ABSTRACT

We consider the shape of the posterior distribution to be used when fitting cosmological models to power spectra measured from galaxy surveys. At very large scales, Gaussian posterior distributions in the power do not approximate the posterior distribution \( P_R \) we expect for a Gaussian density field \( \delta_k \), even if we vary the covariance matrix according to the model to be tested. We compare alternative posterior distributions with \( P_R \), both mode-by-mode and in terms of expected measurements of primordial non-Gaussianity parameterised by \( f_{\text{NL}} \). Marginalising over a Gaussian posterior distribution \( P_f \) with fixed covariance matrix yields a posterior mean value of \( f_{\text{NL}} \) which, for a data set with the characteristics of Euclid, will be underestimated by \( \Delta f_{\text{NL}} = 0.4 \), while for the data release 9 (DR9) of the Sloan Digital Sky Survey (SDSS)-III Baryon Oscillation Spectroscopic Survey (BOSS) it will be underestimated by \( \Delta f_{\text{NL}} = 19.1 \). Adopting a different form of the posterior function means that we do not necessarily require a different covariance matrix for each model to be tested: this dependence is absorbed into the functional form of the posterior. Thus, the computational burden of analysis is significantly reduced.

1 INTRODUCTION

Forthcoming galaxy surveys, such as the Dark Energy Spectroscopic Instrument (DESI; Schlegel et al. 2011), Euclid (Laureijs et al. 2011)\textsuperscript{1} and the Square Kilometre Array (SKA) \textsuperscript{2}, will constrain the Universe’s expansion history, geometry and the growth of structure with unprecedented accuracy. The basic statistics containing large-scale structure information are the 2-point clustering measurements, the correlation function and the galaxy power-spectrum \( P(k) \). As they form a Fourier pair, their information content is the same and we focus only on the latter in this work. The linear galaxy power spectrum encodes a wealth of information about the physics of the Universe, allowing us to constrain cosmological models with baryon acoustic oscillations (BAO), gravitational models with redshift space distortions (RSD) and inflationary models with primordial non-Gaussianity, parametrised to first order by \( f_{\text{NL}} \). In order to do so, one has to know the likelihood and/or posterior of power-spectra, which for simple cases can be calculated analytically. For general cases, one usually assumes the likelihood or posterior to be multi-variate Gaussian with a covariance matrix \( C_{ij} \equiv \langle P(k_i)P(k_j) \rangle \). The estimation of the covariance matrix is a critical step in the analysis of data. Internal methods such as the sub-sample, jackknife and bootstrap methods have been widely used in the past, but Norberg et al. (2009) have shown that they are not able to faithfully reproduce variances. Robust estimates are often instead obtained from mock galaxy catalogues. In recent analyses of the Baryon Oscillation Spectroscopic Survey (BOSS; Dawson et al. 2013), these were generated from second order Lagrangian Perturbation Theory matter fields using a friends-of-friends group finder (Davis et al. 1985) to find haloes (Scoccimarro & Sheth 2002; Manera et al. 2012). Their masses were calibrated by comparisons with N-body simulations. A Halo Occupation Distribution then prescribed how to populate these haloes with mock galaxies, and the geometry and the efficiency of the survey were sampled. Alternative methods for producing mocks include N-body simulations, comoving Lagrangian acceleration (COLA; Tassev, Zaldarriaga & Eisenstein 2013) simulations or alternative simpler methods such as pinpointing orbit-crossing collapsed hierarchical objects (PINOCCHIO; Monaco, Theuns & Taffoni 2002) or effective Zel’ dovich approximation mocks (EZmocks; Chuang et al. 2015). The covariance matrix is then the sample variance of the power spectra from the different mocks (Manera et al. 2012; Taylor et al. 2013; Percival et al. 2014). The covariance matrix computed from the mocks will depend on the cosmological model that was

2 THE POWER SPECTRUM LIKELIHOOD

In this section, we elaborate the analytic likelihood and posterior functions of the galaxy clustering power spectrum assuming a Gaussian density field. We consider this posterior function as the "truth" and compare it to commonly used approximations of the galaxy power spectrum posterior function for single modes, which we shall introduce in Sec. 2.3.

2.1 The True Distribution of $|\delta_k|$ Under the Assumption of a Gaussian Density Field

The positions of the galaxies in a survey can be transformed into a galaxy over-density field

$$\delta(x) \equiv \frac{n(x) - \bar{n}(x)}{\bar{n}(x)}$$

(2)

where $n(x)$ is the measured galaxy number density and $\bar{n}(x)$ the expected value. Fourier transforming $\delta(x)$ yields

$$\delta_k \equiv \frac{1}{V} \int d^3x \delta(x) \exp(i k x)$$

(3)

whose covariance matrix

$$\langle \delta_k, \delta_{k'} \rangle = \frac{(2\pi)^3}{V} \delta_D(k_1 - k_2) P(k_1)$$

(4)

is given by the power spectrum $P(k)$. Following the standard assumption that $\delta_k$ forms a Gaussian random field, the probability of measuring a particular value of the real and imaginary parts $(\delta_u, \delta_v)$ of a single $\delta_k = \delta_u + i \delta_v$ is a zero centred Gaussian distribution with standard deviation half the true power $\frac{1}{2} P_T(k)$:

$$Z(\delta_u) = \frac{1}{\sqrt{\pi P_T(k)}} \exp \left( -\frac{\delta_u^2}{P_T(k)} \right)$$

$$Z(\delta_v) = \frac{1}{\sqrt{\pi P_T(k)}} \exp \left( -\frac{\delta_v^2}{P_T(k)} \right).$$

(5)

We use the letter $Z$ here, because we have assumed that the true power is known, i.e. the distribution only depends on the data (c.f. Tab. 1). The distribution of the absolute value $|\delta_k| = \sqrt{\delta_u^2 + \delta_v^2}$ is given by a Rayleigh distribution:

$$Z_R(|\delta_k|) = \int d\delta_u \int d\delta_v Z(\delta_u) Z(\delta_v) Z_D(|\delta_k| - \sqrt{\delta_u^2 + \delta_v^2})$$

$$= \frac{2|\delta_k|}{P_T(k)} \exp \left( -\frac{|\delta_k|^2}{P_T(k)} \right).$$

(6)

Throughout this article, we regard Eq. (6) as the "true" distribution of $|\delta_k|$ to which we compare several approximations later.

Any model dependence enters the Rayleigh distribution only in the covariance of the density field, which is equal to the true power spectrum. The position of the distribution’s peak equals the value of the true power. Measurements of $\delta_k$ have been used to make cosmological inferences when they have been further decomposed into spherical harmonics and spherical Bessel functions, because radial and angular modes can be distinguished, allowing an easy analysis of redshift-space distortions. However, this method is rather complex and computationally expensive (Heavens & Taylor 1995; Percival et al. 2004). It is difficult to linearly compress $\delta_k$ efficiently maximally retaining information.

2.2 The Posterior in Terms of the Power

We can rewrite the Rayleigh distribution in terms of the power. We replace $P_T(k)$ with $P_{H}(k)$, and $\delta_k$ with $\sqrt{\hat{P}(k)}$ in equation (6) which in this way depends on both data and model, and hence becomes a likelihood (c.f. Tab. 1):

$$L_R(\hat{P}(k) | P_H(k)) = \frac{2 \sqrt{\hat{P}(k)}}{P_H(k)} \exp \left( -\frac{\hat{P}(k)}{P_H(k)} \right).$$

(7)
We can use Bayes’ theorem (cf. Eq. (1)) to find the posterior. It is standard to assume a uniform prior
\[
\Pi (P_H (k)) = \begin{cases} \frac{1}{P_{\text{max}} (k)} & \text{if } 0 \leq P_H (k) \leq P_{\text{max}} (k), \\ 0 & \text{otherwise}, \end{cases}
\]
which requires an arbitrary choice of \(P_{\text{max}} (k)\). We assume that \(P_{\text{max}} (k)\) is far in the right tail of the likelihood such that \(\Pi (P_H (k)) \equiv \Pi (\hat{P} (k))\) is effectively constant and hence acts only as a normalisation factor. Thus, for the “true” posterior we have
\[
\mathcal{P}_R \left( P_H (k) \bigg| \hat{P} (k) \right) = \frac{L_R \left( \hat{P} (k) \bigg| P_H (k) \right)}{\int dP_H L_R \left( \hat{P} (k) \bigg| P_H (k) \right)} \propto \frac{2 \sqrt{\hat{P} (k)}}{P_H (k)} \exp \left( - \frac{\hat{P} (k)}{P_H (k)} \right).
\]

As \(\hat{P}\) is a constant in the posterior, one can rewrite Eq. (9) such that the log-posterior only depends on the ratio \(\hat{P} (k)/P_H (k)\):
\[
-2 \ln (\mathcal{P}_R) = 2 M \ln \left( \frac{P_H (k)}{\hat{P} (k)} \right) + 2 M \frac{\hat{P} (k)}{P_H (k)} + \text{const.}
\]
Then we follow the method of Hamimeche & Lewis (2008) and introduce
\[
\gamma (x) \equiv \sqrt{- \ln (x)} + x
\]
to make Eq. (10) look more quadratic:
\[
-2 \ln (\mathcal{P}_R) = 2 M \left[ \gamma \left( \frac{\hat{P} (k)}{P_H (k)} \right) \right]^2 + \text{const.}
\]
We can also define
\[
P_\gamma (k) \equiv P_f (k) \gamma \left( \frac{\hat{P} (k)}{P_H (k)} \right)
\]
for some fiducial model with power \(P_f\). \(P_\gamma\) has then a symmetric Gaussian posterior with a fixed variance \(\hat{C}_k = \frac{2 P_f (k)^2}{M}\) evaluated for our fiducial model:
\[
-2 \ln (\mathcal{P}_R) = 4 P_\gamma \hat{C}_k^{-1} P_\gamma + \text{const.}
\]
In general, things are more complicated than this simple picture. For example, the survey geometry leads to a convolution of \(\delta_k\), and non-linear effects distort the small scale mode distribution. Ideally, we would like to use a single distribution, and this should be matched to simulations (e.g. Blot et al. 2015). In order to broaden the choice, we also consider a number of forms for the likelihood inspired by CMB analyses.

2.3 Common Approximations of the Likelihood/Posterior of the Power Spectrum

Often, the power-spectrum is directly analysed, incorrectly assuming it follows a Gaussian distribution, thus the distribution of a finite empirical realisation of the power spectrum \(\hat{P} (k)\) would read
\[
\mathcal{Z} \left( \hat{P} (k) \right) \equiv \frac{\exp \left( - \frac{1}{2} \frac{[\hat{P} (k) - P_H (k)]^2}{C_k} \right)}{\sqrt{2 \pi C_k}},
\]
where \(C_k = \langle P_H^2 (k) \rangle = \frac{2 P_f^2 (k)^2}{M}\) is the variance of the true power spectrum \(P_f\) at a bin centred around \(k\) comprising \(M\) independent modes. Note that we assume that the widths and positions of the \(k\)-bins are such that window effects are negligible (Feldman et al. 1994) and different modes are independent.

As in Sec. 2.2, we replace \(P_f (k)\) with \(P_H (k)\) in equation (15) making it a likelihood (c.f. Tab. 1):
\[
L \left( \hat{P} (k) \bigg| P_H (k) \right) = \frac{\exp \left( - \frac{1}{2} \frac{[\hat{P} (k) - P_H (k)]^2}{C_k} \right)}{\sqrt{2 \pi C_k}},
\]
where \(C_k = \langle \hat{P}_H^2 (k) \rangle\) is the variance for the hypothetical power spectrum \(P_H (k)\).

However, in practice one chooses a fiducial model with power spectrum \(\hat{P} (k)\) and estimates the variance \(\hat{C}_k = \langle \hat{P}^2 (k) \rangle\) for this particular choice:
\[
L \left( \hat{P} (k) \bigg| P_H (k) \right) = \frac{\exp \left( - \frac{1}{2} \frac{[\hat{P} (k) - P_H (k)]^2}{C_k} \right)}{\sqrt{2 \pi C_k}}.
\]
For mock based variance calculations, \(\hat{P} (k)\) is the cosmology of the mocks used in their analysis.

We can again use Bayes’ theorem (cf. Eq. 1) and assume the same uniform prior as before to find the posterior. For the posterior assuming a Gaussian distribution in \(\hat{P} (k)\) with model-dependent covariance we have
\[
\mathcal{P}_D \left( P_H (k) \bigg| \hat{P} (k) \right) = \frac{L \left( \hat{P} (k) \bigg| P_H (k) \right)}{\int dP_H L \left( \hat{P} (k) \bigg| P_H (k) \right)} \exp \left( - \frac{1}{2} \frac{[\hat{P} (k) - P_H (k)]^2}{C_k} \right) \propto \frac{1}{\sqrt{2 \pi C_k}},
\]
where we adopt the subscript notation \(\mathcal{P}_D\) of Hamimeche & Lewis (2008). Note that both the exponential and the covariance matrix \(C_k\) depend on \(P_H (k)\).

If a fixed covariance is assumed, we have to apply the Bayesian Eq. (1) to Eq. (17) giving
\[
\mathcal{P}_D \left( P_H (k) \bigg| \hat{P} (k) \right) \propto \frac{1}{\sqrt{2 \pi C_k}}.
\]

2.4 A Simple Test of the Posterior Shapes for the isotropically averaged power spectrum

In this subsection we combine the single mode posterior functions to posterior functions of the band-power. We do not take any anisotropic effects, such as redshift space distortions, into account. This is conservative because the effective volume for higher multipoles moments (cf. Eq. 25) is smaller, therefore containing fewer independent modes and thence amplifying the effect of choosing different posterior shapes.

In Gaussian cases, we suppose that our volume is large enough to accommodate \(M\) independent complex Gaussian distributed samples of \(\delta_k\) such that we can use
\[
C_{ab} = \frac{2}{M} \delta_D (k_a - k_b) P^2 (k_a).
\]
to calculate the covariance matrices at higher numbers of modes \(M\). We can obtain the band-power version of \(\mathcal{P}_R \left( \hat{P} (k) \bigg| \delta_k \right)\) by multiplying together the single mode expressions.
The three different posterior shapes of $P_H$ are plotted in Fig. 1. In the top panel of Fig. 1, we plot single mode posterior distributions for which we adopt $|\hat{\delta}_k| = 100$ and $P_f(k) = \tilde{P}(k) = |\hat{\delta}_k|^2 = 10000$. Note that a different choice would shift the peak positions and normalisation factor, but preserve the shapes. We make two different choices for the fixed covariance to see the effect of making the wrong assumption. For the dotted red line, we choose the covariance matrix which corresponds to the true power spectrum $P_T(k)$, i.e. $C_k = 2P_T^2(k) = 50000000$, and for the dashed-dotted line, we consider that our guess of the power spectrum is 5 per cent lower than the actual power spectrum, i.e. $C_k = 45125000$. The panels in the middle and at the bottom of Fig. 1 show the posterior distributions for 10 and 100 independent modes respectively.

Fig. 1 and 2 show that different choices of the covariance matrix provide very different posterior distributions for a small number of modes, but if we can increase the number of independent modes, we see the effect of the central limit theorem and the posterior distribution functions become more and more similar. We observe that the maximum of the fixed-covariance posterior always agrees with the true value, even if the wrong fiducial model has been chosen. However, if we choose the wrong covariance matrix, we over- or underestimate the error of our measurements. If we do not fix the covariance, the best fit, i.e. the maximum of the posterior, has an offset with regard to the true value, which decreases as the number of modes increases. We also notice the long right tails of the varying-covariance Gaussian and the posterior measured from $|\hat{\delta}_k|$. The logarithmic plot in Fig. 2 shows that the tails of all approximations disagree with the true posterior distribution. However, $P_D$ is closest to the truth.

### 2.5 Application to a Real Survey

We have seen that a Gaussian distribution for $P_H(k)$ is not a good approximation to the true Rayleigh distribution if the number of modes is small. In this section, we study whether this has an impact on a real survey. We will base our analysis on an analytic linear error for the power spectrum and errors, but use survey parameters for the data release 11 (DR11) of BOSS. For a real survey, we have to take into account that the discrete positions of the galaxies in a given survey are sampled from a continuous random field by a Poisson point process (Feldman et al. 1994). To take this sampling process into account, Eq. (4) becomes

$$\langle \delta_k, \delta_{k_2} \rangle = \frac{(2\pi)^3}{V} \delta_D(k_1 - k_2) \left[ P(k_1) + \bar{n}^{-1} \right],$$

and hence also

$$P \left( P_H(k) \mid |\hat{\delta}_k| \right) \propto \frac{\hat{\delta}_k}{|P_H(k) + \bar{n}^{-1}|}. \quad (22)$$

The average number density $\bar{n} = 2 \times 10^{-4} \frac{h^3}{\Delta k^3}$ can be calculated from the number of galaxies contained in the BOSS DR11 CMASS sample (620,826) and its survey volume $V_S = 10 \text{ Gpc}^3$ (Anderson et al. 2013) assuming $h = 0.7$. For the covariance matrices of the Gaussians, we need to know the number of modes (Feldman et al. 1994; Tegmark 1997)

$$M = V_n V_{\text{eff}}(k),$$

where

$$V_n \equiv \frac{k^2 \Delta k_n}{2\pi^2} \quad (24)$$

is the $k$-space-“volume” of the $n$th $k$-bin centred at $k_n$ with width $\Delta k_n$, and

$$V_{\text{eff}}(k) \equiv V_S \left[ \frac{\bar{n} P(k)}{1 + \bar{n} P(k)} \right]^2 \quad (25)$$

is the approximate "volume" of the $n$th $k$-bin centred at $k_n$ with width $\Delta k_n$, and
is the effective volume. Anderson et al. (2013) calculate the power spectrum in Fourier modes averaged over bin widths of $\Delta k = 0.008h$ Mpc$^{-1}$. The values of the $k$-bin centres and their corresponding number of modes $M$ are $M = 18, 150$ and $500$ in the three lowest $k$-bins centred at $k = 0.004, 0.012$ and $0.02$ Mpc$^{-1}$. We model the measured power spectrum as $\tilde{P}(k) = b^2 P_{\text{true}}(k)$, where $b = 1.87$ is the large-scale bias and $P_{\text{true}}(k)$ is a linear power spectrum produced by CAMB (Lewis et al. 2000). For the other measurement we take the effective volume. Anderson et al. (2013) calculate the power spectrum $P_{H}$ for BOSS DR11 CMASS.

Table 2: Kullback-Leibler divergences of the different approximations with respect to the true $P_R$ at different scales $k_n$, for BOSS DR11 CMASS.

| $k_n$ Mpc$^{-1}$ | $D_{KL}(P_{22}||P_R)$ | $D_{KL}(P_f||P_R)$ | $D_{KL}(P_{H}^\text{true}||P_R)$ |
|-----------------|------------------------|----------------------|-----------------------------|
| 0.004           | 0.0213221              | 0.382926             | 0.335588                    |
| 0.012           | 0.00451188             | 0.0341685            | 0.0374833                   |
| 0.02            | 0.00336263             | 0.013853             | 0.0199032                   |

We can see from Fig. 4 that the 3rd order diverges for large values of the model power spectrum $P_H$. Hence the optimal free parameter $a$ might differ from $a = -1/4$. Therefore, we use the KL divergence to optimise $a$ in the offset log-normal distribution $P_{OLN}$. It can be found to be $a = -0.201$ at $k = 0.004$ Mpc$^{-1}$, $a = -0.240$ at $k = 0.012$ Mpc$^{-1}$ and $a = -0.242$ at higher values of $k$. $P_{OLN}$ peaks at the maximum of the true distribution $P_R$ and it approximates the tails of the true distribution a bit better than the Gaussian approximations, but as Fig. 3 shows, it is still obviously different from $P_R$.

The ICN distribution (Smith et al. 2006) fits the true distribution better. Fig. 4 shows a remarkable agreement between $P_R$ and $P_{ICN}$. Writing both $-2\ln(P_R)$ and $-2\ln(P_{ICN})$ as Taylor series, we see that their Taylor coefficients are equal for $k \leq 3$ and approximately equal for much higher orders (cf. Appendix A).

4 THE EFFECT ON $f_{\text{NL}}$ MEASUREMENTS

4.1 Physical Model

In this section, we test the effect of using different posterior distribution shapes on the inference of a real observable. The largest deviations between the posteriors are at small $k$ and we would therefore expect the largest effects for parameters dependent on these modes. At these scales, (local) primordial non-Gaussianity alters the biasing law between dark-matter halos and the underlying mass-density field (Dalal et al. 2009; Matarrese & Verde 2008;
Slosar et al. 2008; Afshordi & Tolley 2008; Valageas 2010; Giannantonio & Porciani 2010; Schmidt & Kamionkowski 2010; Desjacques et al. 2011), making $f_{NL}$ a perfect test parameter of our analysis. The parameter arises in models where the potential has a local quadratic term

$$\Phi = \phi + f_{NL} \left( \phi^2 - \langle \phi^2 \rangle \right).$$

The resulting alteration of the bias can be written as

$$b(k, f_{NL}) = b_0 + \delta b(f_{NL}) + \Delta b(k, f_{NL}),$$

where $b_0$ is the bias in a Universe without primordial non-Gaussianity, $\delta b(f_{NL})$ is the scale-independent modification to the bias from the non-Gaussian form of the mass functions and (Schmidt & Kamionkowski 2010; Desjacques et al. 2011)

$$\Delta b(k, f_{NL}) \approx (b_0 - 1) f_{NL} A(k)$$

is the local scale-dependent correction due to the easier halo formation with additional long-wavelength fluctuations, which depends on the critical density $\delta_c(z)$ in the peak-background split model, as well as the matter transfer function $T(k)$, the matter density $\Omega_m$, the present-time Hubble parameter $H_0$ and the linear growth function $D(z)$ through the parameter

$$A(k, z) = \frac{3 \Omega_m \delta_c(z)}{k^2 T(k)} \left( \frac{H_0}{c} \right)^2.$$

As $\delta b(f_{NL}) \ll \Delta b(k, f_{NL})$ at our scales of interest (Slosar et al. 2008; Giannantonio & Porciani 2010), we neglect $\delta b(f_{NL})$.

Fig. 5 shows the effect of $f_{NL}$ on the galaxy power spectrum at large scales. We plot the galaxy power spectrum $P_g$ divided by the galaxy power spectrum at $f_{NL} = 0$, hence what we plot is proportional to the square of Eq. (31). At lowest $k$, negative $f_{NL}$ enhances the power spectrum due to the fact that the term proportional to $f_{NL}^2$ dominates the total bias. At slightly higher $k$, but still at large scales, the term linear in $f_{NL}$ dominates, and the power is enhanced or decreased depending on the sign of $f_{NL}$. At small, yet still linear, scales, $A(k, z)$ becomes small, thus initial local non-Gaussianities do not have an effect on the galaxy power spectrum at these scales.

Here we work to first order in $\delta$, so that we can continue to assume that $\delta_k$ is drawn from a Gaussian distribution, with an altered $P(k)$, i.e. the first order effect of non-Gaussianity is to $P_H(k)$, keeping the distribution the same. Furthermore, we do not alter $V_n$ (Eq. (24)) to include any coupling between modes from the non-Gaussian signal. Where $k$ is very small, higher order corrections to $\delta$ will become increasingly important (e.g. Tellarini et al. 2015), suggesting that the Gaussian limit for $\delta$ will break down here.
normal distribution agrees again very well with the quadratic term of the prior mean using the underlying posterior functions in Fig. 6, assuming a measurement of a power spectrum with $P_{NL}$ as expected from the spherical collapse model in an Einstein-de Sitter universe and a flat prior for $f_{NL}$. We plot $f_{NL}$ posterior functions in Fig. 6, assuming a measurement of a power spectrum with underlying $f_{NL} = 0$. $P_f$ is not symmetric, as both a linear and a quadratic term of $f_{NL}$ enter the power spectrum. The inverse cubic normal distribution agrees again very well with $P_R$. $P_R$, $P_f$ and $P_{ICN}$ reproduce the true value as their best fit estimate. Using $P_D$, the most likely value of $f_{NL}$ is $f_{NL} = -25.5$ considering the same $k$-bins as Ross et al. (2013) in their analysis of DR9 BOSS data, i.e. $0.004 \, h_{\text{Mpc}}^{-1} \lessapprox k \lessapprox 0.06 \, h_{\text{Mpc}}^{-1}$.

One has to keep in mind that there are different definitions of the measured value. The commonly published value is the posterior mean $\langle f_{NL} \rangle$, due to the fact that if $f_{NL}$ is fitted as part of a longer list of cosmological parameters, one has to rely on Markov chain Monte Carlo techniques (e.g. Lewis & Bridle 2002). In general, such techniques cannot provide accurate estimates of the best-fit value. Hence, data analysis papers more often present $\langle f_{NL} \rangle$ as their results. If the posterior is asymmetric, the best fit and posterior mean do not agree. Given a flat $f_{NL}$-prior, we expect $f_{NL} = 11.4$ using $P_R$. Based on our arguments in Sec. 2.1 and 4.1, we think of the mean of $P_R$ as the correct estimate of $f_{NL}$. This seems counterintuitive because our input was that we measure a power spectrum which corresponds to $f_{NL} = 0$, but we have to consider that $\bar{P}(k)$ is a finite empirical realisation in our part of the universe corresponding to the value of $f_{NL} = 0$ we have assumed we would measure locally, but due to the non-Gaussian shape of the posterior distribution, the ensemble average of $f_{NL}$ measured in other parts of the universe is higher than the value we set as an input for our local environment.

Our results are summarised in Tab. 3. $P_{ICN}$ reproduces the correct estimate of $f_{NL}$, whereas $P_D$ and $P_f$ estimate $f_{NL} = -11.9$ and $f_{NL} = -7.7$ respectively. The choice of the posterior distribution also affects the error estimation. If we use $P_R$ or $P_{ICN}$, the length of our postdicted 95% $f_{NL}$-confidence interval (C.I., cf. Tab. 3) is similar to the length of Ross et al. (2013)’s most naïve case ii 95% C.I., i.e. 32 < $f_{NL}$ < 198.

### 4.2 BOSS Results

We use BOSS DR9 parameters and the same CAMB linear matter power spectrum as Ross et al. (2013). We also assume $\delta_c = \frac{1.696}{D(z)}$ as expected from the spherical collapse model in an Einstein-de Sitter universe and a flat prior for $f_{NL}$. We plot $f_{NL}$ posterior functions in Fig. 6, assuming a measurement of a power spectrum with underlying $f_{NL} = 0$. $P_f$ is not symmetric, as both a linear and a quadratic term of $f_{NL}$ enter the power spectrum. The inverse cubic normal distribution agrees again very well with $P_R$. $P_R$, $P_f$ and $P_{ICN}$ reproduce the true value as their best fit estimate. Using $P_D$, the most likely value of $f_{NL}$ is $f_{NL} = -25.5$ considering the same $k$-bins as Ross et al. (2013) in their analysis of DR9 BOSS data, i.e. $0.004 \, h_{\text{Mpc}}^{-1} \lessapprox k \lessapprox 0.06 \, h_{\text{Mpc}}^{-1}$.

One has to keep in mind that there are different definitions of the measured value. The commonly published value is the posterior mean $\langle f_{NL} \rangle$, due to the fact that if $f_{NL}$ is fitted as part of a longer list of cosmological parameters, one has to rely on Markov chain Monte Carlo techniques (e.g. Lewis & Bridle 2002). In general, such techniques cannot provide accurate estimates of the best-fit value. Hence, data analysis papers more often present $\langle f_{NL} \rangle$ as their results. If the posterior is asymmetric, the best fit and posterior mean do not agree. Given a flat $f_{NL}$-prior, we expect $f_{NL} = 11.4$ using $P_R$. Based on our arguments in Sec. 2.1 and 4.1, we think of the mean of $P_R$ as the correct estimate of $f_{NL}$. This seems counterintuitive because our input was that we measure a power spectrum which corresponds to $f_{NL} = 0$, but we have to consider that $\bar{P}(k)$ is a finite empirical realisation in our part of the universe corresponding to the value of $f_{NL} = 0$ we have assumed we would measure locally, but due to the non-Gaussian shape of the posterior distribution, the ensemble average of $f_{NL}$ measured in other parts of the universe is higher than the value we set as an input for our local environment.

Our results are summarised in Tab. 3. $P_{ICN}$ reproduces the correct estimate of $f_{NL}$, whereas $P_D$ and $P_f$ estimate $f_{NL} = -11.9$ and $f_{NL} = -7.7$ respectively. The choice of the posterior distribution also affects the error estimation. If we use $P_R$ or $P_{ICN}$, the length of our postdicted 95% $f_{NL}$-confidence interval (C.I., cf. Tab. 3) is similar to the length of Ross et al. (2013)’s most naïve case ii 95% C.I., i.e. 32 < $f_{NL}$ < 198.

### 4.3 Euclid Results

We make similar predictions for the Euclid survey (Laureijs et al. 2011). We assume bias values $b(z) = \sqrt{1+z}$, matched to simulations of Orsi et al. (2010) and also assumed in Amendola et al. (2013), and number densities $\bar{n}(z)$ predicted for Euclid by Pozzetti, Hirata & Geach (2015), and a survey covering 15000 square degrees. We generate CAMB matter power spectra $P(k, z)$ for the redshift range $0.9 < z < 1.74$. Note that the aim of this article is to test how the use of different posterior shapes influences cosmological measurements, but not primarily to make $f_{NL}$-predictions. We refer to more rigorous predictions which can be found e.g. in Fedeli et al. (2011); Laureijs et al. (2011); Giannantonio et al. (2012); Yamauchi, Takahashi & Oguri (2014). These studies also include 3-point statistics, weak lensing tomography, measurements of the integrated Sachs-Wolfe effect and/or the use of the multi-tracer technique. Their constraints are therefore tighter than ours.

As Euclid will probe a much larger volume, it will accommodate many more $k$-modes and hence we see good agreement of $P_f$ with $P_R$ in Fig. 7. As against our results in Sec. 2.5, fixing the covariance provides better $f_{NL}$ results than the inferences from a posterior with varying covariance. However, $P_{ICN}$ is still the best approximation and accurately reproduces the marginalised $f_{NL}$-value of $P_R$ and its 95% C.I., whereas using $P_f$ yields the correct width of the 95% C.I., but its position and the marginalised value have an offset of 0.38 (cf. Tab. 4). We therefore still recommend either using $P_{ICN}$ or $P_R$ when cosmological models are fitted to power spectra from galaxy surveys even as large as Euclid.

|  | $f_{NL}$-predictions similar to Tab. 3, but for Euclid. |
|-------------------------------|-----------------------------------|
| posterior | $f_{NL}$ (BF) | $\langle f_{NL} \rangle$ | 95% confidence interval |
| $P_R$ | 0 | 0.24 | $9.0< f_{NL} <9.4$ |
| $P_D$ | -1.0 | -0.30 | $8.4< f_{NL} <7.8$ |
| $P_f$ | 0 | -0.14 | $9.4< f_{NL} <9.0$ |
| $P_{ICN}$ | 0 | 0.24 | $9.0< f_{NL} <9.4$ |
5 CONCLUSIONS

We have studied different posterior shapes that can be used in the fitting process of cosmological models to power spectra from galaxy surveys. As the underlying matter density field is at least approximately Gaussian, we assume that the true posterior distribution $p_H$ is based on a Rayleigh likelihood distribution in δ. Assuming Gaussian posteriors in $P(k)$, be it with a fixed or a varying covariance matrix, does not approximate $p_H$ well and yields biased best-fit values and wrong error estimates especially on large scales where statistics are not good enough to make use of the central limit theorem.

If one confines oneself to use Gaussian posterior shapes, it depends on the parameter one wants to constrain whether a fixed or varying covariance matrix provides more accurate results. We found that the posterior shape $p_D$ with varying covariance follows $p_H$ closer than $p_F$ with a fixed covariance when the power spectrum $P_H$ (or any parameter linear in the power spectrum) is fitted to the power spectrum $P$, but when $f_{NL}$ is fitted to $P$ it is the other way round.

Due to these reasons, we advise against using Gaussian posterior distributions. Instead, we have found that posterior distributions, such as the inverse cubic normal distribution, provide simple, more accurate alternatives. They confidently reproduce the correct width of the 95% confidence intervals in our simplified predictions of $f_{NL}$-measurements. However, the final decision about which posterior is the best to use should be done after testing these methods against simulations which account for the non-linear effects that we have ignored for simplicity in our analytic calculations. We leave this for future work.

A major advantage of the non-Gaussian posteriors presented in this paper, is the fact that their covariance matrices do not depend on the power spectrum of the model to be tested. The estimation of covariance matrices is a critical and computationally expensive step in the data analysis. Extensions to configuration-space analyses based on the correlation function $\xi(r)$ are left for future work.

ACKNOWLEDGMENTS

The authors would like to thank Matteo Tellarini, Ashley Ross and David Wands for valuable discussions about primordial non-Gaussianity. We thank the referee Andrew Jaffe for his helpful comments.

Some of the results in this paper have been generated using the CAMB package (Lewis et al. 2000). For some of the other results, we made use of the facilities and staff of the UK Sciama High Performance Computing cluster supported by the ICG, SEPNel and the University of Portsmouth.

WJP acknowledges support from UK STFC through the consolidated grant ST/K0090X/1, and from the European Research Council through the Darksurvey grant. LS is grateful for support from the University of Portsmouth.

APPENDIX A: COMPARISON OF $P_R$ AND $P_{ICN}$ TAYLOR SERIES

In this appendix, we compare the Taylor Series of $P_R$ and $P_{ICN}$ to explain why they are so similar. We write the hypothetical power spectrum $P_R \equiv (1+\varepsilon)|\delta_k|^2$ as a perturbation around the measured power. The Rayleigh posterior hence becomes

$$-2 \ln(P_R) = 2 \ln(1+\varepsilon) + \frac{2}{\varepsilon}.$$  \hspace{1cm} (A1)

Ignoring the irrelevant zero order contribution, the Taylor series reads

$$-2 \ln(P_R) \approx 2 \sum_{k=1}^{\infty} (-1)^k \varepsilon^k \frac{k-1}{k}. \hspace{1cm} (A2)$$

The ICN distribution in terms of $\varepsilon$ is given by

$$-2 \ln(P_{ICN}) = 9 \left[ 1 - (1+\varepsilon)^{-1/3} \right]^2$$

$$= 9 \left[ 1 - 2(1+\varepsilon)^{-1/3} + (1+\varepsilon)^{-2/3} \right]. \hspace{1cm} (A3)$$

We make use of the generalised binomial series $(1+\varepsilon)^\alpha = \sum_{\alpha=0}^{\infty} \binom{\alpha}{\alpha} \varepsilon^\alpha$, where $\binom{\alpha}{\alpha} \equiv \frac{\Gamma(\alpha+1)}{\Gamma(\alpha+1)\Gamma(\alpha+1)}$ is the generalised binomial coefficient, and obtain the series

$$-2 \ln(P_{ICN}) = 9 \sum_{\alpha=1}^{\infty} \varepsilon^\alpha \left[ \left( -\frac{\varepsilon}{\alpha} \right) - 2 \left( -\frac{\varepsilon}{\alpha} \right)^2 \right]. \hspace{1cm} (A4)$$

Again, we have ignored irrelevant constant terms. The negative entries in the binomial coefficients can be removed using $\binom{\alpha}{\alpha} = (-1)^\alpha (\alpha^-\alpha^{-1})$:

$$-2 \ln(P_{ICN}) = 9 \sum_{\alpha=1}^{\infty} (-1)^\alpha \varepsilon^\alpha \left[ \left( -\frac{\varepsilon}{\alpha} \right) - 2 \left( -\frac{\varepsilon}{\alpha} \right)^2 \right]. \hspace{1cm} (A5)$$

If we insert values for $\alpha \leq 3$, we find the equality

$$2 \frac{\alpha-1}{\alpha} = 9 \left[ \left( -\frac{\varepsilon}{\alpha} \right) - 2 \left( -\frac{\varepsilon}{\alpha} \right)^2 \right]. \hspace{1cm} (A6)$$

Thus, $P_R$ and $P_{ICN}$ are the same to third order. What is even more striking is that for larger $\alpha$, the approximation

$$2 \frac{\alpha-1}{\alpha} \approx 9 \left[ \left( -\frac{\varepsilon}{\alpha} \right) - 2 \left( -\frac{\varepsilon}{\alpha} \right)^2 \right]. \hspace{1cm} (A7)$$

still holds. For $\alpha < 17$, the two sides differ by less than 20%. Therefore, the agreement between $P_R$ and $P_{ICN}$ is high.
