\delta_{xy} Q_{x,\pm k}.$$  (27)

Finally, the commutation relations of the constituent quark operators take the form

$$[Q_{x,\pm k}, Q^\dagger_{y,\pm l}] = \delta_{xy} (\Phi_{x,\pm k,\pm l} - \delta_{\pm k,\pm l} M_x),$$

$$[Q_{x,\pm k}, Q_{y,\pm l}] = [Q^\dagger_{x,\pm k}, Q^\dagger_{y,\pm l}] = 0.$$  (30)

Thus, the inclusion of the constituent quark operators completes the site-based algebra of $U(2d) \times U(1)$ to $U(2d+1)$.

Let us now consider a single rishon per link, i.e. $\mathcal{N}_{xy} = 1$. Then $\text{det} U$ vanishes and the electric flux terms in the Hamiltonian of Eq. (25) (proportional to $g^2$ and $g'^2$) are trivial constants. Expressing the Hamiltonian in terms of glueball, meson, and constituent quark operators then leads to

$$H = -i \sum_{(xy)} (s_{xy} \psi^\dagger_{x} \psi^\dagger_{y} + h.c.) + m \sum_{x} s_{x} \psi^\dagger_{x} \psi_{x}$$

$$- \frac{1}{4g^2} \sum_{(wxyz)} (U_{wx} U_{xy} U_{yz} U_{zw} + h.c.)$$

$$- i \sum_{(xy)} (s_{xy} Q^\dagger_{x,+x} Q_{y,-x} + h.c.) + m \sum_{x} s_{x} M_{x}$$

$$+ \frac{1}{4g'^2} \sum_{(wxyz)} \Phi_{w,+x+k,l} \Phi_{x,+l+k} \Phi_{y,-x-k,l} \Phi_{z,-l-k}.$$  (32)

where $y = x + k$, $z = y + l$, and $w = x + l$. Remarkably, this expresses the Hamiltonian entirely in terms of $U(N)$ gauge invariant operators. Still, it should be noted that the number of rishons per link is conserved, i.e. $[H, \mathcal{N}_{xy}] = 0$. Also note that

$$\mathcal{N}_{xy} = \Phi_{x,+x+k} + \Phi_{y,-x-k}.$$  (33)

This framework is well suited for exact diagonalization studies because it explicitly eliminates gauge variant states.

Under the various global symmetries the glueball, meson, and constituent quark operators transform as

$S_k \Phi_{x,\pm l,\pm m} = \Phi_{x+k,\pm l,\pm m}$,

$S_k Q_{x,\pm l,t} = Q_{x+k,\pm l,t}$,

$C_k \Phi_{x,\pm l,\pm m} = -s_{\pm l} s_{\pm m} (\Phi_{x+k,\pm l,\pm m} - N \delta_{\pm l,\pm m})$,

$C_k M_x = -M_{x+k} + N$,

$C_k Q_{x,\pm l,t} = \mp (-1)^{x_1 + \cdots + x_k} Q_{x+k,\pm l,t}$,

$P \Phi_{x,\pm l,\pm m} = \Phi_{-x,\mp l,\mp m}$,

$P M_x = -M_{x}$,

$P Q_{x,\pm l,t} = Q_{-x,\mp l,t}$.  (34)

Here the sign $s_{\pm l} = \pm 1$ is the sign in $\pm l$. The above symmetry transformations follow directly from the transformation properties of the fermions and of the rishons (Eq. (25)). It is straightforward to show that they leave the commutation relations between the glueball, meson, and constituent quark operators invariant.

SUPPLEMENTARY MATERIAL II:
NON-ABELIAN LATTICE GAUGE THEORIES IN ALKALINE-EARTH GASES: THE EFFECT OF IMPERFECTIONS IN ATOMIC IMPLEMENTATIONS AND STRUCTURE OF OPTICAL LATTICES

Introduction

Impurities in atomic physics implementations have to be carefully analyzed in order to understand the minimal experimental requirement to perform accurate quantum simulations. Here, we discuss how typical experimental errors affect the precision of quantum simulations.
of non-Abelian lattice gauge theories in alkaline-earth set-
ups, considering the paradigmatic case study of \( U(2) \) quantum link models. In the next section, we briefly
describe our model Hamiltonian, its experimentally relevant
perturbations, and a set of observables quantitatively
describing the departure from gauge invariance. In the last
section, we present numerical results based on Lanczos
diagonalization of small systems to underpin the
validation issue at a quantitative level.

Microscopic model Hamiltonian, imperfections, and
observables

For simplicity, here we consider a \((1 + 1)D\) \( U(2) \) QLM
with two rishons per link. As discussed in the main text,
the QLM Hamiltonian \( H \) is induced in second order per-
turbation theory from the microscopic Hamiltonian

\[
\tilde{H} = U \sum_x (n_{x,+} + n_{x+1,-} - 2)^2 + m \sum_x (-1)^x \psi_x^\dagger \psi_x
+ i \sum_x (c_{x,+}^\dagger \psi_x + c_{x,-}^\dagger \psi_x + \text{h.c.}),
\]

where \( n_{x,\pm} = c_{x,\pm}^\dagger c_{x,\pm} \). This Hamiltonian is manifestly
\( SU(2) \) gauge invariant, i.e. \([\tilde{H}, G_x^a] = 0\). Unlike the QLM
without the det\( U \) term, it is, however, not necessarily
also \( U(1) \) gauge invariant. Also the constraint of \( N_{xy} = 2 \)
lishons per link will only be satisfied approximately for
sufficiently large \( U \).

In an experimental realization with ultracold alkaline-
earth atoms in an optical lattice, one may expect
some deviations from the ideal microscopic Hamiltonian.
While interactions do not need any particular fine-tuning
in our implementation, since the difference in scattering
lengths for the different \( m_I \) states are negligible compared
to all other energy scales, different tunneling rates and
local potentials require accurate lattice design, and
may be subject to experimentally relevant imperfections.
Such imperfections may give rise to color-dependent tun-
neling rates \( t_i \). The actual Hamiltonian of a slightly im-
perfect experimental realization may take the form

\[
\tilde{H}_{\text{imp}} = U \sum_x (n_{x,+} + n_{x+1,-} - 2)^2 + m \sum_x (-1)^x \psi_x^\dagger \psi_x
+ \sum_x t_i (\psi_x^\dagger a_{x,+}^i + \psi_{x+1}^\dagger a_{x,-}^i + \text{h.c.})
+ 2\Delta U \sum_x (n_{x,+} - 1)(n_{x+1,-} - 1).
\]

It should be noted that repeated indices are still summed.
Due to the color-dependent hopping terms \( t_i \), this Hamil-
tonian is no longer \( SU(2) \) gauge invariant. The \( \Delta U \) term,
resulting from different overlaps of the Wannier func-
tions in the partially overlapping rishon-sites, provides
a source for the implementation of the det\( U \) term in the
\( SU(2) \) model, but should be viewed as an imperfection
in the \( U(2) \) context. In the following, we particularly fo-
cus on the effect of different tunneling rates for the two
color species, investigating to what extent they can affect
gauge invariance. Other sources of imperfections, such as
trapping potentials and small corrections to the interac-
tion couplings, are expected to slightly shift the effective
parameters. Nevertheless, let us point out that, even in
presence of explicitly gauge variant terms, the low-energy
properties of the system are expected to be robust (see
main text).

Accuracy of gauge invariance: relevant observables

In this section we investigate how deviations from a
fixed rishon number per link in the microscopic Hamil-
tonian \( \tilde{H} \) and color-dependent tunneling rates in \( \tilde{H}_{\text{imp}} \)
affect the accuracy of the gauge symmetries.

Abelian \( U(1) \) gauge symmetry

Let us first discuss the \( U(1) \) symmetry generated by

\[
G_x = n_x^1 + n_x^2 - \frac{1}{2}(N_{x,x+1} + N_{x-1,x}),
\]

where

\[
n_x^i = \psi_x^\dagger \psi_x + c_{x,+}^\dagger c_{x,+} + c_{x,-}^\dagger c_{x,-},
\]

counts the number of fermions of color \( i \) on a basic build-
ing block consisting of a quark- and the two adjacent
rishon-sites forming a triple-well. Since the fermion num-
bers \( n_x^i \) are exactly conserved by construction, one should
check whether the number \( N_{x,x+1} = 2 \) of rishons per link
remains constant. Deviations from this constraint are
quantified by

\[
\langle N_{x,x+1} \rangle = 2 + \Delta_{\text{link}},
\]

which should be small for sufficiently large \( U \).

Non-Abelian \( SU(2) \) symmetry

We now focus on the non-Abelian part of the symmetry
group, \( SU(2) \), and check the expectation values of the
generators

\[
G_x^a = \psi_x^\dagger \sigma_x^a \psi_x + c_{x,+}^\dagger \sigma_x^a c_{x,+} + c_{x,-}^\dagger \sigma_x^a c_{x,-},
\]

which should be zero in case of exact gauge symmetry.
Here, \( \sigma_x^a \) are the Pauli matrices. Notice that the diagonal
\( U(1) \) subgroup of the \( SU(2) \) symmetry is also automati-
cally fulfilled. This is because the generator

\[
G_x^3 = n_x^1 - n_x^2
\]
always has a vanishing expectation value by initial state preparation: the number of particles assigned to each basic building block (consisting of a quark- and two adjacent rishon-sites forming a triple-well) is strictly conserved. Here, we focus on the generator $G^1_x$ and calculate the expectation value in the ground state of $H_{\text{imp}}$ (with $\Delta U = 0$)

$$D_1 = \frac{1}{L} \sum_{x} (G^1_x)^2. \quad (42)$$

**Numerical results**

In this section, we present numerical results based on the previous theoretical considerations.

**$U(1)$ rishon number symmetry: validation**

In Fig. 5, we present exact diagonalization results for a system with 12 sites (4 quark- and 8 rishon-sites). This shows how the number of rishons per link, indicating the accuracy of the $U(1)$ symmetry, is very close to the desired value even for relatively small values of the interaction strength $U$. This is similar to the previously studied $U(1)$ case.

![Fig. 5. Deviations from the conserved number of rishons as a function of $t/2U$ for different values of $m/t$.](image)

**SU(2) symmetry: validation**

In Table II, we list typical values of $D_1$ as a function of the interaction strength $U$ (still considered SU(2) symmetric) for approximate tunneling symmetries, where $t_2 = t$, $t_1 = (1-z)t$. Remarkably, even for relatively large values of $z \approx 0.1$, errors due to approximate gauge invariance are extremely small, well beyond all other possible imperfections such as, e.g., the effect of the trapping potential or the space-dependent tuning of optical Feshbach resonances.

**Further remarks on the lattice structure**

Here we illustrate in a schematic way how the combination of triple-wells and the additional potential offsets required to impose the rishon constraint discussed in the previous subsection emerge from the lattice structure. For the sake of simplicity, we focus here on the 1D case, although the results generalize straightforwardly in 2D and 3D.

We define a set of color indices, $j = 1, 2, ..., N$, for the fermions. We denote with $x$ the triple-well label, and with $x, x+, x-$ the site in the center of the well, on the right and on the left, respectively, according to the notation in Fig. 2a of the main text and the previous discussion. The corresponding potential off-sets are then

$$H_{\text{off}} = \sum_j \sum_{x \text{ odd}} \mu_1 n_x^j + \sum_j \sum_{x \text{ even}} \mu_1 n_x^j +$$

$$+ \sum_j \sum_{x \text{ odd}} 4\mu_{11} [n_{x,+}^j + n_{x,-}^j] +$$

$$+ \sum_j \sum_{x \text{ even}} 4\mu_{11} [n_{x,+}^j + n_{x,-}^j]. \quad (43)$$

The lattice has to realize a periodic structure of this kind, either holographically or by employing a proper combination of laser beams: in the 1D case, a combination of three lattice beams, just one of them being state-dependent, provides almost full tunability of the microscopic parameters in $H_{\text{off}}$, although simpler, less flexible choices might be employed for specific cases. The corresponding microscopic terms in Eq. (43) then read

$\bar{m} = (\mu_1 - \mu_{11})/2$, $U = \mu_{11}$. Arrays of double-wells are routinely managed in current experiments, and the triple-well structure should constitute a variant of the same setups.
