The synthesis of 60S ribosomal subunits in \textit{Saccharomyces cerevisiae} requires Tif6p, the yeast homologue of mammalian eukaryotic translation initiation factor 6 (eIF6). In the present work, we have isolated a protein kinase from rabbit reticulocyte lysates on the basis of its ability to phosphorylate recombinant human eIF6. Mass spectrometric analysis as well as antigenic properties of the purified kinase identified it as casein kinase I. The site of in vitro phosphorylation, which is highly conserved from yeast to mammals, was identified as the serine residues at positions 174 (major site) and 175 (minor site). The homologous yeast protein Tif6p was also phosphorylated in vivo in yeast cells. Mutation of Tif6p at serine-174 to alanine reduced phosphorylation drastically and caused loss of cell growth and viability. When both Ser-174 and Ser-175 were mutated to alanine, phosphorylation of Tif6p was completely abolished. Furthermore, while wild-type Tif6p was distributed both in nuclei and the cytoplasm of yeast cells, the mutant Tif6p (with Ser174Ala and Ser175Ala) became a constitutively nuclear protein. These results suggest that phosphorylatable Ser-174 and Ser-175 play a critical role in the nuclear export of Tif6p.

Eukaryotic translation initiation factor 6 (eIF6), a monomeric protein of about 26 kDa, was originally isolated from the postribosomal supernatant of both wheat germ and mammalian cell extracts based on an assay that measured the ability of the protein to bind to the cytoplasmic 60S ribosomal subunit and prevent its association with the 40S ribosomal subunit (18, 21, 22, 25, 27). Because of this ribosomal subunit antiassoication property, eIF6 was thought to provide a pool of free ribosomal subunits required for translation initiation in eukaryotic cells. The protein was therefore classified as an eIF (16), although its role in translation of mRNAs was not defined in these original studies. More recently, the cloning of the human cDNA (25) and then of the \textit{Saccharomyces cerevisiae} gene encoding eIF6 has allowed detailed characterization of the function of eIF6 in yeast cells (23, 26, 30). Molecular genetic analysis has now provided compelling evidence that at least in yeast cells, eIF6, encoded by the essential gene, TIF6, does not function as a canonical translation initiation factor (26). Rather, eIF6, designated Tif6p in yeast, is necessary for the formation of 60S ribosomal subunits. Lack of Tif6p prevents the processing of pre-rRNA to form the mature 25S and 5.8S rRNAs, the constituents of the 60S ribosomal particle (2). In agreement with this observation, it was observed that Tif6p, in addition to its localization in the cytoplasm, is also present in the nuclei of yeast cells (2). Furthermore, recent proteomic analysis of yeast nucleolar 60S preribosomal particles (also called 66S preribosomes), which are the intermediates in the synthesis and assembly of 60S ribosomal subunits, has shown that Tif6p is part of a multiprotein assembly complex associated with the 60S preribosomal particles (4, 10).

During the course of purification of eIF6 from mammalian and yeast cells, we observed that in cruder protein fractions, eIF6 migrated as a doublet as judged by Western blot analysis. Treatment of these protein fractions with calf intestinal alkaline phosphatase resulted in the migration of eIF6 as a single polypeptide band. These results suggested that eIF6 may be phosphorylated in eukaryotic cells. In view of the well-established notion that phosphorylation regulates the biological activity of many proteins, we purified and characterized the mammalian protein kinase responsible for the phosphorylation of eIF6.

In this paper, we describe the purification and the characterization of the mammalian protein kinase from rabbit reticulocyte lysates that is responsible for phosphorylation of mammalian eIF6 in vitro. We identify the protein kinase as casein kinase I (CK I). The site of phosphorylation, which is highly conserved between yeast and mammals, has been identified as the serine residues at positions 174 and 175. We further show that the yeast protein Tif6p is also phosphorylated in vivo in yeast cells, and mutation of Ser-174 and Ser-175 of Tif6p to alanine completely abolishes phosphorylation of Tif6p and causes loss of yeast cell growth and viability. Furthermore, unphosphorylated Tif6p was localized exclusively in the nuclei.

of yeast cells, suggesting that phosphorylation of Tif6p is involved in passage of Tif6p to the cytoplasm.

MATERIALS AND METHODS

Strains, plasmids, and genetic techniques. The S. cerevisiae haploid strain KSY606, containing the chromosomal copy of the TIF6 gene inactivated by insertion of a HIS3 marker gene and harboring a centromere (CEN) expression plasmid that expresses Tif6p from its natural promoter, was constructed from the diploid yeast strain W303a/a as described previously (2). All other yeast strains in this work were derived from KSY606 and are described in Table 1. Yeast cells were grown at 30°C either in rich YPD medium (1% [wt/vol] yeast extract, 2% [wt/vol] Bacto Peptone) or in YPGal medium, in which 2% [wt/vol] galactose replaced dextrose as the carbon source. Where indicated, haploid yeast cells were also grown in synthetic complete medium (0.67% Bacto Peptone, 2% sodium dodecyl sulfate [SDS], and 0.01% bromphenol blue) and heating of the mixtures at 100°C for 3 min. The reaction mixtures were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) (15% gel), and the dried gel was analyzed by using autoradiography.

Isolation of maximally phosphorylated eIF6 for mass spectrometric analysis. Two reaction mixtures (50 µl each), one containing [γ-32P]ATP (100 cpm/pmol), and the other without ATP, were prepared as described above in “Assay for eIF6 kinase activity” except that each reaction mixture contained 100 pmol of recombinant mammalian eIF6 and 0.5 µg of purified eIF6 kinase. After incubation at 30°C for 30 min, each reaction mixture was subjected to SDS-PAGE, the polypeptide band corresponding to eIF6 was excised and destained, and enzymatic digestion with trypsin was performed in-gel. Resultant peptides were extracted and analyzed by mass spectrometry by using a PerSeptive Biosystems matrix-assisted laser desorption ionization–time of flight voyager DE-STR mass spectrometer in the laboratory for macromolecular analysis at the Albert Einstein College of Medicine of Yeshiva University.

Purification of eIF6 kinase from rabbit reticulocyte lysate. The preparation of crude ribosomal 0.5 M KCl wash proteins from 300 ml of rabbit reticulocyte lysates was as described previously for the isolation of eIF5 (3). The dialyzed 0.5 M KCl wash proteins were loaded onto a DEAE cellulose column (60-ml bed volume), previously equilibrated in buffer A (20 mM Tris-HCl [pH 7.5], 1 mM dithiothreitol [DTT], 0.2 mM EDTA, 0.5 mM phenylmethylsulfonyl fluoride [PMSF], and 5% glycerol) containing 100 mM KCl. The column was washed with the same equilibration buffer. The unretarded protein fraction was then applied to a 60-ml-bed-volume phosphocellulose column equilibrated in a buffer A–500 mM KCl. After the column was washed with buffer A–100 mM KCl, the bound proteins were eluted stepwise with buffer A–300 mM KCl followed by buffer A–750 mM KCl. The eIF6 kinase activity was detected in the 750 mM KCl eluate. Fractions containing the bulk of the kinase activity were pooled, and the proteins present in the pooled fractions were precipitated by adding solid ammonium sulfate to 70% saturation. The precipitated proteins were dialyzed in 1.5 ml of buffer A–500 mM KCl, dialyzed for about 2 h against the same buffer, and then concentrated to about 0.5 ml by Centricon-10 filtration. The concentrated protein sample (5 mg of protein) was then applied to a 35-ml-bed-volume Sephadex G-75 superline column (1.4 by 89 cm) equilibrated in buffer A–500 mM KCl. The column was developed with the same buffer, and fractions of 1 ml were collected. Fractions 17 to 20 containing eIF6 kinase activity (500 µg of protein) were pooled, dialyzed against buffer A–100 mM KCl to reduce the ionic strength of the pooled fraction to that of buffer A–100 mM KCl, and then purified by gradient elution (buffer A–100 mM KCl to buffer A–500 mM KCl) from a fast-performance liquid chromatography (FPLC) Mono S column (1-ml bed volume). eIF6 kinase activity eluted at about 320 mM KCl. Active fractions were pooled and stored in small aliquots at −70°C.

Assay for eIF6 kinase activity. Phosphorylation of eIF6 was carried out in reaction mixtures (10 µl each) containing 20 mM Tris-HCl (pH 7.5), 1 mM MgCl2, 100 mM KCl, 1 mM DTT, 1 mM γ-[32P]ATP (2,000 cpm/pmol), and 50 to 200 ng of eIF6 kinase-containing protein fraction. Following incubation for 15 min at 30°C, the reactions were terminated by the addition of 10 µl of an electrophoresis loading buffer (250 mM Tris-HCl [pH 6.8], 570 mM 2-mercaptoethanol, 2% sodium dodecyl sulfate [SDS], and 0.01% bromphenol blue) and then disrupted by sonication. After the cell debris was removed by centrifugation, a cocktail of protease inhibitors was added to the supernatant and heating of the mixtures at 100°C for 3 min. The reaction mixtures were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) (15% gel), and the dried gel was analyzed by using autoradiography.

FIG. 1. eIF6 is phosphorylated in HeLa and yeast cells. (A) Cell extracts of HeLa cells were fractionated into nuclear (N) and cytoplasmic (C) fractions. Where indicated, aliquots of each fraction were preincubated with calf intestinal alkaline phosphatase (CIAP). These fractions (lanes d and c) and untreated controls (lanes b and a) were preincubated with calf intestinal alkaline phosphatase (CIAP). These fractions (lanes d and c) and untreated controls (lanes b and a) were subjected to Western blot analysis by using anti-mammalian eIF6 antibodies as probes. (B) Nuclear and cytoplasmic fractions derived from extracts of KSY607 yeast cells, expressing HA-tagged Tif6p, were preincubated either with calf intestinal alkaline phosphatase (lanes c and d) or with buffer (lanes a and b) and then subjected to Western blot analysis by using anti-HA antibodies as probes. (C) Cell extracts of 32P-labeled yeast cells expressing either HA-Tif6p (strain KSY607) or untagged Tif6p (strain KSY606) were immunoprecipitated with anti-HA antibodies. The washed immunocomplexes were subjected to SDS-PAGE followed by electrophoretic transfer onto a polyvinylidene difluoride membrane.
RESULTS

**eIF6 appears to be phosphorylated in mammalian and yeast cells.** Our initial experiments were to determine whether eIF6 is phosphorylated in eukaryotic cells. HeLa cell extracts were fractionated into nuclear and cytoplasmic fractions. Western blot analysis of these fractions showed that eIF6 migrated as multiple immunoreactive bands. In contrast, purified mammalian eIF6 from rabbit reticulocyte lysates migrated as a single band (Fig. 1A, compare lanes b and c with lane a). When these extracts were preincubated with calf intestinal phosphatase prior to Western blot analysis (Fig. 1A, lanes d and e), a single immunoreactive polypeptide corresponding to the faster-migrating polypeptide was observed. These results suggested that in HeLa cell extracts, a fraction of eIF6 is phosphorylated.
When extracts of KSY607 yeast cells, expressing HA-tagged Tif6p (Table 1), were fractionated into nuclear and cytoplasmic fractions and then subjected to Western blot analysis, two immunoreactive polypeptide bands were observed, although the faster-migrating band was much more intense than the slower-migrating polypeptide (Fig. 1B, lanes a and b). Here again, treatment of these fractions with calf intestinal phosphatase prior to Western blot analysis resulted in the appearance of only one immunoreactive polypeptide band corresponding to the faster-migrating band of Tif6p (Fig. 1B, lanes c and d).

To confirm that Tif6p is indeed phosphorylated in vivo in yeast cells, we labeled KSY607 cells with [32P]orthophosphate, and Tif6p present in cell lysates was immunoprecipitated by using monoclonal anti-HA antibodies. The immunocomplexes were resolved by SDS-PAGE followed by autoradiography of the dried gel. A major [32P]-labeled polypeptide, which migrated with the same mobility as HA-Tif6p isolated from KSY607 cells, was observed (Fig. 1C, compare lanes b and d). No radioactive polypeptide band corresponding to Tif6p was immunoprecipitated from [32P]-labeled cell extracts of an isogenic yeast strain KSY606, whose Tif6p was not tagged (Fig. 1C, lanes a and c). These results suggest that Tif6p is phosphorylated in yeast cells.

**Isolation and initial characterization of an eIF6 protein kinase from rabbit reticulocyte lysate.** We made the initial observation that rabbit reticulocyte lysates contain a protein kinase activity that phosphorylates bacterially expressed recombinant human eIF6 by using [γ-32P]ATP as the phosphorylation donor (data not shown). Fractionation of the crude lysate into ribosomes and postribosomal supernatant showed that eIF6 kinase activity was associated mainly with ribosomes, from which it can be eluted by treatment of the ribosomes with 0.5 M KCl (data not shown). The purification of the eIF6 kinase from 0.5 M KCl ribosomal wash fraction is outlined in Materials and Methods. The eIF6 kinase activity was unretarded in the DEAE cellulose column but bound strongly to a phosphocellulose column from which the kinase activity was eluted with a buffer containing 0.75 M KCl. When the concentrated phosphocellulose eluate was purified by using a Sephadex G-75 gel filtration column, the eIF6 kinase activity eluted as a protein of about 30 to 35 kDa (Fig. 2A). The pooled phosphocellulose fractions were further purified by FPLC on a Mono S column (Fig. 2B). Analysis of the purified Mono S fraction by SDS-PAGE followed by silver staining showed one major polypeptide band of apparent molecular mass of about 35 kDa and two minor higher-molecular-mass bands of about 45 to 48 kDa (Fig. 2C).

Tryptic peptides from the major species were fractionated by high-performance liquid chromatography and analyzed by mass spectrometry and Edman degradation sequencing. The derived peptide sequences were identified to be those of CK Iα (20). In agreement with these results, we observed that when the pooled Sephadex G-75 fractions as well as eluates from the Mono S column were subjected to Western blot analysis by using polyclonal anti-human CK Iα antibodies (Santa Cruz) as probes (Fig. 2D), immunoreactive polypeptide bands corresponding to mammalian CK Iα were found to comigrate with the eIF6 kinase activity. These results suggested that eIF6 kinase present in rabbit reticulocyte lysates is CK Iα. Further confirmation for this conclusion came from the observation that recombinant eIF6 was efficiently phosphorylated by purified CK I from rat liver (Fig. 2E) as well as by purified bacteria expressed recombinant mammalian CK Iα and CK Iβ isoforms (Fig. 2F and G, respectively).

**Identification of the amino acid residues of eIF6 phosphorylated by purified eIF6 kinase.** Phosphoamino acid analysis of mammalian eIF6 phosphorylated in vitro by purified eIF6 kinase from rabbit reticulocyte lysates showed that serine was the...
only amino acid residue phosphorylated (data not shown). To identify the serine residue(s) in mammalian eIF6 that is phosphorylated in vitro, eIF6 was maximally phosphorylated in vitro by the purified kinase, and phosphorylated eIF6 was isolated free of the unreactive components by SDS-PAGE as described in Materials and Methods. Both the maximally phosphorylated and the unphosphorylated eIF6 (40 pmol each) were digested completely with trypsin by following established protocols. The digested products were divided into two parts, and one part was treated with alkaline phosphatase. By comparing matrix-assisted laser desorption ionization–time of flight spectra recorded before and after alkaline phosphatase treatment, we concluded that a serine residue present in the tryptic peptide spanning from Thr-165 to Arg-183 (Fig. 3A) was phosphorylated. This tryptic peptide contains three serine residues at positions 166, 174, and 175. In this tryptic peptide, the possible serine phosphorylation sites for CK I are Ser-174 and Ser-175, as predicted from the known phosphorylation motif (D/E)_nX-X-S/T for CK I (where X is any amino acid) (9).

The greater number of acidic amino acids in the vicinity of the serine residue, the stronger is the site of serine phosphorylation since CK I is one of the small family of acidotropic protein kinases (6).

To verify that Ser-174 and/or Ser-175 is indeed the site for in vitro eIF6 phosphorylation, we carried out site-directed mutagenesis in the eIF6-encoding sequence of mammalian cDNA such that each of these two serine residues, either alone or in combination, was converted to alanine in the bacterially expressed eIF6 protein. The purified mutant eIF6 proteins (Fig. 3B) were then used as substrates for in vitro phosphorylation by purified rabbit reticulocyte eIF6 kinase (CK I/H9251) and by the recombinant CK I/H9254 isoform. As shown in Fig. 3C and D, mutation of Ser-174 to alanine completely abolished in vitro phosphorylation both by purified rabbit reticulocyte eIF6 kinase and by the recombinant CK I/H9254 isoform. Among these two sites, Ser-174 appears to be the major phosphorylation site since mutation of Ser-175 alone to alanine abolished phosphorylation by only about 15% while mutation of Ser-174 to alanine
The eIF6 protein was efficiently phosphorylated both by purified reticulocyte kinase (data not shown) and by purified CK I (Fig. 3D), as expected. Taken together, these results show that the serine residue at position 174 of Tif6p is essential for cell growth and viability. Furthermore, mutation of Ser-174 and Ser-175 of Tif6p to aspartate, to mimic negatively charged phosphate residues, also failed to support yeast cell growth (Fig. 4B). Taken together, these results show that the serine residue at position 174 of Tif6p is essential for cell growth and viability.

To investigate the phosphorylation status of Tif6p expressed from the mutant Tif6p expression plasmids, we grew the yeast strains (the His \(^+\) Ura \(^-\) Leu \(^+\) transformants shown in Fig. 4B, left panel), harboring both the untagged wild-type TIF6 gene in a URA3 plasmid and the HA-tagged mutant or wild-type TIF6 in a LEU2 plasmid, in low-phosphate medium. These cells were labeled with \(^{32}\text{P}\)orthophosphate, and Tif6p present in the cell lysates was immunoprecipitated with anti-HA antibodies (Fig. 5). Whereas the wild-type HA-Tif6p was phosphorylated with \(^{32}\text{P}\) as expected, there was virtually no incorporation of \(^{32}\text{P}\) into the mutant HA-Tif6p (S174A, S175A) (Fig. 5, lower panel, compare lanes b and c). In contrast, the amount of \(^{32}\text{P}\) in the mutant Tif6p protein (S175A) was only somewhat reduced (approximately 15% reduction) (Fig. 5, lane e) while in the Tif6p (S174A) mutant, the \(^{32}\text{P}\) level was drastically reduced (about 75% reduction) compared to that in the wild-type protein (Fig. 5, lane d). Taken together, these results suggest that Tif6p, like its mammalian homologue eIF6, is also phosphorylated at Ser-174 and Ser-175 residues. Furthermore, phosphorylatable serine residues of Tif6p at these sites are essential for cell growth and viability (see Fig. 4).

Lack of phosphorylation of Tif6p affects its subcellular localization. Cell fractionation as well as indirect immunofluorescence studies have shown previously that Tif6p is distributed throughout both cytoplasm and nuclei of yeast cells (2). To investigate whether mutation of Tif6p at Ser-174 and Ser-175, which results in the lack of phosphorylation of Tif6p, affects its subcellular localization, we constructed a strain in which the wild-type Tif6p is expressed as a Myc-tagged Tif6p fusion protein and the mutant Tif6p (S174A, S175A) is expressed as a HA-tagged protein. Cell extracts of this strain, UBY608, as well as a control strain UBY610 in which wild-type Tif6p is expressed as both a HA-tagged and a Myc-tagged protein from two \(CEN\) plasmids, were fractionated into nuclear and cytoplasmic fractions, and the proteins in these fractions were analyzed by Western blotting using anti-c-Myc antibodies and anti-HA antibodies. Figure 6A shows that wild-type Tif6p tagged either with Myc or with HA (in UBY610) was present in both nuclear and cytoplasmic extracts, in agreement with previous results (2). In contrast, HA-tagged mutant Tif6p was present only in the nuclear fraction and was not...
FIG. 6. Subcellular distribution of wild-type Tif6p and the serine phosphorylation mutant of Tif6p. (A, left panel) Lysates of haploid yeast strain UBY608 carrying an inactive chromosomal TIF6 gene and harboring both the TRP1 plasmid pRS314-mycTIF6 (which expresses Myc-tagged Tif6p from its natural promoter) and a recombinant LEU2 plasmid pRS315-TIF6 (S174A, S175A), which expresses mutant HA-Tif6p protein (S174A, S175A) from its natural promoter, were fractionated into postnuclear supernatant (cytosolic fraction) and nuclear pellet as described by Aris and Blobel (1). (Right panel) Similar analysis was carried out with lysates of yeast strain UBY610 expressing both the Myc-tagged Tif6p and the...
detected in the cytoplasmic fraction. The validity of the fractionation was verified by using antibodies for eIF5 (a marker for cytoplasmic proteins) and Nop1p (a marker for nucleolar proteins) (Fig. 6A).

To visualize directly the presence of Tif6p in subcellular fractions, exponentially growing cells of UBY608, expressing both wild-type Myc-Tif6p and mutant HA-Tif6p, were examined by indirect immunofluorescence by using anti-Myc and anti-HA antibodies followed by decoration with anti-rabbit red Alexa Fluor 568 (for wild-type Myc-Tif6p) and with anti-mouse green Alexa Fluor 488 (for mutant HA-Tif6p). Control cells, UBY610 expressing wild-type HA-Tif6p as well as wild-type Myc-Tif6p, were examined similarly. The nuclei were stained by using antibodies for eIF5 (a marker for cytoplasmic proteins) (Fig. 6A).

In contrast, mutant HA-tagged Tif6p in UBY608 cells was localized only in the nuclei (Fig. 6B, panels a to c and g to i). No signal was obtained when cells in which untagged Tif6p was expressed were treated with a combination of the primary and secondary antibodies (data not shown).

Similar localization of wild-type and Ala mutant Tif6p proteins was also observed when the wild-type or mutant protein was expressed as a C-terminally GFP-tagged Tif6p fusion protein in yeast cells (Fig. 7). Taken together, these results show that mutations of serine residues at positions 174 and 175 of Tif6p that abolish phosphorylation of Tif6p prevent its passage from the nucleus to the cytoplasm.

Effect of phosphorylation of Tif6p on pre-rRNA processing.

To date, the most well-characterized function of Tif6p in yeast cells is its requirement in the processing of pre-rRNA into mature 25S and 5.8S rRNAs that are the constituents of the 60S ribosomal subunit (2). Specifically, depletion of Tif6p from yeast cells blocks processing of 275H pre-rRNA into 25S rRNA and 78 pre-rRNA, the latter being the precursor of 5.8S rRNA (2). In agreement with this essential function of Tif6p in pre-rRNA processing, it has been demonstrated that Tif6p is associated with the 60S preribosomal particles (also called 66S preribosomes) in the nucleolus (4, 10). To determine whether mutation of Ser-174 and Ser-175 of Tif6p to alanine that results in the formation of unphosphorylated Tif6p affects its ability to associate with the 60S preribosomal particles, cell fractions were isolated and 60S preribosomes were analyzed for the association of wild-type and mutant Tif6p proteins (S174A, S175A) were subjected to sucrose gradient centrifugation. Polysome-ribosome fractions were then subjected to Western blot analysis expressing both the wild-type Myc-Tif6p and mutant HA-tagged Tif6p (S174A, S175A) were subjected to sucrose gradient centrifugation. Polysome-ribosome fractions were then analyzed for the association of wild-type and mutant Tif6p proteins with the 60S and/or 66S ribosomal particles. As shown in Fig. 8, both the wild-type (Fig. 8A) and mutant (Fig. 8B) Tif6p proteins were associated with the 60S preribosomal particles. Further confirmation that this fraction contains 60S preribosomal particles was obtained by showing the presence of 27S pre-rRNA in this fraction (Fig. 8C). The presence of 25S rRNA was used as a marker to identify the positions of 60S ribosomes in the gradient fractions (Fig. 8D). These results show that lack of phosphorylatable serine residues at positions 174 and 175 of Tif6p does not abolish the ability of Tif6p to associate with the 60S preribosomal particles.

Experiments were also carried out to determine whether the presence of phosphorylatable serine residues at positions 174 and 175 of Tif6p is required for proper processing of pre-rRNA into mature 25S and 18S rRNAs. For this purpose, we constructed a yeast strain UBY609 (tif6::HIS3 p[URA3 GAL10::Ub-HA-TIF6] p[LEU2 tif6-GFP]) in which both the wild-type Tif6p and the Ala mutant Tif6p (S174A, S175A) were expressed from two different CEN plasmids. In this strain, while the wild-type Tif6p was expressed from the GAL10 promoter as an N-terminally ubiquitinated HA-tagged fusion protein, the mutant Tif6p was expressed from its own promoter as a C-terminally GFP-tagged fusion protein. In addition, we constructed another control yeast strain, UBY611 (tif6::HIS3 p[URA3 GAL10::Ub-HA-TIF6] p[LEU2 TIF6-GFP]) in which similar to UBY609 except that it expresses the wild-type GFP-tagged Tif6p from its own promoter. Exponentially growing cultures of these strains and the parental strain KSY603 (tif6::HIS3 p[URA3 GAL10::Ub-HA-TIF6]) in SGal medium were transferred to SD-Ura (glucose) medium, and cells were allowed to grow for 120 min to deplete the wild-type HA-Tif6p from KSY603, UBY609, and UBY611 cells. As shown in Fig. 9B, there was a rapid decline of wild-type HA-Tif6p in both UBY609 and UBY611 cells. Within 2 h, the wild-type Tif6p was barely detectable. This was also true for KSY603 cells, as previously observed (2) (data not shown). In contrast, the expression of the GFP-tagged Ala mutant Tif6p in UBY609 cells as well as that of GFP-tagged wild-type Tif6p in UBY611 cells remained uninhibited under these conditions (Fig. 9B). Cells were then pulse-labeled with [5,6-3H]uracil for 3 min and chased for 5, 20, and 60 min with an excess of unlabeled uracil. As a control, the strain KSY603 growing in SGal medium was also subjected to pulse-chase labeling under similar experimental conditions. Analysis of total [3H]RNA samples by formamide-agarose gel electrophoresis showed that in control KSY603 cells growing in SGal medium as well as in UBY611 cells growing in SD medium, the pre-rRNA was chased into mature 25S and 18S rRNAs as expected (Fig. 9A), while in Tif6p-depleted KSY603 cells growing in SD medium, virtually no 25S and 18S rRNA was formed (Fig. 9A).
with previous results (2). More importantly, in UBY609 cells, growing in glucose medium and expressing only the Ala mutant Tif6p (Fig. 9B), the formation of both 25S and 18S rRNAs was readily observed, although there was clearly a significant inhibition in the formation of mature 25S rRNA without affecting the level of 18S rRNA (Fig. 9A). Additionally, from three such independent sets of experiments, we have calculated the ratios of 25S rRNA to 18S rRNA formed in strains UBY609 and UBY611. The results show there was about 50 to 70% inhibition of the formation of 25S rRNA in strain UBY609 expressing Ala mutant Tif6p compared to that in strain UBY611 expressing wild-type Tif6p.

DISCUSSION

The synthesis of 60S ribosomes is a highly complex process requiring the participation of a large number (>100) of trans-acting factors that are required for pre-rRNA processing, pre-rRNA modification, and ribosome assembly (5, 13, 29). Tif6p, the yeast homologue of mammalian eIF6, is one of these essential 60S ribosomal assembly proteins that associates with the 60S preribosomal particles and is required for the subsequent maturation of the 60S ribosomal particle (2, 4, 10).

In this study, using in vitro biochemical techniques, we initially show that mammalian eIF6 is phosphorylated at Ser-174.
and Ser-175 by mammalian CK I. Among these residues, Ser-174 is the major site of phosphorylation, accounting for nearly 90% of the total in vitro phosphorylation, while Ser-175 is phosphorylated quite inefficiently. The high conservation of the amino acid sequence surrounding these serine residues in nucleated cells from yeast to mammals suggested the possibility that these residues of eIF6 (Tif6p) are also phosphorylated in yeast cells. Indeed, we observed that while wild-type yeast eIF6 (Tif6p) isolated from 32P-labeled yeast cells was phosphorylated, mutation of Tif6p at the same residues, present in a highly conserved consensus CK I sequence motif, abolished phosphorylation of Tif6p. In yeast cells also, mutation of Ser-174 to alanine in Tif6p led to a marked reduction (about 75%) in phosphorylation of Tif6p, while mutation of Ser-175 inhibited phosphorylation only marginally. These observations, which showed a strong correlation between in vitro phosphorylation of mammalian eIF6 and in vivo phosphorylation of Tif6p in yeast, have been taken as evidence that these two serine residues, Ser-174 and Ser-175, are the sites of in vivo phosphorylation in yeast cells. It should be noted that the mammalian and the yeast eIF6 proteins are 72% identical and 85% similar to each other (25), suggesting a strong conservation in structure and function of the proteins.

The question naturally arises whether replacement of highly conserved serine residues with alanine in Tif6p causes alteration in the overall structure of Tif6p so as to prevent phosphorylation at other sites in the protein. The following evidence (data not shown) strongly suggests that this is not the case. First, derivation of the Stokes’ radius by Sephadex G-75 gel filtration showed that both the wild-type eIF6 and the Ala mutant recombinant eIF6 have the same values as that obtained for native eIF6 isolated from rabbit reticulocyte lysates. Second, an important biochemical property of eIF6 isolated from both mammalian and wheat germ cell extracts is its ability to bind specifically to mature 60S ribosomal subunits (21, 22, 25–27). Both the wild-type and the Ala mutant mammalian eIF6 proteins can also bind to mature 60S ribosomal subunits quite efficiently. Additionally, as shown in Fig. 8, in yeast cells, both the wild-type and the Ala mutant Tif6p proteins were found to be associated with the pre-60S ribosomal particles. Furthermore, the crystal structures of yeast and archaeabacteria eIF6 proteins (8) show a very compact domain without any unstructured regions, indicating that any binding surface requires intact, properly folded protein. In view of our finding that the binding property of eIF6 with regard to 60S particles in vivo and in vitro remains intact, these observations support strongly the notion that these mutations do not affect the overall tertiary structure of the protein.

Systematic investigation of the known properties of Tif6p in yeast showed that nuclear export of Tif6p requires the presence of the phosphorylatable serine residues, Ser-174 and Ser-175. In yeast cells expressing the wild-type as well as the mutant (S174A, S175A) Tif6p proteins, while the wild-type protein is distributed in both the nuclei and the cytoplasm, the Ala mutant Tif6p is localized exclusively in the nuclei (Fig. 6 and 7). In fact, consistent with our observation that mutation of Ser-174 alone to alanine in Tif6p led to a drastic reduction in phosphorylation of Tif6p in yeast cells (Fig. 5) as well as to a loss of cell growth and viability (Fig. 4), we have observed that in yeast cells expressing mutant Tif6p in which only Ser-174 was mutated to alanine, the mutant protein was localized exclusively in the nuclei (data not shown). In contrast, Tif6p in which only the minor phosphorylatable site, Ser-175, was mutated to alanine was distributed both in the nuclei and the cytoplasm (data not shown). Taken together, these results show a strong correlation between phosphorylation of Tif6p...
An important function of Tif6p in yeast cells is its association with 60S preribosomal particles (4, 10, 17) and participation in the processing of the 27S pre-rRNA to form mature 25S and 5.8S rRNAs (2). In yeast cells depleted of Tif6p, the processing of 27S pre-rRNA is blocked and virtually no 25S rRNA (and 5.8S rRNA) is formed (2). We observed that phosphorylatable serine residues Ser-174 and Ser-175 are not essential for the ability of Tif6p to bind to the 60S preribosomal particles (Fig. 8A and B). Likewise, when the ability of the mutant Tif6p to participate in the pre-rRNA processing reaction was measured, we observed that in contrast to Tif6p-depleted yeast cells, where virtually no 25S rRNA was formed, yeast cells expressing only the Ala mutant Tif6p showed formation of 25S rRNA, albeit at a somewhat lower level than cells expressing the wild-type Tif6p (Fig. 9). It is not immediately apparent why the lack of phosphorylation of Tif6p leads to a reduction in the formation of mature 25S rRNA. It has been postulated that the nuclear export of 60S ribosomes to the cytoplasm, which requires association of the protein NMD3 containing a nuclear export signal to the 60S preribosomal particles (7, 11), also requires Tif6p (12, 24). The possibility exists that lack of phosphorylation of Tif6p affects nuclear export of pre-60S ribosomal particles containing bound Tif6p. In the absence of such an export of pre-60S ribosomal particles, the 25S rRNA formed may be degraded. This may explain our observation that in the absence of nuclear export of Tif6p, the formation of mature 25S rRNA was eventually affected. Additionally, our observation that Tif6p in which Ser-174 and Ser-175 were mutated to aspartate residues also failed to substitute for the wild-type Tif6p in sustaining yeast cell growth and viability suggests that dephosphorylation of Tif6p may also be essential for its function. It should be noted that nucleocytoplasmic

and its transport from the nucleus to the cytoplasm as well as its ability to support yeast cell growth.

An important function of Tif6p in yeast cells is its association with 60S preribosomal particles (4, 10, 17) and participation in the processing of the 27S pre-rRNA to form mature 25S and 5.8S rRNAs (2). In yeast cells depleted of Tif6p, the processing of 27S pre-rRNA is blocked and virtually no 25S rRNA (and 5.8S rRNA) is formed (2). We observed that phosphorylatable serine residues Ser-174 and Ser-175 are not essential for the ability of Tif6p to bind to the 60S preribosomal particles (Fig. 8A and B). Likewise, when the ability of the mutant Tif6p to participate in the pre-rRNA processing reaction was measured, we observed that in contrast to Tif6p-depleted yeast cells, where virtually no 25S rRNA was formed, yeast cells expressing only the Ala mutant Tif6p showed formation of 25S rRNA, albeit at a somewhat lower level than cells expressing the wild-type Tif6p (Fig. 9). It is not immediately apparent why the lack of phosphorylation of Tif6p leads to a reduction in the formation of mature 25S rRNA. It has been postulated that the nuclear export of 60S ribosomes to the cytoplasm, which requires association of the protein NMD3 containing a nuclear export signal to the 60S preribosomal particles (7, 11), also requires Tif6p (12, 24). The possibility exists that lack of phosphorylation of Tif6p affects nuclear export of pre-60S ribosomal particles containing bound Tif6p. In the absence of such an export of pre-60S ribosomal particles, the 25S rRNA formed may be degraded. This may explain our observation that in the absence of nuclear export of Tif6p, the formation of mature 25S rRNA was eventually affected. Additionally, our observation that Tif6p in which Ser-174 and Ser-175 were mutated to aspartate residues also failed to substitute for the wild-type Tif6p in sustaining yeast cell growth and viability suggests that dephosphorylation of Tif6p may also be essential for its function. It should be noted that nucleocytoplasmic...
transport of many proteins is regulated by signals that result in the change in their phosphorylation states (for review, see reference 15). We postulate that phosphorylation and dephosphorylation of Tif6p may also be involved in nucleocytoplasmic shuttling of the protein, which is essential for its function.

Finally, because in vitro biochemical work has shown that mammalian eIF6 is phosphorylated in vitro at Ser-174 and Ser-175 by CK I and that mutation to alanine of the same residues of yeast eIF6, present in a highly conserved consensus CK I sequence, abolishes phosphorylation of eIF6 in yeast cells, it is presumed that yeast CK I is responsible for phosphorylation of Tif6p at the same residues. Both mammalian and yeast cells contain multiple isoforms of CK I that are associated with different compartments of the cell (9). These isoforms have highly conserved catalytic domains but differ from one another in having divergent amino- and carboxy-terminal domains. These noncatalytic domains are responsible for discrete cellular localization of each isoform, which is essential for the respective function of each isoform (9). In yeast there are five isoforms of CK I, only one (HRR25) of which is present in the nucleus (9). This isoform is the yeast homologue of mammalian CK I6, which is also predominantly nuclear and is shown in this work to phosphorylate mammalian eIF6. It remains to be determined whether the protein kinase responsible for phosphorylation of yeast eIF6 is indeed CK I and, if so, which isoform(s) of CK I is responsible for phosphorylation of Tif6p in yeast and at which subcellular location phosphorylation of Tif6p occurs. Additionally, it will be important to investigate the effect of mutational inactivation of the kinase on Tif6p function as well as on its nucleocytoplasmic distribution.

ACKNOWLEDGMENTS

We are especially indebted to Steven Almo of our institution for many helpful discussions regarding the effect of mutations on the tertiary structure of eIF6. We thank Jonathan Warner and Romit Majumdar for critically reading the manuscript.
