Abstract
Background/Aims: Abnormal QT prolongation is the most prominent cardiac electrical disturbance in patients with diabetes mellitus (DM). It is well known that the human ether-a-go-go-related gene (hERG) controls the rapid delayed rectifier K⁺ current (I_{Kr}) in cardiac cells. The expression of the hERG channel is severely down-regulated in diabetic hearts, and this down-regulation is a critical contributor to the slowing of repolarization and QT prolongation. However, the intracellular mechanisms underlying the diabetes-induced hERG deficiency remain unknown. Methods: The expression of the hERG channel was assessed via western blot analysis, and the hERG current was detected with a patch-clamp technique. Results: The results of our study revealed that the expression of the hERG protein and the hERG current were substantially decreased in high-glucose-treated hERG-HEK cells. Moreover, we demonstrated that the high-glucose-mediated damage to the hERG channel depended on the down-regulation of protein levels but not the alteration of channel kinetics. These discoveries indicated that high glucose likely disrupted hERG channel trafficking. From the western blot and immunoprecipitation analyses, we found that high glucose induced trafficking inhibition through an effect on the expression of Hsp90 and its interaction with hERG. Furthermore, the high-glucose-induced inhibition of hERG channel trafficking could activate the unfolded protein response (UPR) by up-regulating the expression levels of activating transcription factor-6 (ATF-6) and the ER chaperone protein calnexin. In addition, we demonstrated that 100 nM insulin up-regulated the expression of the hERG channel and rescued the hERG channel repression caused by high glucose. Conclusion: The results of our study provide the first evidence of a high-glucose-induced hERG channel deficiency resulting from the inhibition of channel trafficking. Furthermore, insulin promotes the expression of the hERG channel and ameliorates the high-glucose-induced inhibition of the hERG channel.
Introduction

An abnormal prolongation of the QT interval is a prominent electrical disorder in patients with diabetes mellitus (DM). The prevalence is up to approximately 25% in both type 1 insulin-dependent DM (IDDM) and type 2 insulin-independent DM (NIDDM) patients. QT prolongation has been proposed as a predictor of mortality in IDDM and NIDDM because this abnormality is associated with an increased risk of sudden cardiac death subsequent to lethal ventricular arrhythmias [1-4]. The QT interval reflects the integrated action potential duration (APD) in cardiac myocytes. Ion currents play an important role in cardiac APD, and multiple ion currents are decreased in the experimental animal models of diabetes [5, 6]. Therefore, sufficient knowledge of the ionic mechanisms underlying the diabetic QT in diabetes is urgently needed.

Long QT syndrome (LQTs) can be induced by a reduction in the rapid delayed rectifier potassium current (I_{Kr}), the pore-forming subunits for which are encoded by the human ether-a-go-go related gene (hERG) [7, 8]. It has been reported that the expression of the hERG channel is significantly down-regulated in diabetic hearts, and this down-regulation is a critical contributor to diabetic repolarization slowing and QT prolongation [6, 9]. However, there is still an incomplete understanding of the diabetes-induced I_{Kr}/hERG dysfunction. Immature hERG channels are folded and initially glycosylated in the ER. Subsequently, the incompletely glycosylated channels are sent to the Golgi to be fully glycosylated, followed by translocation to the cell membrane. The phosphorylation of hERG potassium channel is mainly achieved by protein kinase A, B and C (PKA, PKB, PKC) [10, 11]. The hERG channel trafficking process is monitored through quality control (QC) and the unfolded protein response (UPR), comprising a complex molecular chaperone system [12]. Therefore, hERG protein trafficking is a major factor in hERG channel expression and is under the regulation of a cytosolic chaperone network [13]. Numerous studies have shown that the inhibition of hERG protein trafficking could reduce hERG channel expression. However, it remains uncertain whether hERG protein trafficking is altered in diabetic cardiomyocytes. Therefore, the aim of our study was to further the current mechanistic understanding of diabetes-induced hERG channel abnormalities, which may aid in developing potential therapeutic approaches for this disease.

In our study, we incubated cells with high-glucose medium to generate an in vitro cellular model [14, 15]. We investigated whether the hERG protein and current were inhibited by high glucose levels in HEK293 cells that stably expressed the wild-type hERG gene. We also focused on whether high-glucose incubation could induce a trafficking dysfunction and subsequently increase degradation. Finally, we determined whether insulin affected the hERG channel expression that had been reduced by high glucose.

Materials and Methods

Cell culture

HEK293 cells stably expressing the wild-type hERG gene were used to study the effects of different concentrations of high glucose on the hERG channel. The hERG-HEK cells were cultured at 37°C in a humidified atmosphere of 5% CO₂ in Dulbecco’s modified Eagle’s Medium (DMEM; HyClone, Logan, UT, USA) supplemented with 10% (v/v) foetal bovine serum (FBS; TBD, Tianjin, China). For the hERG-HEK cells, the medium was supplemented with 400 mg/ml of geneticin (G-418, Invitrogen, Carlsbad, CA, USA) for the selection of stably transfected cells. For electrophysiological studies, the cells were harvested via trypsinization, washed twice with standard DMEM, and stored in the same medium at room temperature until further use. The cells were studied within 8 h of harvesting.

Western blot analysis

The expression of high levels of the hERG protein was monitored using western blot experiments. High glucose at different concentrations was diluted and added to hERG-HEK cells for 48 h at 37°C prior
to the western blot analysis. The cells were placed on ice and washed 3 times with 3 ml of ice-cold PBS. Subsequently, 60 µl of RIPA buffer (Bi Yun Tian, Jiangsu, China) and 0.6 µl of PMSF (Shenneng Bocai, Shanghai, China) were added to the plates, and the cells were scraped from the plates and transferred into tubes. Proteins (150 µg per sample) were separated using SDS-PAGE, transferred onto nitrocellulose membranes (Stratagene, La Jolla, CA) and incubated with primary antibodies against GAPDH (Affinity Reagents) and a specific polyclonal rabbit anti-hERG antibody (Santa Cruz Biotechnology, CA) at a 1:100 dilution. Goat anti-rabbit Alexa Fluor 700 (dilution 1:2,000, Molecular Probes, Eugene, OR) was used as the secondary antibody. An Odyssey infrared fluorescent scanning system (LI-COR, Lincoln, NE) was used to detect the membrane proteins. The band densities were quantified through densitometry using the Scion Image software (Scion, Frederick, MD). The data were normalized to GAPDH.

**Immunoprecipitation**

The hERG-HEK cells were washed 3 times with PBS on ice and transferred to a 1.5-ml tube. The cells were centrifuged for 5 min at 3,000 rpm, and 300 µl of RIPA plus 3 µl of PMSF was added to the pellet. The uniformly mixed suspension was placed on ice for 10 min and then centrifuged for 10 min at 12,000 rpm. The supernatant protein concentration was measured using the Bradford method. Two micrograms of anti-hERG, anti-Hsp70 or anti-Hsp90 antibody was separately mixed with the protein, and the mixture was placed on a 360° shaker overnight at 4°C. Subsequently, 40 µl of beads (Santa Cruz A-G SC-2003) was added to the mixture, and the tubes were placed on a shaker overnight at 4°C. The mixture was centrifuged at 1,500 rpm for 5 min, and the pellet was washed 6 times with TBST on ice. Next, 100 µl of loading buffer was added to the pellet, and the tubes were boiled for 10 min, followed by centrifugation. The supernatants were collected and separated via SDS-PAGE; proteins were transferred to a PVDF membrane, which was then blocked with 5% non-fat milk, incubated with anti-hERG, anti-Hsp90, or anti-Hsp70 (Santa Cruz, sc-8-17) antibody, and then a secondary antibody. The supernatants were collected and analysed through western blot analysis.

**Patch-clamp recording techniques**

For the electrophysiological recordings, submaximally confluent cells were used after 1–3 days of culture at a seeding density of 1–4 × 10⁵ cells per flask (NEST). After incubation with high glucose for 48 h, the hERG-HEK cells were trypsinized, centrifuged and stored at 4°C in a bath solution for 1 h to stabilize separated single cells. The cells were transferred to a small cell bath mounted on the stage of an inverted microscope (IX-70; Olympus, Tokyo) and incubated for approximately 10 min to facilitate attachment to the glass bottom. The cells were then continuously superfused at a rate of 1.5 ml/min.

The hERG currents were measured using the whole-cell configuration patch-clamp recording technique. The whole-cell configuration was formed using a glass pipette with a tip resistance of 2–5 MΩ when filled with the following pipette solution: 130 mM KCl, 1 mM MgCl₂•6H₂O, 10 mM HEPES, 5 mM Mg-ATP, 5 mM EGTA, and 0.1 mM GTP (pH 7.3 with KOH). The extracellular solution contained 136 mM NaCl, 5.4 mM KCl, 5 mM HEPES, 1 mM MgCl₂•6H₂O, 1 mM CaCl₂ and 10 mM glucose (pH 7.4 with NaOH). An Axopatch-200B patch-clamp amplifier was used to record the membrane current. Computer software (Clampex 9.2; Axon Instruments, USA) was used to generate the voltage clamp protocols and acquire data. The capacitance and series resistance compensation were optimized. The data were recorded on a computer via Digidata 1322A and analysed using Clampfit 9.2 (Axon Instruments) and Prism (GraphPad Inc., San Diego, CA, USA) software. Graphical fits of the data were generated using previously described standard equations [16].

**Statistical analyses**

The data are presented as the means ± S.E.M. Statistic analysis was performed using the SPSS 16.0 software to evaluate statistically significant differences. Student’s t-test was used for comparisons between two groups, and a one-way or two-way analysis of variance (ANOVA) was used to analyse significant differences between groups under different conditions. Differences between the two groups were considered significant when the P-values were < 0.05 (two-tailed). All the graphs were drawn using GraphPad Prism 5.0 software.
Results

**High-glucose treatment reduces hERG protein levels and hERG current**

High blood glucose is a major factor for cardiomyopathy in patients with diabetes DM [17]. Therefore, in the present study, we incubated cells with 50, 75 and 100 mM glucose to mimic hyperglycaemia (HG). To investigate the long-term effects of high glucose on the expression of hERG channels, western blot analysis was performed. As shown in Fig. 1A, hERG protein levels were significantly decreased after incubation with different high-glucose concentrations for 48 h. Fig. 1A indicates the densities of the hERG 155- and 135-kDa bands after high-glucose treatment relative to the respective control values. High-glucose treatment reduced the density of the 155-kDa band by 25.57% ± 2.32% (50 mM),

---

**Fig. 1.** The different high-glucose concentrations down-regulated both the mature and immature forms of the hERG channel. (A) Western blot results showing that high-glucose significantly reduced both the 135-kDa and 155-kDa of hERG channel in a concentration-dependent manner (50, 75 and 100 mM). *P < 0.05 vs. control, n = 6. (B) Voltage clamp protocol and representative hERG current traces recorded from different experimental groups under the same conditions as described above. 33.05% ± 5.24% (75 mM) and 51.35% ± 3.46% (100 mM). The density of the 135-kDa band was reduced by 28.99% ± 4.64% (50 mM), 37.83% ± 3.83% (75 mM) and 42.89% ± 5.28% (100 mM).

To determine whether the reduction in the level of mature hERG protein causes a dysfunction in the hERG current, patch-clamp recordings were used to detect the hERG...
Shi et al.: High Glucose Inhibits hERG Trafficking

Current. Fig. 1B and C illustrates the effects of high glucose on the tail current of the hERG channel. The hERG current was substantially reduced in a concentration-dependent manner with high-glucose treatment. The ratio of inhibition by high glucose was calculated using the tail current from -20 to 30 mV and the function \( \frac{I_{\text{high-glucose}} - I_{\text{Control}}}{I_{\text{Control}}} \). As depicted in Fig. 1E, the ratios in the 50 mM, 75 mM and 100 mM groups were -0.27, -0.47 and -0.60 at +30 mV, respectively.

Long-term treatment with high glucose does not affect channel kinetics

We used patch-clamp recordings to detect the long-term effects of high glucose on the hERG channel kinetics. The steady-state activation curves in Fig. 2A were constructed after normalizing the tail currents at various test potentials to the maximum current and were plotted against the pre-pulse voltages. The data were fitted using the Boltzmann function. As shown in Fig. 2A, the activation voltage \( V_{1/2} \) values were -6.12 ± 0.57 mV in the control group and -6.44 ± 0.64 mV in the 50 mM high-glucose group. The corresponding slope factor \( k \) values were 7.68 ± 0.51 and 8.67 ± 0.58, respectively. High glucose did not affect the activation of the hERG channel.

Furthermore, we determined whether high glucose affects the inactivation of the hERG channel. Fig. 2B illustrates the voltage clamp protocol and representative current tracing for...
High glucose inhibits hERG trafficking

Figure 2C demonstrates the effect of high glucose on the inactivation curve after a 48-h incubation. High glucose did not significantly shift the inactivation curve: the $V_{1/2}$ was $-79.58 \pm 9.87$ mV in the control group and $-69.82 \pm 7.81$ mV in the 50 mM high-glucose group, and the $k$ was $-50.27 \pm 9.25$ and $-50.73 \pm 9.12$, respectively.

The time courses for the development of and recovery from inactivation were also assessed. Figure 2D and E depicts the voltage clamp protocol and a representative current tracing for the onset of inactivation and recovery from inactivation. Figure 2F shows the differences in the time constants for steady-state inactivation and recovery between the control group and the group exposed to 50 mM high glucose were not significant. Moreover, we observed that high glucose inhibited the hERG current but did not alter the kinetics of channel gating, suggesting that the high-glucose-mediated damage of the hERG channel is dependent upon a reduction in the protein level.

**High-glucose induces a trafficking deficiency of the hERG channel**

The inhibition of trafficking is known to be one mechanism for the hERG deficiency. Because the cytosolic chaperones Hsp70 and Hsp90 participate in hERG trafficking, we used western blot analysis to investigate whether high glucose alters the steady-state expression...

Fig. 3A and B shows that the expression of Hsp90 is decreased in the presence of high glucose, whereas Hsp70 expression is not changed. In addition, we used immunoprecipitation to detect whether high glucose modifies the association of hERG channels with Hsp70 and/or Hsp90. As indicted by Fig. 3C and D, in the presence of high glucose at 75 mM, the interaction between the hERG protein and Hsp90 was significantly decreased, while the interaction between the hERG protein and Hsp70 was increased. Taken together, these results demonstrated that the high-glucose-induced trafficking deficiency of hERG channels likely reflects alterations in the interactions between the hERG proteins and chaperones.

High glucose activates unfolded protein response (UPR)

The UPR is a process that prevents the accumulation of unfolded proteins in the ER. Active transcription factor-6 (ATF-6) has been identified as a marker protein of the UPR; therefore, we further detected the effect of high glucose on ATF-6. Fig. 4A reveals that the expression of ATF-6 (~90 kDa) was significantly decreased, while the expression of the cleaved form of ATF-6 (~50 kDa) was proportionally increased. These results demonstrate that ER stress is activated after incubation with high glucose for 48 h. Calnexin and calreticulin, identified as chaperone proteins and downstream targets of cleaved ATF-6, have been reported to interact with unfolded hERG proteins and subsequently contribute to their degradation. Based on these findings, we further tested whether calnexin/calreticulin expression was altered by high glucose treatment. Based upon the results depicted in Fig. 4B and C, we found that the expression of calnexin was significantly increased, while the expression of calreticulin was not altered in the presence of high glucose for 48 h.

High-glucose enhances the degradation of hERG channels

To assess the effects of high glucose on the degradation of mature hERG channels, we used the Golgi transit inhibitor brefeldin A (BFA) to inhibit the conversion of hERG from the immature 135-kDa form to the mature 155-kDa form [18]. The hERG-HEK cells were pretreated with BFA (10 µM) for 1 h and then cultured in the absence or presence of high glucose at 75 mM in the continued presence of BFA. Western blot analysis was used to detect the expression of the 155-kDa band at different time points after BFA treatment. The degradation rate of hERG was indicated by the normalized 155-kDa band intensity. As shown in Fig. 5, the expression of mature hERG protein is reduced in a time-dependent manner in presence of BFA. The image on the right side of Fig. 5 indicates that, in control cells, incubation with BFA for 8 h decreased the 155-kDa hERG band intensity by approximately 40%. In contrast, in the high-glucose-treated cells, the 155-kDa hERG band intensity decreased approximately 62%. Therefore, these results demonstrated that the degradation rate of mature hERG channels was significantly enhanced after exposure to high glucose at 75 mM.

Fig. 5. Western blot results reveal that high-glucose incubation accelerated the degradation of the mature form of the hERG channel. hERG-HEK cells were treated without (control) or with high glucose (75 mM) in the presence of BFA (10 µM), which blocks hERG protein transport from the ER to the Golgi. Experimental cells were harvested at the indicated time points for western blot analysis. The intensities of the 155-kDa mature hERG bands at each time point were normalized to the time 0 h value. *P < 0.05 vs. control, n = 3.
Insulin rescues hERG deficiency after high-glucose treatment

We determined the effect on hERG channel expression of long-term treatment (48 h) with 100 nM insulin by assessing the levels of mature hERG protein and hERG current. As illustrated in Fig. 6A, the results indicated that the expression of the 155-kDa hERG band...
increased after treatment with 100 nM insulin for 48 h. Subsequently, we used patch-clamp recordings to detect the effect of the chronic application of insulin on the hERG current. The increased expression of the mature hERG protein on western blots was also reflected in the electrophysiological recordings. The results shown in Fig. 6B revealed that the hERG tail current is significantly increased after treatment with 100 nM insulin for 48 h.

We also used western blot analysis to investigate whether 100 nM insulin could rescue the hERG protein reduction caused by high glucose at 75 mM. As depicted in Fig. 6C, the expression level of the hERG protein was significantly reduced after incubation with 75 mM glucose. However, the application of 100 nM insulin ameliorated the inhibition of the hERG channel caused by high glucose. To further demonstrate whether the hERG protein that was restored by insulin treatment is functional, we used a patch-clamp technique to record the hERG current under the same conditions as described above. In a similar manner, 100 nM insulin reversed the down-regulation of the hERG current induced by high glucose at 75 mM (Fig. 6D). The inhibitory ratio of high glucose was calculated from the tail current at +30 mV using the function $(I_{\text{high-glucose}} - I_{\text{Control}})/I_{\text{Control}}$. As indicated in Fig. 6E, the ratio was -0.44 at 30 mV. The rescue ratio for 100 nM insulin was 0.31 at +30 mV, calculated using the function $(I_{\text{Insulin}} - I_{\text{Control}})/I_{\text{Control}}$.

To determine how insulin reverses the down-regulation of the hERG channel, we examined the effect of insulin on Hsp90 protein expression. As displayed in Fig. 6F, the expression of Hsp90 was decreased in the presence of high glucose, and insulin significantly recovered the Hsp90 expression. Moreover, the expression of Hsp90 increased after incubation with 100 nM insulin. These data indicated that insulin likely ameliorated hERG inhibition through improved hERG protein trafficking.

**Discussion**

In the present study, we demonstrated for the first time that both hERG protein expression and hERG current were decreased in high-glucose-treated hERG-HEK cells. A novel mechanism was revealed, which is that high glucose induces a hERG channel trafficking deficiency by inhibiting the expression of Hsp90 and the hERG/Hsp90 complex. Subsequently, the ER stress response and increased protein degradation are activated in high-glucose-treated hERG-HEK cells. Moreover, the application of 100 nM insulin restored the expression of the hERG protein and hERG current. These findings indicate that the inhibition of trafficking represents a potential mechanism underlying the hERG deficiency in diabetic cardiomyopathy.

In our study, a reduction in the expression of the hERG protein and hERG current was observed after treatment with high glucose (Fig. 1); nevertheless, hERG channel kinetics were not altered (Fig. 2). These results indicated that high glucose inhibited the hERG channel through a disruption in hERG protein expression. It is well known that hERG protein trafficking is regulated through a cytosolic chaperone network [13]. Currently, only a few chaperones participating in hERG trafficking have been confirmed, including Hsp70, Hsp90, GM130 and the 14-3-3 protein [19]. Among these chaperones, Hsp70 and Hsp90 are the best characterized and play the most important roles. In the ER, Hsp70 binds to the initial hERG, while in the cytoplasm, Hsp90 binds to the terminal hERG to assist in folding [20]. These proteins co-precipitate with the hERG protein and are essential for hERG maturation [20, 21]. Therefore, we determined whether high glucose levels modified the expression levels of Hsp90 and/or Hsp70 and the association of hERG channels with Hsp90 and/or Hsp70. In our study, we found that the expression of Hsp90 was reduced but Hsp70 expression was not altered in the presence of high glucose (Fig. 3A and B). These results are similar to those of a previous study showing that Hsp90 expression was significantly decreased in diabetic glomeruli [22]. Furthermore, treatment with high glucose at 75 mM reduced the formation of hERG/Hsp90 complexes, while the formation of hERG/Hsp70 complexes was increased (Fig. 3C and D). Taken together, these data demonstrate that the high-glucose-induced trafficking
deficiency is likely caused by the inhibition of Hsp90 expression and alterations in hERG/Hsp90 interactions.

A trafficking deficiency in the hERG channel is activated through the ER stress response [23-25]. The UPR, which indicates the occurrence of an ER stress response, increases the synthesis of chaperone proteins and prevents the accumulation of unfolded protein in the ER [26, 27]. The UPR comprises three pathways: ATF-6, IRE-1 and PERK, and ATF-6 is a key regulator in the initial response [28]. ATF-6 comprises two forms: an inactive form (90 kDa) and an active, cleaved form (50 kDa). Cleaved ATF-6 initiates the expression of target genes and increases the expression of chaperone proteins to assist in hERG channel folding [26, 28]. Calnexin and calreticulin are two key ER chaperone proteins that ensure the proper folding of newly synthesized proteins and other QC mechanisms [27, 29]. The results of our study revealed that the application of high glucose impedes hERG channel trafficking. We consistently found that a decreased expression of inactive ATF-6 and increased expression of active, cleaved ATF-6 were induced in the presence of high glucose (Fig. 4A). Moreover, the expression of calnexin was up-regulated, although calreticulin expression was not changed (Fig. 4B and C). These results indicate that the trafficking deficiency in the hERG channel caused by high glucose activates the UPR. In addition, recent studies have shown that misfolded and retained trafficking-defective proteins are eventually degraded by a process termed ER-associated degradation [24, 30]. Thus, we used western blot analysis to monitor the rate of hERG degradation. The results indicated that the application of high glucose for 48 h enhances the degradation rate of mature hERG channels (Fig. 5).

Several studies have reported that hERG depression is induced by oxidative stress, and indeed insulin has antioxidant properties and reduces intracellular levels of ROS [31-33]. Moreover, insulin improves I\textsubscript{Kr}/hERG function in IDDM rabbits via its antioxidative actions [9]. Another study demonstrated that insulin improves depressed I\textsubscript{Kr} in diabetic rats [34]. In the present study, insulin significantly increased the expression of the hERG protein and hERG current (Fig. 6A and B). Furthermore, the high-glucose-induced reduction of the hERG protein and hERG current can be ameliorated by insulin, due to insulin’s effect in promoting the expression of the hERG channel (Fig. 6C to E). The reduced expression level of Hsp90 negatively affects hERG channel folding and maturation [20]. The expression of Hsp90 thus plays an important role in the expression of the hERG channel. Therefore, in this study, we assessed the effect of insulin and high-glucose on Hsp90 protein expression. The results (Fig. 6F) revealed that, in the presence of insulin, the depression of Hsp90 that was caused by high glucose was significantly recovered, and the expression of Hsp90 was increased. These results indicated that insulin has the potential to improve the hERG protein trafficking deficiency, demonstrating an important mechanism whereby insulin ameliorates high-glucose-induced hERG inhibition. Our results demonstrate that high-glucose-induced hERG dysfunction is both preventable and reversible, and insulin is highly effective in the treatment of these diabetic electrical problems.

In summary, our results provide the first evidence that high glucose induces hERG channel deficiency by impairing hERG channel trafficking. This finding illustrates a novel intracellular mechanism underlying the diabetic-induced hERG channel expression deficiency. Furthermore, we demonstrated that insulin is highly effective in rescuing the hERG deficiency induced by high-glucose treatment in hERG-HEK cells. Taken together, these findings will greatly improve the current understanding of the hERG deficiency in diabetic cardiomyopathy and may provide an effective therapeutic approach for the electrical problems in diabetic patients.
