The $LQ\bar{D}$ operator in R-parity-violating supersymmetry can lead to meson decays to light neutralinos and neutralino decays to lighter mesons, with a long lifetime. Since the high-luminosity LHC is expected to accumulate as much as $3/ab$ of data, several detectors proposed to be built at the LHC may probe unexplored regions in the parameter space, for long-lived neutralinos. We estimate the sensitivity of the recently proposed detectors, CODEX-b, FASER, and MATHUSLA, for detecting such light neutralinos singly produced from $D$- and $B$-meson decays in a list of benchmark scenarios, and discuss the advantages and disadvantages of the proposed detectors in this context. We also present our results in a model independent fashion, which can be applied to any long-lived particle with mass in the GeV regime.

I. INTRODUCTION

The discovery of a Standard-Model (SM) like Higgs boson in 2012 has been a highlight of the Large Hadron Collider (LHC) \cite{1, 2}. The small Higgs mass, $m_h = 125.09$ GeV \cite{3}, has since, however, consolidated the hierarchy problem \cite{4, 5}. Supersymmetric (SUSY) theories offer an elegant solution, for reviews see Ref. \cite{6, 7}. All searches for the new fields predicted by SUSY however, have been unsuccessful yet. This leads to lower limits on the masses of squarks and gluinos in various supersymmetric models of order 1 TeV and above \cite{8-12}. On the other hand, the lightest neutralino is not similarly constrained. In fact, if we drop the assumption for the gaugino masses, $M_1 = \frac{5}{3} \tan^2 \theta_W M_2$, which is motivated by grand unified theories (GUTs), and do not require the lightest neutralino to comprise the dark matter of the Universe, light neutralino masses below $\sim 10$ GeV are still allowed \cite{13, 18}. For neutralino masses between about 1 eV and 10 GeV the relic energy density of the neutralinos would close the Universe \cite{11}, such that neutralinos must decay. Since they are light they will typically have long lifetimes.

In R-parity-violating (RPV) SUSY (for reviews see Ref. \cite{19-21}), the lightest neutralino is no longer stable and decays via RPV couplings. Thus such a neutralino can be light. For small couplings and small mass these neutralinos can be long-lived enough to escape the reach of the LHC detectors. Moreover, the RPV couplings can induce single production of neutralinos via rare meson decays. Such scenarios have been investigated in various fixed-target set-ups \cite{13, 26-28}. More recently they have also been studied in the context of the proposed SHiP experiment \cite{29-31}. Ref. \cite{31} studied the expected LHC sensitivity to such scenarios assuming an integrated luminosity of 250/fb. Ignoring differences in the reconstruction efficiency the sensitivity in the R-parity violating couplings at ATLAS was lower than at SHiP by roughly a factor of 2.

It is expected that the high-luminosity LHC (HL-LHC) will deliver up to $3/ab$ of luminosity in the coming 20 years \cite{32}. As the cross sections for producing long-lived particles (LLPs) are typically small, such a large amount of data is required for high sensitivity to LLPs. Unsurprisingly, there have appeared several proposals to build new detectors near the interaction points (IPs) at the LHC, exploiting the projected large luminosity: CODEX-b \cite{33}, FASER \cite{34}, and MATHUSLA \cite{35}. In this study, we estimate the sensitivity reach of these detectors for discovering singly produced light neutralinos from $D$- and $B$-mesons via RPV $LQ\bar{D}$ couplings, and compare them with each other. We also interpret our studies in a model

\footnote{Incidentally in such RPV SUSY models the dark matter can be composed of axinos \cite{22, 25}.}
independent way, independently of the RPV couplings. Instead we set bounds on the product of the branching ratios of the production of an LLP from a meson decay and the decay of the LLP to a meson and charged lepton in terms of the neutralino decay length \( c \tau \). This can be applied to any potential LLP.

CODEX-\( b \) is a comparatively small cubic detector making use of a shielded space near the LHC\( b \) IP that is expected to be free soon. Since it is to be installed at LHC\( b \) instead of ATLAS or CMS, CODEX-\( b \) will have an expected luminosity of 300 fb\(^{-1} \), one order of magnitude smaller than ATLAS or CMS, if LHC\( b \) runs until 2035 with upgrades to a Phase-II \[36\]. FASER was proposed as a small cylindrical detector to be built in the very forward region several hundred meters downstream of the ATLAS or CMS IP. In comparison, MATHUSLA would be built as a massive surface detector above the ATLAS IP. The details of the experimental setups are summarized in Sec. III.

The CODEX-\( b \) physics proposal \[33\] examined two benchmark models, i.e. Higgs decay to dark photons, and \( B \)-meson decays via a Higgs mixing portal. Several FASER papers have respectively studied dark photons produced through light meson decays and photon bremsstrahlung \[34\], dark Higgs bosons produced through \( B \)- and \( K \)-mesons \[37\], heavy neutral leptons \[38\] and axion-like particles \[39\]. There are also studies investigating MATHUSLA with dark Higgs \[40\], exotic Higgs decays to LLPs \[35\], and the Dynamical Dark Matter framework \[12\]. Recently a MATHUSLA white paper \[41\] appeared, where the theory community presented detailed studies of MATHUSLA’s potential of detecting LLPs in many different models. Ref. \[44\] studied all these three detectors with heavy neutral leptons in the Type-I Seesaw model, and the lightest neutralino pair-produced from Z bosons with the RPV-SUSY model. Very recently Ref. \[45\] investigated inelastic dark matter models at various existing and proposed LHC experiments including CODEX-\( b \), FASER and MATHUSLA. We extend this work to consider the production of supersymmetric neutralinos via both \( D \)- and \( B \)-mesons, as well as the decays of the neutralinos to a charged meson and a charged lepton. RPV-SUSY is a complete model and we thus also consider the full kinematic constraints due to phase space.

It is the purpose of this paper to investigate the discovery potential of light neutralinos at the detectors CODEX-\( b \), FASER, and MATHUSLA. The primary motivation of this scenario is that supersymmetry is a potential solution to the hierarchy problem. Light neutralinos are consistent with all laboratory and astrophysical data \[10, 14, 16, 17\]. Thus this is an allowed supersymmetric parameter range, and should be investigated. Such a light neutralino is only consistent with the observed dark matter density if it decays on time-scales much shorter than the age of the universe. This is the case for R-parity violating scenarios. R-parity violating supersymmetry naturally obtains light neutrino masses, without introducing a super heavy see-saw Majorana mass of order \( 10^{10} \) GeV or higher \[18, 19\]. The scenario of an \( \mathcal{O}(1 \, \text{GeV}) \) neutralino does not in itself resolve any discrepancy between the Standard Model and current data.

This paper is organized as follows. In Sec. II we briefly introduce the model of RPV-SUSY. In Sec. III we describe the three experiments for which we estimate the sensitivities, and explain the details of the numerical simulation. In Sec. IV we present results for various benchmark choices for RPV couplings. We summarize and conclude in Sec. V.
decays and for the partial widths of neutralino decays via \( LQ\bar{D} \) couplings can be found in Refs. \[\text{13, 16, 20, 31}\].

In principle, one single \( LQ\bar{D} \) coupling introduces several effective SM operators and hence may simultaneously induce both meson decays to neutralinos and neutralino decays to lighter mesons. However, as Ref. \[\text{31}\] points out, due to kinematic constraints only the coupling \( \lambda_{112}' \) may lead to such a complete decay chain:

\[
K_{L/S}^0 \to \tilde{\chi}^0_{1}\nu, \quad \tilde{\chi}^0_1 \to K^\pm l^\mp. \tag{2}
\]

Moreover, since the mass difference between \( K_{L/S}^0 \) and \( K^\pm \) is only 4 MeV, the kinematically allowed neutralino mass range is very small and this case is not worth studying. Therefore, we only consider scenarios with two distinct non-vanishing RPV operators, one for the production of the neutralinos and the other for the decay.

The couplings \( \lambda'_{ijk} \) for the operator \( L_iQ_j\bar{D}_k \) have strict bounds from different sources, though the bounds can be substantially weakened for heavy sfermion masses above 1 TeV. For reviews, see Refs. \[\text{19, 53–56}\]. Since we investigate the same benchmark scenarios as in Ref. \[\text{31}\], we only list the relevant bounds, reproduced from Ref. \[\text{56}\]:

\[
\lambda_{112}' < 0.03 \frac{m_{s_R}}{100 \text{ GeV}}, \quad \lambda_{121}' < 0.2 \frac{m_{d_R}}{100 \text{ GeV}}, \tag{3}
\]

\[
\lambda_{122}' < 0.2 \frac{m_{s_R}}{100 \text{ GeV}}, \quad \lambda_{131}' < 0.03 \frac{m_{d_R}}{100 \text{ GeV}}, \tag{4}
\]

\[
\lambda_{132}' < 0.06 \frac{m_{s_R}}{100 \text{ GeV}}, \quad \lambda_{313}' < 0.06 \frac{m_{s_R}}{100 \text{ GeV}}. \tag{5}
\]

Some pairs of operators have even stricter product bounds. We take the relevant bounds from Ref. \[\text{53}\]:

\[
\sqrt{\lambda_{121}'\lambda_{112}' < 3 \times 10^{-5} \frac{m_{s_L}}{100 \text{ GeV}}}, \tag{6}
\]

\[
\sqrt{\lambda_{122}'\lambda_{112}' < 4.7 \times 10^{-3} \frac{m_{s_R}}{100 \text{ GeV}}}, \tag{7}
\]

\[
\sqrt{\lambda_{131}'\lambda_{112}' < 4.7 \times 10^{-3} \frac{m_{s_L}}{100 \text{ GeV}}}. \tag{8}
\]

Throughout this work, we assume that all sfermions have degenerate masses \( m_j \). This allows us to directly compare the above bounds to our results even though the respectively relevant operators depend on the masses of possibly different SUSY particles. Note that results for significantly non-degenerate SUSY spectra may therefore differ significantly and can change the relative importance of bounds from different sources.

III. EXPERIMENTAL SETUPS AND SIMULATION

In this section we summarize the setups of the detectors, and explain in detail our simulation procedure. For more information on the proposed detectors we refer to Refs. \[\text{33–35}\]. The main difference between them lies in the projected luminosity, the geometry and installed position (large or small pseudorapidity \( \eta \)). Moreover, whether installed underground or above the ground, these proposals all argue that the background influence, for example from cosmic rays, can be well controlled. Therefore, we do not discuss it and always assume 100% detector efficiency.

In order to estimate the number of LLP decays inside the respective detector’s chamber, we take into consideration both the production of the mesons and hence the neutralinos, and the decay of the neutralinos via mesons. On the production side, since we study neutralinos produced from meson decays, we use results published by the LHCb collaboration \[\text{57, 58}\] for estimating \( N_M \), the total number of the meson type “M” produced at the LHC. For \( D \)-mesons, we consider only neutralinos produced from \( D^+ \)- and \( D_s \)-mesons which are relevant for the benchmark scenarios we consider. Ref. \[\text{57}\] gives the cross section for producing \( D^+ \) and \( D^+ \). The latter decays to \( D^+ \)- and \( D_s \)-mesons at the 13-TeV LHC for a certain kinematic range: \( 0 < p_T < 15 \text{ GeV/c} \) and \( 2.0 < y < 4.5 \), where \( p_T \) denotes transverse momentum and \( y \) rapidity. We use the computer program \[\text{FONLL, 69–62}\] to extrapolate these numbers to the whole kinematic range, and, after taking into account the decay of the \( D^+ \)- to \( D^+ \)-mesons, we obtain the total numbers of \( D^+ \) and \( D_s \) produced over the hemisphere for \( \eta = 3/\alpha_b \):

\[
N_{D^+} = 1.58 \times 10^{16}, \quad (9)
\]

\[
N_{D_s} = 5.11 \times 10^{15}. \quad (10)
\]

At the LHC the mesons are produced over the full \( 4\pi \). However the detectors we are considering here for LLPs are always off to one side of the collision point. Thus we first only consider the forward or backward hemisphere (2\( \pi \)) which contains the respective detector. We then later impose the necessary geometric cuts corresponding to a specific detector.

Among the \( B \)-mesons, \( B^0 \) and \( B^\pm \) are of interest here. Ref. \[\text{55}\] presents the experimentally measured \( b \)-quark production cross section at the 13-TeV LHC for \( 2 < \eta < 5 \), and the corresponding number after extrapolation over the full \( \eta \) range with the numerical tool \[\text{Pythia 8, 63–64}\]. We take the fragmentation factors of \( B \)-mesons directly from Ref. \[\text{31}\], which were obtained by simulating 1 M
events of HardQCD:hardbbbar in Pythia 8 \cite{63,64}. We obtain
\begin{align}
N_{B^+} &= 7.30 \times 10^{14}, \\
N_{B^0} &= 7.28 \times 10^{14},
\end{align}
over a hemisphere for \( L = 3/ab \). The branching ratios of these mesons decaying to neutralinos are easily calculated with the formulas given in Ref. \cite{31}. We arrive at the following expression for the total number of neutralinos produced in a hemisphere
\[ N_{\tilde{\chi}^0}^{\text{prod}} = \sum_M N_M \cdot \text{BR}(M \rightarrow \tilde{\chi}_1^0 + l), \]
where \( l \) is the associated lepton in the meson decay, which can be charged or neutral.

We then apply Monte Carlo (MC) techniques to determine the average probability of the neutralinos decaying inside the detector chamber,
\[ \langle P[\tilde{\chi}_1^0 \text{ in d.r.}] \rangle = \frac{1}{N_{\tilde{\chi}^0}^{MC}} \sum_{i=1}^{N_{\tilde{\chi}^0}^{MC}} P[\tilde{\chi}_1^0 | \text{in d.r.}], \]
where \( P[\tilde{\chi}_1^0 | \text{in d.r.}] \) is the probability for a given generated neutralino to decay in the “detectable region”, “d.r.”. Dividing by the total number of simulated neutralinos produced, \( N_{\tilde{\chi}^0}^{MC} \), gives the average. We explain how to calculate \( \langle P[\tilde{\chi}_1^0 \text{ in d.r.}] \rangle \) for each detector in detail below.

Since it is difficult to experimentally reconstruct the trajectory of the neutral final-state particles of the neutralino decays, we consider only charged decay products to be detectable. (See Ref. \cite{31} for a discussion of the potential influence of decays to \( K^0 \)‘s.) The final number of observed neutralino decays is expressed as
\[ N_{\tilde{\chi}^0}^{\text{obs}} = N_{\tilde{\chi}^0}^{\text{prod}} \cdot \langle P[\tilde{\chi}_1^0 \text{ in d.r.}] \rangle \cdot \text{BR}(\tilde{\chi}_1^0 \rightarrow \text{char.}). \]

We use Pythia 8.205 \cite{63,64} to perform the MC simulation in order to calculate \( \langle P[\tilde{\chi}_1^0 \text{ in d.r.}] \rangle \) in Eq. \ref{eq:14}. We use two matrix element calculators of Pythia, namely HardQCD:hardccbar and HardQCD:hardbbbar, to generate initial \( D \) - and \( B \)-mesons, respectively. Note that the differential cross section of producing heavy flavor mesons in the very forward direction, where FASER sits, is not validated in Pythia. In order to solve this problem, we reweigh the Pythia meson production cross section at different ranges of transverse momentum and pseudorapidity by the corresponding more reliable numbers calculated by using FONLL. We simulate 20,000 events for each benchmark scenario and extract the kinematical information of each neutralino \((\tilde{\chi}_1^0)_i\) from Pythia: \((E_i, p_i^z, \theta_i, \phi_i)\).

Here the \( z \)-direction is along the beam pipe, \( p_i^z \) is the component of the 3-momentum along the \( z \)-axis, \( E_i \) is the total energy of the neutralino, and \( \theta_i, \phi_i \) are the polar and azimuthal angles, respectively. With the kinematical information we derive the relativistic quantities as follows:
\begin{align}
\gamma_i &= E_i/m_{\tilde{\chi}_1^0}, \\
\beta_i &= \sqrt{1 - \gamma_i^{-2}}, \\
\lambda_i &= \beta_i \gamma_i / \Gamma_{\text{tot}}(\tilde{\chi}_1^0), \\
\beta_i^z &= p_i^z / E_i, \\
\lambda_i^z &= \beta_i^z \gamma_i / \Gamma_{\text{tot}}(\tilde{\chi}_1^0),
\end{align}
where \( \Gamma_{\text{tot}}(\tilde{\chi}_1^0) \) is the total decay width of \( \tilde{\chi}_1^0 \) and can be calculated with formulas given in Ref. \cite{31}. \( \lambda_i \) is the decay length of \((\tilde{\chi}_1^0)_i\), along the direction of its movement in the lab frame and \( \lambda_i^z \) is the \( z \)-component of \( \lambda_i \). These quantities are used to calculate \( P[(\tilde{\chi}_1^0)_i \text{ in d.r.}] \) for each detector. We now discuss the detectors in turn.

**A. CODEX-b**

CODEX-b (“Compact detector for Exotics at LHCb”) \cite{31} was proposed as a cubic detector with dimension \( 10^3 \) m\(^3\), sitting inside an underground cavity at a distance \( L = 25 \) m from the LHCb IP. The differential production distribution is flat in the azimuthal angle and the azimuthal coverage of the detector is about \( 0.4/2\pi \approx 6\% \). The polar angle range of the CODEX-b experiment at the appropriate azimuthal angle is between \( 11.4^0 \) and \( 32.5^0 \). This corresponds to the pseudo-rapidity range \( \eta \in [0.2, 0.6] \). For this narrow range, and at the precision
of this analysis, we also treat the polar angle differential production distribution as flat. As we mentioned earlier, LHCb is expected to have a total integrated luminosity of 300/ fb, smaller by one order of magnitude than ATLAS or CMS. We calculate $P[\chi_1^0_i]$ in d.r. [21] with the following expression:

$$P[\chi_1^0_i \text{ in d.r.}] = \begin{cases} 
0.4 \cdot \frac{1-e^{-\frac{L_d}{\lambda_i}}}{e^{\frac{L_d}{\lambda_i}}}, & \eta_i \in [0.2, 0.6], \\
0, & \text{else}, 
\end{cases}$$

where we approximately treat the box detector as a spherical shell segment with the volume length $L_d = 10 m$. $\eta_i$ is the pseudorapidity of $(\chi_1^0_i)$ and $\eta_i = -\ln[\tan \theta_i/2]$. A brief sketch of the setup of CODEX-b is shown in Fig. [1].

B. FASER

**FIG. 2.** Side-view sketch of the FASER detector with definition of distances and angles used in text. The dashed line describes an example LLP track.

FASER (“ForwArd Search ExpeRiment”) [34] proposes to build a small cylindrical detector placed a few hundred meters downstream of the ATLAS or CMS IP in the very forward region. In a series of papers [34, 37, 39] several different variants of FASER have been proposed. In this paper, we focus on a recent setup, which would sit at a particularly promising location in the side tunnel TI18 [39]. We denote the distance from the IP to the near end of the detector as $L = 470 m$, the radius of FASER as $R = 1 m$, and the detector length as $L_d = 10 m$. Following is the expression for calculating the probability for a given neutralino to decay inside FASER:

$$P[\chi_1^0_i \text{ in d.r.}] = \frac{1-e^{-\frac{L_d}{\lambda_i}}}{e^{\frac{L_d}{\lambda_i}}},$$

$$L_i = \begin{cases} 
0, & \tan \theta_i > \frac{R}{L}, \\
L_d, & \tan \theta_i < \frac{R}{L + L_d}, \\
\frac{R}{\tan \theta_i} - L, & \text{else}. 
\end{cases}$$

There is no azimuthal angle suppression because the FASER detector is cylindrical. Here the three cases correspond respectively to 1) the extended potential neutralino trajectory misses the decay chamber, 2) the extended potential neutralino trajectory passes through the entire length of the detector, and 3) the extended neutralino trajectory exits through the side of the detector. In practice, we treat the third case as negligible. It corresponds to the very narrow angular range $\theta_i \in [0.119^\circ, 0.1219^\circ]$. And furthermore the decay products of the neutralinos may exit through the side and may thus miss the detector. These neutralinos hence would not be detected. A sketch of the geometric configuration of FASER is shown in Fig. [2].

C. MATHUSLA

**FIG. 3.** Side-view sketch of the MATHUSLA detector with definition of distances and angles used in text. The dashed line describes an example LLP track.

In Ref. [35] it has been proposed to construct a surface detector 100 m above the ATLAS IP called MATHUSLA (“MAssive Timing Hodoscope for Ultra Stable neutralL pArticles”). The detector should be horizontally offset by 100 m from the ATLAS IP and with a massive dimension of 200 m\(\times\)200 m\(\times\)20 m. MATHUSLA is expected to have excellent sensitivity for detecting LLPs. Below we show the formulæ for calculating $P[\chi_1^0_i \text{ in d.r.}]$ in MATHUSLA:

$$P[\chi_1^0_i \text{ in d.r.}] = \frac{11}{4} \frac{1-e^{-\frac{L_d}{\lambda_i}}}{e^{\frac{L_d}{\lambda_i}}},$$

$$L_i = \min \left( \max \left( \frac{L_h}{\tan \theta_i}, \frac{L_v}{\tan \theta_i} \right), L_h + L_d \right),$$

$$L'_i = \min \left( \max \left( \frac{L_h}{\tan \theta_i}, \frac{L_v + H}{\tan \theta_i} \right), L_h + L_d \right) - L_i.$$  

Here, $L_h$ and $L_v$ are the horizontal and vertical distance from the IP to the near end of MATHUSLA, and they both equal 100 m. $L_d = 200 m$ is the horizontal length of MATHUSLA and $H = 20 m$ is its height. The factor $1/4$ comes from the azimuthal angle coverage. Both
MATHUSLA and FASER expect to have 3/ab luminosity of data by $\sim 2035$. We show the schematic plot of MATHUSLA in Fig. 2.

IV. RESULTS

We present our numerical results in this section. In Ref. [31], a series of benchmark scenarios representative of $LQ\bar{D}$ couplings were investigated. In these scenarios, both the light lepton flavor (electron/muon) and the heavy tau flavor are considered, as the $\tau$ lepton leads to large phase space suppression effects. Also, different neutral or charged $D$- and $B$-mesons which would decay to the neutralino are considered; this is important because the cross sections of producing these mesons substantially differ, cf. Eqs. (9)-(12). In the present study, as a follow-up work to Ref. [31], we choose to focus only on one key benchmark scenario which features the important characteristics for a comparison of the proposed LHC(b) detectors’ sensitivities, while only briefly discussing the other scenarios. We first consider the explicit RPV model and then also discuss the model-independent case.

Since the operators for production and decay scale with $\lambda'/m_{\tilde{f}}$, we have three free parameters in the theory, after assuming that all SUSY fermions $\tilde{f}$ have degenerate masses, cf. Sec. II, namely: $\lambda_{P}/m_{\tilde{f}}^{2}$, $\lambda_{D}/m_{\tilde{f}}^{2}$, and $m_{\tilde{\chi}^{0}_{1}}$. Here $\lambda_{P}/D$ is the $LQ\bar{D}$ coupling giving rise to the production/decay of the $\tilde{\chi}^{0}_{1}$, and $m_{\tilde{f}}^{2}$ is the sfermion mass relevant for the production/decay process, respectively.\[7\]

We therefore show model-dependent plots in two separate planes for the aforementioned benchmark scenarios: $m_{\tilde{\chi}^{0}_{1}}$ vs. $(\lambda_{P}/m_{\tilde{f}}^{2} = \lambda_{D}/m_{\tilde{f}}^{2})$ and $\lambda_{P}/m_{\tilde{f}}^{2}$ vs. $\lambda_{D}/m_{\tilde{f}}^{2}$. For the latter plane, we present results for three different values of $m_{\tilde{\chi}^{0}_{1}}$.

In addition, we present model-independent results in the plane BR vs. $c\tau$ for a generic LLP. Here $c\tau$ is the decay length of the LLP, and BR is the product of the branching ratios of the respective meson decaying to the LLP and of the LLP decaying to a charged meson and a charged lepton. These results can be interpreted in terms of any LLP which has the same or similar reaction chain.

For the key benchmark scenario, we choose to show all three types of plots while for the others we select only one single type of plot, where the distinctive features of the scenario may be best emphasized. Depending on the exact construction of the detectors, they can possibly also track neutral mesons. We thus show sensitivity estimates for two cases: 1) only charged final states can be tracked, and 2) both neutral and charged ones.

A. Benchmark Scenario 1

We begin with the RPV scenario we consider in detail in this study with $D_{s}$-mesons produced at the LHC, which decay to a neutralino, which in turn travels for a macroscopic distance before decaying to a kaon and a lepton. In this scenario we assume $\lambda'_{122}$ and $\lambda'_{112}$ are the only non-vanishing $LQ\bar{D}$ couplings. $\lambda'_{122}$ gives rise to the production of $\tilde{\chi}^{0}_{1}$ via

$$D_{s} \rightarrow \tilde{\chi}^{0}_{1} + e^{\pm}, \quad \text{(production)} \quad (27)$$

and to the invisible neutralino decay

$$\tilde{\chi}^{0}_{1} \rightarrow (\eta/\eta' / \phi) + \nu_{e}, \quad \text{(decay via } \lambda'_{122}) \quad (28)$$

On the other hand, $\lambda'_{112}$ leads to both visible and invisible decays

$$\tilde{\chi}^{0}_{1} \rightarrow \begin{cases} K^{(*)\pm} + e^{\mp}, \quad \text{(decay via } \lambda'_{112}) \quad (29) \end{cases}$$

The invisible decays are important to take into account in the evaluation because they affect the total width of $\tilde{\chi}^{0}_{1}$. We summarize this scenario in Tab. 1.

We now present our results. In Fig. 4 we show model-dependent sensitivity estimates for the three detectors: CODEX-b, FASER and MATHUSLA. In the left column, plots are presented in the plane $m_{\tilde{\chi}^{0}_{1}}$ vs. $(\lambda_{P}/m_{\tilde{f}}^{2} = \lambda_{D}/m_{\tilde{f}}^{2})$. We have set $\lambda_{D}' = \lambda_{P}'$, and vary their values and the mass of $\tilde{\chi}^{0}_{1}$. In order to see how the number of neutralino decay events change with varying mass and RPV couplings, we show the light blue, blue, and dark blue areas corresponding to the parameter space where respectively $\geq 3$, $\geq 3 \times 10^{3}$ and $\geq 3 \times 10^{4}$ events are observed. The hashed solid lines denote the present RPV limits for a set of sfermion mass values, Eqs. (3), (4), translated to $\lambda'/m_{\tilde{f}}^{2}$.

| $\lambda_{P}'$ for production | $\lambda_{122}$ |
|-----------------------------|----------------|
| $\lambda_{D}'$ for decay    | $\lambda_{112}$ |
| produced meson(s)           | $D_{s}$       |
| visible final state(s)      | $K^{+}e^{\mp}, K^{*\pm}e^{\mp}$ |
| invisible final state(s) via $\lambda_{P}'$ | $(\eta, \eta', \phi) + (\nu_{e}, \bar{\nu}_{e})$ |
| invisible final state(s) via $\lambda_{D}'$ | $(K \chi_{1}^{0}, K_{3}^{0}, K^{*}) + (\nu_{e}, \bar{\nu}_{e})$ |

TABLE I. Features of Benchmark Scenario 1.
FIG. 4. Sensitivity estimate of CODEX-b, FASER and MATHUSLA for Benchmark Scenario 1. On the left, we show the reach in terms of $m_{\tilde{\chi}_0^1}$ and $\frac{X_D}{m_f^2} = \frac{X_D}{m_f^2}$. The light blue/blue/dark blue regions enclosed by the solid black lines correspond to $\geq 3/3 \times 10^3/3 \times 10^6$ events. The light blue region is extended only slightly below by a dashed curve, representing the extended sensitivity reach if we assume our detectors can also detect neutral decays of the neutralino. The hashed solid lines correspond to the single RPV couplings’ limit for different sfermion masses. On the right, the two couplings are not required to be identical and plots in the plane $\frac{X_D}{m_f^2}$ vs. $\frac{X_D}{m_f^2}$ are shown for the detectors. We consider three choices of $m_{\tilde{\chi}_0^1}$: 600 MeV (light blue), 1200 MeV (blue), 1800 MeV (dark blue). The solid hashed lines again represent the individual coupling bounds and the hashed dot-dashed line is the upper bound derived from the limit on the product of the two $LQD$ couplings for $m_f = 1$ TeV.
We do not show the product bound from Eq. (7), as for a 1 TeV sfermion mass it coincides almost exactly with the 5 TeV bound on the single couplings. The bound on $\lambda'/m^2$ scales linearly with the sfermion mass, when taking the scaling of the bound on $\lambda'$ into account.

The 3-event dashed contour isocurve is extended to the lighter shaded region, bounded by a dotted line; this is obtained when we assume that invisible decays of the neutralinos can be detected as well. Whether this will be possible is an outstanding experimental question. In any case, we observe that for this benchmark scenario this would only give a very small extension in the sensitivity reach.

The range of sensitivity in the neutralino mass $m_{\tilde{\chi}^0_1}$ is strictly determined by the kinematics of the production and decay

\[(M_{K^\pm} + m_e) < m_{\tilde{\chi}^0_1} < (M_{D^*} - m_e).\]  

and is thus identical for the three experiments. The range in sensitivity in $\lambda'/m^2$ is determined by the experimental set-up. Comparing the results for the three detectors, we find that for this model CODEX-b and FASER reach similar values of $\lambda'/m^2_1$, while MATHUSLA is more sensitive by a factor $\sim 5$. Furthermore they can all extend well beyond existing low-energy limits on the R-parity violating couplings.

On the right in Fig. [4] we show plots in the plane $\lambda'_p/m_f^2$ vs. $\lambda'_D/m_f^2$ for three values of $m_{\tilde{\chi}^0_1}$: 600 MeV (light blue region), 1200 MeV (blue region), 1800 MeV (dark blue region). In this benchmark scenario, $\lambda'_p = \lambda'_{122}$ and $\lambda'_D = \lambda'_{112}$. For these results, the requirement that $\lambda'_p = \lambda'_D$ is lifted, so we observe an interplay between the production and decay of $\tilde{\chi}^0_1$. We may compare each detector’s sensitivity range in different parameters. For example, the $\lambda'_p/m_f^2$ reach of FASER is only weaker than that of MATHUSLA by a factor $\sim 3$, even though FASER is more than 25,000 times smaller than MATHUSLA. This arises because FASER exploits very well the advantage of receiving the light $D$-mesons (and the produced neutralinos) boosted in the very forward direction, where the differential production cross section is significantly higher. As for the reach in $\lambda'_D/m_f^2$, MATHUSLA shows again the strongest potential. Here we include single coupling bounds as solid hashed lines for three different sfermion masses (250, 1000 and 5000 GeV) and now also the product bound as a dashed hashed line for a 1 TeV sfermion mass. Again all experiments are sensitive well beyond existing limits.

We next consider a model-independent description, where we interpret our results in terms of the physical observables, $\text{BR} = \text{BR}_P \cdot \text{BR}_D$, instead of the RPV-SUSY parameters. Here

\[\text{BR}_P = \text{BR}(D_s \rightarrow \text{LLP} + e^\pm),\]
\[\text{BR}_D = \text{BR}(\text{LLP} \rightarrow K^{(*)\pm} + e^\mp),\]

and we allow for any LLP. The results are shown in Fig. [5]. The dashed blue isocurves are for 3 events of visible decays inside the FASER decay chamber for the two lighter LLP mass values $m_{\text{LLP}}$ values of those considered in Fig. [4]. The solid pink curves are for CODEX-b and the dot-dashed red for MATHUSLA. The light and medium colors correspond respectively to the smallest (600 MeV) and medium (1200 MeV) values for the LLP mass we choose to investigate. We do not show the curve for the heaviest mass value (1800 MeV) because it is almost the same as that for 1200 MeV. The $c\tau$ position of the valley of the isocurves, the point of maximal sensitivity, is determined by

\[\langle \beta\gamma \rangle c\tau \approx \langle L \rangle,\]

where $\langle \beta\gamma \rangle$ is the average boost of the neutralinos flying in the direction of the detector and $\langle L \rangle$ is the distance from the IP to the middle of the respective detector. We estimate $\langle \beta\gamma \rangle$ of the neutralinos that fly inside each detector by simulating 10,000 events in each case.
and summarize the results for each Benchmark Scenario and detector in Tab. II. The values for $\langle L \rangle$ are

$$\langle L \rangle = \begin{cases} 
30.0 \text{ m} & \text{for CODEX-b}, \\
475 \text{ m} & \text{for FASER}, \\
223 \text{ m} & \text{for MATHUSLA}
\end{cases} \quad (34)$$

Using the values of Benchmark Scenario 1, we get for the most sensitive $c\tau$ value

$$\langle c\tau \rangle_{\text{max. sensitivity}} = \begin{cases} 
18.3 \text{ m} & \text{for CODEX-b}, \\
0.85 \text{ m} & \text{for FASER}, \\
77 \text{ m} & \text{for MATHUSLA}
\end{cases} \quad (35)$$

which agrees with Fig. 3.

The BR position of the valleys is determined by the luminosity of the experiment, the cross section of producing $D_s$-mesons, the pseudorapidity coverage, the volume of the detector and the product of the branching ratios. The BR reach of CODEX-b is roughly one order of magnitude larger than that of FASER. This is mainly due to the fact that LHCb has a one order of magnitude lower projected luminosity than that of ATLAS/CMS. Perhaps more important, in spite of the huge volume difference between MATHUSLA and CODEX-b/FASER, the BR reach in MATHUSLA is only one order of magnitude stronger than that in FASER. For large $c\tau$ values MATHUSLA performs far better than CODEX-b, but for shorter neutralino lifetimes the detectors perform equally well. The reason is that the distance traveled to MATHUSLA is about ten times larger than for CODEX-b, such that less neutralinos reach the former detector for short-lived neutralinos. This leads to a similar sensitivity despite the larger integrated luminosity and the larger detector size of MATHUSLA.

Note that Fig. 3 is very similar to the first plot of Fig. 1 in Ref. [44], the result of which was obtained in the context of a Type-I Seesaw model, where the right-handed neutrino is the LLP with a mass of 1 GeV produced from $D$-meson decays. This illustrates the model-independence of the results shown in the BR-$c\tau$-plane.

### B. Benchmark Scenario 2

Now we briefly study the other the benchmark scenarios. In Benchmark Scenario 2, $\lambda_P = \lambda_{121}'$ instead of $\lambda_{122}'$, so that a $D^{\pm}$, instead of a $D_s$, decays to the lightest neutralino. Correspondingly, the invisible final states due to $\lambda_P$ are now kaons, instead of $\eta, \eta', \phi$. The relevant information is summarized in Table III.

The model-dependent results are very similar to those shown in Fig. 4. We do not show them again. One difference is that the low-energy product bound is stricter in this case, cf. Eq. (6). It is due to $K^0-\bar{K}^0$-mixing and scales linearly with the sneutrino mass. As pointed out

![Image](image_url)

**FIG. 6.** Model-independent sensitivity estimate of CODEX-b, FASER and MATHUSLA for Benchmark Scenario 2. The format is the same as in Fig. 5. The plot corresponds to visible decay products only. The two LLP mass values are 600 and 1200 MeV. $\lambda_P = \lambda_{121}', \lambda_D = \lambda_{112}'$. 

| Benchm. Sc. | $m_{\tilde{\chi}^0}$ (MeV) | $\langle \beta\gamma \rangle_{\text{CODEX-b}}$ | $\langle \beta\gamma \rangle_{\text{FASER}}$ | $\langle \beta\gamma \rangle_{\text{MATHUSLA}}$ |
|-------------|------------------|-----------------|-----------------|-----------------|
| 1 ($D_s$)   | 1200             | 1.64            | 560             | 2.87            |
| 2 ($D^\pm$) | 1200             | 1.50            | 682             | 2.90            |
| 3 ($B^0$ & $\bar{B}^0$) | 1000 | 4.07            | 793             | 7.32            |

| 5 ($B^0$ & $\bar{B}^0$) | 2500 | 1.88            | 308             | 3.36            |
| 5 ($B^\pm$) | 2500             | 1.55            | 358             | 2.95            |

**TABLE II.** Summary of $\langle \beta\gamma \rangle$ values for each detector in all the Benchmark Scenarios. Inside the parenthesis in each column, the type of the mother meson of the neutralino is given. In particular, in Benchmark Scenario 5, neutralinos can be produced from decay of either $B^0$ or $B^\pm$; therefore we show the results in two separate rows.

| $\lambda_P$ for production | $\lambda_D$ for decay |
|---------------------------|-----------------------|
| $\lambda_{121}'$         | $\lambda_{112}'$      |

| visible final state(s) | invisible final state(s) via $\lambda_P$ (FASER) | invisible final state(s) via $\lambda_D$ (CODEX-b) |
|------------------------|--------------------------------------------------|--------------------------------------------------|
| $K^\pm e^\mp, K^*\pm e^\mp$ | $K^0_L, K^0_S, K^*$ + ($\nu_e, \bar{\nu}_e$) | $K^0_L, K^0_S, K^*$ + ($\nu_e, \bar{\nu}_e$) |

**TABLE III.** Features of Benchmark Scenario 2.
in Ref. [31], in the case of SHiP, also here, if the sneutrino mass is equal to the relevant squark mass of production and decay, the sensitivity reach of CODEX-b and FASER is excluded by these low-energy bounds. If there is a strong hierarchy and the sneutrinos are (unexpectedly) significantly heavier than the relevant squarks, this scenario is still viable. All the same, we present the model-independent results in Fig. 4 for the same LLP mass values as in Benchmark Scenario 1: 600 and 1200 MeV. We again drop the curve for the 1800 MeV neutralino mass. The main difference between Fig. 5 and Fig. 6 is the BR reach. Benchmark Scenario 1 has a weaker BR reach mainly because $N_{D\pi} \approx 3 \cdot N_{D\pi}$, cf. Eqs. (9), (10), and the neutralinos have a smaller branching ratio to charged particles.

C. Benchmark Scenario 3

We now study several scenarios where bottom mesons decay to a neutralino. Since the bottom mesons are much heavier than the charm mesons, the mass reach improves compared to the previous scenarios. In the present Benchmark Scenario 3, as before, we have $\chi_D^0 = \chi_{112}^0$ giving both invisible and visible neutralino decays. For the neutralino production we have $\lambda_p' = \lambda_{113}^0$ such that $B^0$ (and $\bar{B}^0$) decay to a neutralino. This is summarized in Tab. IV. Kinematically we can thus probe

$$(M_{K\pi} + m_e) < m_{\tilde{\chi}_1^0} < (M_{B^0} - m_e).$$

For this scenario we only show the model-dependent plots in the plane $\lambda_p'/m_f^2$ vs. $\lambda_{Df}/m_f^2$ in Fig. 7. Here the sensitivity reach in $\lambda_{p/D}/m_f^2$ is only slightly weaker than the previous $D$-meson scenarios, mainly because at the LHC, the cross section of producing $B$-mesons is only smaller than that of $D$-mesons by a factor of $\sim 10 - 50$, cf. Eqs. (9) - (12). In the previous scenarios, CODEX-b shows similar sensitivity reach in $\lambda_{p/D}/m_f^2$ to that of FASER, but now the former exceeds the latter, despite the fact that its projected luminosity is smaller by one order of magnitude. This is because the $B$-meson mass

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
\lambda_p' for production & \lambda_{113} \\
\lambda_D^0 for decay & \lambda_{112} \\
produced meson(s) & $B^0, \bar{B}^0$ \\
visible final state(s) & $K^\pm e^\mp, K^{*\pm} e^\mp$ \\
invisible final state(s) via $\lambda_p'$ & none \\
invisible final state(s) via $\lambda_D^0$ & $(K_2^0, K_5^0, K^{*}) + (\nu_e, \bar{\nu}_e)$ \\
\hline
\end{tabular}
\caption{Features of Benchmark Scenario 3}
\end{table}

is more than twice the $D$-meson mass, and hence the produced $B$-mesons are not as much boosted in the very forward direction as the $D$-mesons. For the same reason, we also have a larger sensitive mass range than in the previous benchmark scenarios. MATHUSLA again has the most extensive sensitivity range.

D. Benchmark Scenario 4

In this scenario, we use the same $\lambda_p'$ as in the previous scenario, but change $\lambda_D^0$ from $\lambda_{112}^0$ to $\lambda_{121}^0$. Correspondingly the decay mode of the neutralino changes from the decay to a $K^\pm$ to a $D^{\pm}$, though the invisible decay mode remains the same. We summarize the relevant information in Tab. V. The kinematic reach in the neutralino mass is

$$(M_{D^{\pm}} + m_e) < m_{\tilde{\chi}_1^0} < (M_{B^0} - m_e),$$

for the charged decay modes. It is extended when the invisible modes are included by replacing $M_{D^{\pm}} \rightarrow M_{K^0}$. We present the results of this scenario in the plane $(\lambda_{p'/f}/m_f^2 = \lambda_{D/f}/m_f^2)$ vs. $m_{\tilde{\chi}_1^0}$ in Fig. 8. The lower mass sensitivity is now raised up to the $D$-meson mass, if only the visible decays of the neutralinos are considered. If we consider the detectors able to track neutral final states, the lower mass sensitivity is dramatically extended, as expected, down to $m_K \sim 500$ MeV. For large values of $(\lambda_{p'/f}/m_f^2 = \lambda_{D/f}/m_f^2)$ we produce many more neutralinos, but they now mostly decay before reaching the detector. That is why there is no sensitivity here. For very small values of $(\lambda_{p'/f}/m_f^2 = \lambda_{D/f}/m_f^2)$ we produce too few neutralinos and the neutralinos decay well after the detector. Otherwise the results are similar to those in Benchmark Scenario 3.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
\lambda_p' for production & \lambda_{113} \\
\lambda_D^0 for decay & \lambda_{121} \\
produced meson(s) & $B^0, \bar{B}^0$ \\
visible final state(s) & $D^{\pm} e^\mp, D^{*\pm} e^\mp$ \\
invisible final state(s) via $\lambda_p'$ & none \\
invisible final state(s) via $\lambda_D^0$ & $(K_2^0, K_5^0, K^{*}) + (\nu_e, \bar{\nu}_e)$ \\
\hline
\end{tabular}
\caption{Features of Benchmark Scenario 4}
\end{table}

FIG. 8. Model-dependent sensitivity estimate of CODEX-b, FASER and MATHUSLA for Benchmark Scenario 4. The format is the same as in Fig. 4.
TABLE VI. Features of Benchmark Scenario 5. At the end of the third row we emphasize that the charged B-meson decay to the neutralino is accompanied by a tau lepton.

| Scenario | Production | Final State | 
|----------|-------------|-------------|
| Scenario 1 | $\lambda'_{313}$ | $B^0, B^0, B^\pm (+\tau^\mp)$ |  
| Scenario 2 | $\lambda'_{312}$ | $K^{\pm} \tau^\mp, K^{*\pm} \tau^\mp$ |  
| Scenario 3 | none | invisible state(s) |  
| Scenario 4 | $\lambda'_{313}$ | $K^0, K_S^0, K^*$, $\nu, \bar{\nu}$ |  
| Scenario 5 | $\lambda'_{312}$ | invisible state(s) |  

E. Benchmark Scenario 5

While the previous benchmark scenarios concern only the light electron, we here explore the effect of the heaviest lepton $\tau$ on the sensitivity estimates. We consider $\lambda'_{D} = \lambda'_{313}$ and $\lambda'_{D} = \lambda'_{312}$. Then both $B^0(B^0)$ and $B^\pm$ may decay to a neutralino. In particular, $B^\pm$ decays then include a $\tau$ lepton along with a neutralino. This gives a large suppression in phase space and a correspondingly lower neutralino mass sensitivity. While $\lambda'_{D}$ does not induce any invisible decay of the lightest neutralino, $\lambda'_{D} = \lambda'_{312}$ leads to both visible decays to a kaon and a $\tau$, and invisible decays to a kaon and a $\nu$. We summarize the information in Tab. VI. The mass sensitivity is given by

$$m_{\chi_1^0} \begin{cases} M_{K^\pm} + m_\tau & \text{if only obs. visible decays,} \\ M_{K^0} & \text{if also obs. invisible decays} \end{cases}$$

$$m_{\chi_1^0} \begin{cases} M_{B^\pm} - m_\tau & \text{if produced via } B^\pm \\ M_{B^0} & \text{if produced via } B^0 \end{cases}$$

We present a plot for this benchmark scenario in the plane BR vs. $\sigma \tau$ in Fig. 9. We restrict ourselves to the production via $B^0$. As can be seen in Tab. VI, between the $B^0$ and the $B^\pm$ cases the $\langle \beta\gamma \rangle$ values, which determine the $\sigma \tau$ sensitivity, differ between 15 and 20%. This is below the resolution of our logarithmic plot. For the BR sensitivity the dominant contribution is the $B^0$ vs. $B^\pm$ production rate, however they are almost identical, cf. Eqs. (11), (12). The only real difference is that for $B^\pm$ we must have $m_{\chi_1^0} \leq 3500$ MeV, i.e. the medium mass case (3750 MeV) is not possible.

In Fig. 9 the labeling is similar to the previous scenarios. For each detector, i.e. FASER (blue), CODEX–b (pink) and MATHUSLA (red), the light/medium colors correspond to the lightest (2500 MeV)/medium (3750 MeV) $m_{\chi_1^0}$. Fig. 9 is very similar to the right panel of Fig. 1 of Ref. [44] where the sensitivity to sterile neutrinos was discussed. This again shows that most features of the figures are relativity insensitive to the nature of the LLP.

F. Decay Branching Ratios of the $\tilde{\chi}_1^0$

After having presented results of different benchmark scenarios in the previous subsections, we supplement our results by showing in Fig. 10 the decay branching ratios of the $\tilde{\chi}_1^0$ to visible, i.e. charged meson final states, as a function of $m_{\chi_1^0}$ in the kinematically allowed range for all the scenarios. The curves can be well understood.
by considering the kinematic thresholds for the various neutralino decays. For Benchmark Scenarios 1, 2 and 3 the first decay channel to open is to the charged kaon: \(\tilde{\chi}_1^0 \rightarrow K^\pm e^\mp\). Thus the visible branching ratio starts at 1. It rapidly drops as the \(K^0\)-threshold is crossed. The asymptotic value of the branching ratios in Benchmark Scenarios 1, 2 and 3 is simply determined by the number of charged or neutral decay channels. For example, in Benchmark Scenario 2 above all thresholds there are 4 visible final states and 8 invisible final states, giving a branching ratio to visible \(\frac{4}{4+8}=1/3\). The bump shows the largest sensitivity reach.

As discussed above, our results in terms of \(c\tau\) vs. BR can be used to estimate experimental sensitivities for long-lived particles different from RPV neutralinos. We used our results for Benchmark Scenario 1 as an example by pointing out the strong resemblance of Fig. 5 and the first plot of Fig. 1 in Ref. [44] determined for a different BSM model albeit with similar decay topology. Though we use this observation to label these limits as model independent, our combined set of results still points to several sources of model-dependence. An important degree of freedom to mention here is the LLP mass. For fixed \(c\tau\) and branching ratio, changing the mass of the LLP has an important impact on its kinematic parameters \(\beta\gamma\) and \(\eta\) which, as we have shown, play a non-negligible role as they are strongly connected to the preferred distance \(L\) of the detector to the primary interaction vertex. Another important aspect neither covered in \(c\tau\) nor the LLP BR is the overall topology which leads to the production of the LLP. Though all our benchmarks share the same topology \(pp \rightarrow \text{meson}+X, \text{meson} \rightarrow \text{LLP}+Y\), we observe sizable differences in the experimental coverages depending on the flavor of the produced meson, here \(D\) or \(B\). Not only do these have different total production cross sections but also their own kinematics — and with that the kinematics of the LLPs they decay into — differ.

A full “model-independent” analysis would require the consideration of several additional degrees of freedom, some of which cannot be formulated as a continuous parameter like the overall production-and-decay-topology of the LLP. This results in an unfeasible, if not impossible, exercise. Nevertheless, although the dependence on these additional parameters may not be explicitly covered in our chosen degrees of freedom \(c\tau\) and BR, our results can still be applied to a large class of LLP models different from RPV as long as they share similarities to the topologies discussed here.

G. Summary of our Results

We finish this section with some conclusions drawn from the above results for specific benchmarks. For all scenarios, we observe similar reach in \(\lambda/m^2_f\) for the two experiments CODEX-b and FASER and the strongest sensitivity for MATHUSLA. Even though FASER takes good advantage of the boost of the \(D\)- and \(B\)-mesons in the very forward direction, MATHUSLA overcomes this disadvantage by virtue of its much larger volume. Compared to earlier results determined for the SHiP experiment [31], both FASER and CODEX-b have a smaller expected reach in \(\lambda/m^2_f\). Even MATHUSLA cannot outperform SHiP in scenarios with \(D\)-meson dependence, because SHiP’s centre-of-mass energy of \(\approx 27\) GeV results in very high sensitivity. For models with \(B\)-meson decays, however, we expect MATHUSLA’s sensitivity to be comparable or even better than SHiPs.

We also translated our results into sensitivity limits on the meson’s branching ratio BR and here we observe differences in the experimental sensitivities of FASER and CODEX-b, depending on the meson flavour: for the \(B\)-meson’s BR we observe a similar ranking of the two experiments in the reach for \(\lambda/m^2_f\), FASER’s reach is expected to be slightly stronger than CODEX-b’s in case of scenarios with \(D\)-meson decays. In all cases MATHUSLA shows the largest sensitivity reach.

V. CONCLUSIONS

We have investigated the sensitivity of three recently proposed detectors at the LHC: CODEX-b, FASER, and MATHUSLA with respect to the detection of light long-lived neutralinos in RPV-SUSY scenarios. The neutralinos are produced and decay via the RPV \(LQD\) oper-
ator with coupling $\lambda'$. We studied five representative benchmark scenarios of the RPV couplings proposed in Ref. [31] where a similar sensitivity study for SHiP was completed. In general CODEX-b and FASER show similar reach in $\lambda'/m_{\tilde{f}}^2$, where $m_{\tilde{f}}$ is the mass of supersymmetric fermion partners, while MATHUSLA performs better by approximately one order of magnitude. Comparing MATHUSLA results with SHiP estimates, we find that MATHUSLA shows a better sensitivity in scenarios involving B-meson while it provides only comparable or slightly weaker results than SHiP for models in which neutralinos interact with $D$-mesons.

We also want to point out that cosmic rays may provide an additional argument to choose an underground experiment like FASER over a surface experiment like MATHUSLA. Although we ignored this allegedly control-
