Assessment of copper-iron catalyst supported on activated carbon for low-temperature nitric oxide reduction by hydrogen

Increasing emissions of nitrogen oxides associated with global industrialization necessitates the development of more sustainable NOₓ-removal systems. This research focused on synthesizing and testing catalytic materials, derived from biomass waste and Earth-abundant metals. These materials were sufficiently reactive to convert NOₓ into nitrogen, employing hydrogen as the reductant. A catalytic activity testing rig was developed for this purpose and was able to continuously monitor the concentration of NOₓ in the effluent, alongside the formation of by-products including ammonia and nitrous oxide. The catalysts in this study were prepared from palm kernel shell (PKS) activated carbon impregnated with copper and iron oxides at various compositions. Synthetic NOₓ gas was passed through the catalyst bed at a controlled temperature. A mass spectrometer MS (Hiden HPR-20, UK) provided on-line monitoring of the concentration of products using m/z ratios of 16, 17, 18, 28, 30, 44, 46 for oxygen, ammonia, water, nitrogen, nitric oxide, nitrous oxide and nitrogen dioxide respectively. Due to the compounds of interest presenting overlapping fragmentation patterns, calibration of the MS using the individual components was performed allowing deconvolution of the data. The catalytic activity of the PKS-supported copper-iron catalyst is shown in Figure 1. It can be seen that total conversion of nitric oxide was achieved beyond 150 °C, however this coincides with the formation of ammonia and nitrous oxide. The catalyst design can be improved to inhibit the formation of these by-products. These findings open the door for opportunities to develop a catalyst system that utilizes biomass waste and a renewable reductant such as green or blue hydrogen, which is cost-effective and attractive industrially [1].
