Abstract. We investigate logics and equivalence relations that capture the qualitative behavior of Markov Decision Processes (MDPs). We present Qualitative Randomized Ctl (Qrctl): formulas of this logic can express the fact that certain temporal properties hold over all paths, or with probability 0 or 1, but they do not distinguish among intermediate probability values. We present a symbolic, polynomial time model-checking algorithm for Qrctl on MDPs.

The logic Qrctl induces an equivalence relation over states of an MDP that we call qualitative equivalence: informally, two states are qualitatively equivalent if the sets of formulas that hold with probability 0 or 1 at the two states are the same. We show that for finite alternating MDPs, where nondeterministic and probabilistic choices occur in different states, qualitative equivalence coincides with alternating bisimulation, and can thus be computed via efficient partition-refinement algorithms. On the other hand, in non-alternating MDPs the equivalence relations cannot be computed via partition-refinement algorithms, but rather, they require non-local computation. Finally, we consider Qrctl∗, that extends Qrctl with nested temporal operators in the same manner in which Ctl∗ extends Ctl. We show that Qrctl and Qrctl∗ induce the same qualitative equivalence on alternating MDPs, while on non-alternating MDPs, the equivalence arising from Qrctl∗ can be strictly finer. We also provide a full characterization of the relation between qualitative equivalence, bisimulation, and alternating bisimulation, according to whether the MDPs are finite, and to whether their transition relations are finitely-branching.

∗ A preliminary version of this paper appeared in the proceedings of the 4th International Conference on the Quantitative Evaluation of Systems (QEST 2007).
1. Introduction

Markov decision processes (MDPs) provide a model for systems exhibiting both probabilistic and nondeterministic behavior. MDPs were originally introduced to model and solve control problems for stochastic systems: there, nondeterminism represented the freedom in the choice of control action, while the probabilistic component of the behavior described the system’s response to the control action [Ber95]. MDPs were later adopted as models for concurrent probabilistic systems, probabilistic systems operating in open environments [Seg95], and under-specified probabilistic systems [BdA95, dA97a].

Given an MDP and a property of interest, we can ask two kinds of verification questions: quantitative and qualitative questions. Quantitative questions relate to the numerical value of the probability with which the property holds in the system; qualitative questions ask whether the property holds with probability 0 or 1. Examples of quantitative questions include the computation of the maximal and minimal probabilities with which the MDP satisfies a safety, reachability, or in general, ω-regular property [BdA95]; the corresponding qualitative questions asks whether said properties hold with probability 0 or 1.

While much recent work on probabilistic verification has focused on answering quantitative questions, the interest in qualitative verification questions predates the one in quantitative ones. Answering qualitative questions about MDPs is useful in a wide range of applications. In the analysis of randomized algorithms, it is natural to require that the correct behavior arises with probability 1, and not just with probability at least \( p \) for some \( p < 1 \). For instance, when analyzing a randomized embedded scheduler, we are interested in whether every thread progresses with probability 1 [dAFMR05]. Such a qualitative question is much easier to study, and to justify, than its quantitative version; indeed, if we asked for a lower bound \( p < 1 \) for the probability of progress, the choice of \( p \) would need to be justified by an analysis of how much failure probability is acceptable in the final system, an analysis that is generally not easy to accomplish. For the same reason, the correctness of randomized distributed algorithms is often established with respect to qualitative, rather than quantitative, criteria (see, e.g., [PSL00, KNP00, Sto02]). Furthermore, since qualitative answers can generally be computed more efficiently than quantitative ones, they are often used as a useful pre-processing step. For instance, when computing the maximal probability of reaching a set of target states \( T \), it is convenient to first pre-compute the set of states \( T_1 \supseteq T \) that can reach \( T \) with probability 1, and then compute the maximal probability of reaching \( T \): this reduces the number of states where the quantitative question needs to be answered, and leads to more efficient algorithms [dAKN+00]. Lastly, we remark that qualitative answers, unlike quantitative ones, are more robust to perturbations in the numerical values of transition probabilities in the MDP. Thus, whenever a system can be modeled only within some approximation, qualitative verification questions yield information about the system that is more robust with respect to modeling errors, and in many ways, more basic in nature.

In this paper, we provide logics for the specification of qualitative properties of Markov decision processes, along with model-checking algorithms for such logics, and we study the equivalence relations arising from such logics. Our starting point for the logics is provided by the probabilistic logics p\text{Ctl} and p\text{Ctl*} [HL94, ASB+95, BdA95]. These logics are able to express bounds on the probability of events: the logic p\text{Ctl} is derived from \text{Ctl} by adding to its path quantifiers \( \forall \) (“for all paths”) and \( \exists \) (“for at least one path”) a probabilistic quantifier \( P \). For a bound \( q \in [0,1] \), an inequality \( \in \{<,\leq,\geq,>\} \), and a path formula \( \varphi \),
the pCtl formula \( P_{\exists q} \phi \) holds at a state if the path formula \( \phi \) holds from that state with probability \( \exists q \). The logic pCtl* is similarly derived from Ctl*. In order to obtain logics for qualitative properties, we consider the subsets of pCtl and pCtl* where \( \forall, \exists \) have been dropped, and where the bound \( q \) against which probabilities are compared can assume only the two values 0, 1. We call the resulting logics Qrctl and Qrctl*, for Qualitative Randomized Ctl and Ctl*.

We provide symbolic model-checking algorithms for the logic Qrctl; these algorithms can be easily extended to Qrctl*, since for MDPs the verification of general temporal-logic properties can be reduced to reachability questions [CY95] [dA97a]. As usual, the model-checking algorithms for Qrctl proceed by induction on the structure of a formula. The cases for some of the operators are known; for others, we give new algorithms, completing the picture of the symbolic algorithms required for Qrctl model checking.

We then proceed to study the equivalence relations that arise from Qrctl. For two states \( s \) and \( t \) of an MDP, we write \( s \approx_{>0} t \) if the states \( s, t \) satisfy the same Qrctl formulas; similarly, Qrctl* induces the relation \( \approx_{s>0} \). Informally, \( s \approx_{>0} t \) holds if the set of properties that hold with probability 0, positive, and 1, at \( s \) and \( t \) coincide. These relations are thus strictly coarser than standard probabilistic bisimulation [SL94], which relates states only when the precise probability values coincide. Other works ([DGJP99]) have introduced distances which quantify the difference in the probabilistic behavior of two MDPs. When the distance between \( s \) and \( t \) is zero, \( s \) and \( t \) are probabilistically bisimilar, and so they are also qualitatively bisimilar. Aside from that, the distance between two states is in general unrelated to the states being qualitatively equivalent or not.

The appeal of the relations \( \approx_{>0} \) and \( \approx_{s>0} \) lies in their ability to relate implementations and specifications in a qualitative way, abstracting away from precise probability values. The relations, and their asymmetrical counterparts related to simulation, are particularly well-suited to the study of refinement and implementation of randomized algorithms, where the properties to be preserved are most often probability-1 properties. For instance, when implementing a randomized thread scheduler [dAFMR05], the implementation needs to guarantee that each thread is scheduled infinitely often with probability 1; it is not important that the implementation realizes exactly the same probability of scheduling each thread as the specification. Our qualitative relations can also be used as a help to analyze qualitative properties of systems, similarly to how bisimulation reductions can help in verification. Given a system, the relations enable the construction of a minimized, qualitatively equivalent system, on which all qualitative questions about the original system can be answered. We will show that our qualitative equivalences are computable by efficient discrete graph-theoretic algorithms that do not refer to numerical computation.

We distinguish between alternating MDPs, where probabilistic and nondeterministic choices occur at different states, from the general case of non-alternating MDPs, where both choices can occur at the same state. Our first result is that on finite, alternating MDPs, the relation \( \approx_{>0} \) coincides with alternating bisimulation [AHKV98] on the MDP regarded as a two-player game of probability vs. nondeterminism. This result enables the computation of \( \approx_{>0} \) via the efficient partition-refinement algorithms developed for alternating bisimulation. We show that the correspondence between \( \approx_{>0} \) and alternating bisimulation breaks down both for infinite MDPs, and for finite, but non-alternating, MDPs. Indeed, we show that on non-alternating MDPs, the relation \( \approx_{>0} \) cannot be computed by any partition-refinement algorithm that is local, in the sense that partitions are refined by looking only at 1-neighbourhoods of states (the classical partition-refinement algorithms for simulation
and bisimulation are local). These results are surprising. One is tempted to consider alternating and non-alternating MDPs as equivalent, since a non-alternating MDP can be translated into an alternating one by splitting its states into multiple alternating ones. The difference between the alternating and non-alternating models was already noted in [ST05] for strong and weak “precise” simulation, and in [BS01] for axiomatizations. Our results indicate that the difference between the alternating and non-alternating model is even more marked for \( \approx > 0 \), which is a local relation on alternating models, and a non-local relation in non-alternating ones.

More surprises follow when examining the roles of the \( \circ \) (“next”) and \( \mathcal{U} \) (“until”) operators, and the distinction between \( \text{Qrctl} \) and \( \text{Qrctl}^* \). For \( \text{Ctl} \), it is known that the \( \circ \) operator alone suffices to characterize bisimulation; the \( \mathcal{U} \) operator does not add distinguishing power. The same is true for \( \text{Qrctl} \) on finite, alternating MDPs. On the other hand, we show that for non-alternating, or infinite, MDPs, \( \mathcal{U} \) adds distinguishing power to the logic. Similarly, the relations induced by \( \text{Qrctl} \) and \( \text{Qrctl}^* \) coincide on finite, alternating MDPs, but \( \text{Qrctl}^* \) has greater distinguishing power, and induces thus finer relations, on non-alternating or infinite MDPs.

In summary, we establish that on finite, alternating MDPs, qualitative equivalence can be computed efficiently, and enjoys many canonical properties. We also show that the situation becomes more complex as soon as infinite or non-alternating MDPs are considered. In all cases, we provide sharp boundaries for the classes of MDPs on which our statements apply, distinguishing also between finitely and infinitely-branching MDPs. Our results also indicate how the distinction between alternating and non-alternating MDPs, while often overlooked, is in fact of great importance where the logical properties of the MDPs are concerned.

Our organization of the paper is as follows: in section 2 we present the formal definitions of MDPs and the logics \( \text{Qrctl} \) and \( \text{Qrctl}^* \). In section 3 we present a model checking algorithm for MDPs with the logic \( \text{Qrctl} \). In section 4 we characterize the equivalence relations of MDPs with respect to \( \text{Qrctl} \). In section 5 we present algorithms to compute the equivalence relations. Finally, in section 6 we discuss the roles of the until and wait-for operators in the logics, and in section 7 we consider the role of linear-time nesting (i.e., the equivalences for the logic \( \text{Qrctl}^* \)).

2. Definitions

2.1. Markov Decision Processes

A probability distribution on a countable set \( X \) is a function \( f : X \rightarrow [0,1] \) such that \( \sum_{x \in X} f(x) = 1 \); we denote the set of all probability distributions on \( X \) by \( \mathcal{D}(X) \). Given \( f \in \mathcal{D}(X) \), we define \( \text{Supp}(f) = \{ x \in X \mid f(x) > 0 \} \) to be the support of \( f \). We consider a fixed set \( AP \) of atomic propositions, which includes the distinguished proposition \( \text{turn} \). Given a set \( S \), we denote \( S^+ \) (respectively \( S^\omega \)) the set of finite (resp. infinite) sequences of elements of \( S \).

A Markov decision process (MDP) \( G = (S, A, \Gamma, \delta, [\cdot]) \) consists of the following components:

- a countable set of states \( S \);
- a finite set of actions \( A \);
• an action assignment \( \Gamma : S \mapsto 2^A \setminus \emptyset \), which associates with each state \( s \in S \) the set \( \Gamma(s) \) of actions that can be chosen at \( s \);
• a transition function \( \delta : S \times A \mapsto \mathcal{D}(S) \), which associates with each state \( s \) and action \( a \) a next-state probability distribution \( \delta(s,a) \);
• a labeling function \( [\cdot] : S \mapsto 2^{\mathcal{AP}} \), which labels all \( s \in S \) with the set \( \{s\} \) of atomic propositions true at \( s \).

For \( s \in S \) and \( a \in \Gamma(s) \), we let \( \text{Dest}(s,a) = \text{Supp}(\delta(s,a)) \) be the set of possible destinations when the action \( a \) is chosen at the state \( s \). The MDP \( G \) is finite if the state space \( S \) is finite, and it is finitely-branching if for all \( s \in S \) and \( a \in \Gamma(s) \), the set \( \text{Dest}(s,a) \) is finite. A play or path is an infinite sequence \( \vec{\omega} = \langle s_0, s_1, \ldots \rangle \in S^\omega \) of states of the MDP. For \( s \in S \) and \( q \in \mathcal{AP} \), we say that \( s \) is a \( q \)-state iff \( q \in \{s\} \). We define an edge relation \( E = \{(s,t) \in S \times S \mid \exists a \in \Gamma(s) . t \in \text{Dest}(s,a)\} \); for \( s \in S \), we let \( E(s) = \{t \mid (s,t) \in E\} \).

An MDP \( G \) is a Markov chain if \( |\Gamma(s)| = 1 \) for all \( s \in S \); in this case, for all \( s,t \in S \) we write \( \delta(s)(t) \) rather than \( \delta(s,a)(t) \) for the unique \( a \in \Gamma(s) \).

Interpretations. We interpret an MDP in two distinct ways: as a 1\( \frac{1}{2} \)-player game, and as a 2-player game. In the 1\( \frac{1}{2} \)-player interpretation, probabilistic choice is resolved probabilistically: at a state \( s \in S \), player 1 chooses an action \( a \in \Gamma(s) \), and the MDP moves to the successor state \( t \in S \) with probability \( \delta(s,a)(t) \). In the 2-player interpretation, we regard probabilistic choice as adversarial, and we treat the MDP as a game between player 1 and player \( p \) (\( p \) for “probability”): at a state \( s \), player 1 chooses an action \( a \in \Gamma(s) \), and player \( p \) chooses a destination \( t \in \text{Dest}(s,a) \). The 1\( \frac{1}{2} \)-player interpretation is the classical one [Der70]. The 2-player interpretation will be used to relate the qualitative equivalence relations for the MDP with the alternating relations of [AHK98], and thereby derive algorithms for computing the qualitative equivalence relations.

Strategies. A player-1 strategy is a function \( \sigma : S^+ \mapsto \mathcal{D}(A) \) that prescribes the probability distribution \( \sigma(\vec{w}) \) over actions to be played, given the past sequence \( \vec{w} \in S^+ \) of states visited in the play. We require that if \( a \in \text{Supp}(\sigma(\vec{w} \cdot s)) \), then \( a \in \Gamma(s) \) for all \( a \in A \), \( s \in S \), and \( \vec{w} \in S^* \). We denote by \( \Sigma \) the set of all player-1 strategies.

A player-\( p \) strategy is a function \( \pi : S^+ \times A \mapsto \mathcal{D}(S) \). The strategy must be such that, for all \( s \in S \), \( \vec{w} \in S^* \), and \( a \in \Gamma(s) \), we have that \( \text{Supp}(\pi(\vec{w} \cdot s,a)) \subseteq \text{Supp}(\delta(s,a)) \). Player \( p \) follows the strategy \( \pi \) if, whenever player 1 chooses move \( a \) after a history of play \( \vec{w} \), she chooses the destination state with probability distribution \( \pi(\vec{w},a) \). Thus, in the 2-player interpretation, nondeterminism plays first, and probability second. We denote by \( \Pi \) the set of all player-\( p \) strategies.

The 2-player interpretation. In the 2-player interpretation, once a starting state \( s \in S \) and two strategies \( \sigma \in \Sigma \) and \( \pi \in \Pi \) have been chosen, the game is reduced to an ordinary stochastic process, and it is possible to define the probabilities of events, where an event \( A \subseteq S^\omega \) is a measurable set of paths. We denote the probability of event \( A \), starting from \( s \in S \), under strategies \( \sigma \in \Sigma \) and \( \pi \in \Pi \) by \( \text{Pr}_s^{\sigma,\pi}(A) \): note that the probability of events given strategies \( \sigma \) and \( \pi \) do not depend on the transition probabilities of the MDP as the strategy \( \pi \) can choose any probability distribution at each step. Given \( s \in S \) and \( \sigma \in \Sigma \), \( \pi \in \Pi \), a play \( \langle s_0, s_1, \ldots \rangle \) is feasible if for every \( k \in \mathbb{N} \), there is \( a \in \Gamma(s_k) \) such that
The probabilistic transition function is defined, for $s$ state alternating: the difference between player-1 and player-$p$:

$\sigma(s_0, s_1, \ldots, s_k)(a) > 0$ and $\pi(s_0, s_1, \ldots, s_k, a)(s_{k+1}) > 0$. We denote by $\text{Outc}(s, \sigma, \pi) \subseteq S^\omega$ the set of feasible plays that start from $s$ given strategies $\sigma$ and $\pi$.

The 1\1/2-player interpretation. In the 1\1/2-player interpretation, we fix for player $p$ the strategy $\pi^*$ that chooses the next state with the distribution prescribed by $\delta$. Precisely, for all $\bar{w} \in S^\ast$, $s \in S$, and $a \in \Gamma(s)$, we let $\pi^*(\bar{w} \cdot s, a) = \delta(s, a)$. We then write $\text{Pr}_s^\ast(A)$ and $\text{Outc}(s, \sigma)$ instead of $\text{Pr}_s^{\sigma, \pi^*}(A)$ and $\text{Outc}(s, \sigma, \pi^*)$, respectively, to underline the fact that these probabilities and set of outcomes are functions only of the initial state and of the strategy of player 1.

Alternating MDPs. An alternating MDP (AMDP) is an MDP $G = (S, A, \Gamma, \delta, [\cdot])$ along with a partition $(S_1, S_p)$ of $S$ such that:

1. If $s \in S_1$, then $\text{turn} \in [s]$ and, for all $a \in \Gamma(s)$, $|\text{Dest}(s, a)| = 1$.
2. If $s \in S_p$, then $\text{turn} \notin [s]$ and $|\Gamma(s)| = 1$.

The states in $S_1$ are the player-1, or nondeterministic states, and the states in $S_p$ are the player-$p$, or probabilistic states. The predicate turn ensures that the MDP is visibly alternating: the difference between player-1 and player-$p$ states is obvious to the players, and we want it to be obvious to the logic too. Alternating MDPs can be represented more succinctly (and more intuitively) by providing, along with the partition $(S_1, S_p)$ of $S$, the edge relation $E \subseteq S \times S$, and a probabilistic transition function $\delta : S_p \mapsto \mathcal{D}(S)$.

The probabilistic transition function is defined, for $s \in S_p$, $t \in S$, and $a \in \Gamma(s)$, by $\hat{\delta}(s)(t) = \delta(s, a)(t)$. A non-alternating MDP is a general (alternating or not) MDP.

We represent MDPs by graphs: vertices correspond to nodes, and each action $a$ from a state $s$ is drawn as a hyperedge from $s$ to $\text{Dest}(s, a)$.

2.2. Logics

We consider two logics for the specification of MDP properties. The first, $\text{Qrctl}^\ast$, is a logic that captures qualitative properties of MDPs, and is a qualitative version of $\text{pCtl}^\ast$ [HJ94, ASB+95, BdA95]. The logic is defined with respect to the classical, 1\1/2-player semantics of MDPs. The second logic, $\text{Atl}^\ast$, is a game logic defined with respect to the 2-player semantics of MDPs as in [AHK02].

Syntax. The syntax of both logics is given by defining the set of path formulas ($\varphi$) and state formulas ($\psi$) via the following inductive clauses:

- **path formulas:** $\varphi ::= \psi \mid \neg \varphi \mid \varphi \lor \varphi \mid \Box \varphi \mid \varphi U \varphi \mid \varphi W \varphi$;
- **state formulas:** $\psi ::= \text{tt} \mid q \mid \neg \psi \mid \psi \lor \psi \mid P Q(\varphi)$;

where $q \in AP$ is an atomic proposition, $\text{tt}$ is the boolean constant with value true, and $P Q$ is a path quantifier. The operators $U, W$ and $\Box$ are temporal operators. The logics $\text{Atl}^\ast$ and $\text{Qrctl}^\ast$ differ in the path quantifiers:

- The path quantifiers in $\text{Qrctl}^\ast$ are: $\exists^\forall, \forall^\exists, \exists^\text{some}, \forall^\text{some}, \exists^1, \forall^1, \exists^>0$ and $\forall^>0$.
- The path quantifiers in $\text{Atl}^\ast$ are: $\langle 1 \rangle, \langle p \rangle, \langle 1, p \rangle, \langle \emptyset \rangle$. 
The fragments ATL of ATL$^*$ and Qrctl of Qrctl$^*$ consist of formulas where every temporal operator is immediately preceded by a path quantifier. In the following, when we refer to a “formula” of a logic, without specifying whether it is a state or path formula, we always mean a state formula. As usual, we define $\Box \varphi$ and $\Diamond \varphi$ to be abbreviations for $\varphi W(-tt)$ and $ttU \varphi$, respectively.

**Semantics.** For a play $\bar{\omega} = \langle s_0, s_1, \ldots \rangle$ we denote by $\bar{\omega}[i]$ the play starting from the $i$-th state of $\bar{\omega}$, i.e., $\bar{\omega}[i] = \langle s_i, s_{i+1}, \ldots \rangle$. The semantics for the path formulas is defined as follows, for path formulas $\varphi, \varphi_1, \varphi_2$:

$\bar{\omega} \models \varphi_1 \lor \varphi_2$ if $\bar{\omega} \models \varphi_1$ or $\bar{\omega} \models \varphi_2$

$\bar{\omega} \models \neg \varphi$ if $\bar{\omega} \not\models \varphi$

$\bar{\omega} \models \bigcirc \varphi$ if $\bar{\omega}[1] \models \varphi$

$\bar{\omega} \models \varphi_1 U \varphi_2$ if $\exists j \in \mathbb{N}. \bar{\omega}[j] \models \varphi_2$ and $\forall 0 \leq i < j. \bar{\omega}[i] \models \varphi_1$

$\bar{\omega} \models \varphi_1 W \varphi_2$ if $(\forall j \in \mathbb{N}. \bar{\omega}[j] \models \varphi_2)$ or $\exists j \in \mathbb{N}. \bar{\omega}[j] \models \varphi_2$ and $\forall 0 \leq i < j. \bar{\omega}[i] \models \varphi_1$.

Observe that

$$-(\psi_1 U \psi_2) = \Box (\neg \psi_2) \lor (\neg \psi_2 U (\neg \psi_1 \land \neg \psi_2)) = \neg \psi_2 W \neg \psi_1.$$

Finally, we have

$\bar{\omega} \models \psi$ if $s_0 \models \psi$.

Given a path formula $\varphi$ we denote by $[\varphi] = \{ \bar{\omega} \mid \bar{\omega} \models \varphi \}$ the set of plays that satisfy $\varphi$. The semantics of the state formulas of ATL$^*$ and Qrctl$^*$ is defined as follows, for a state $s$, path formula $\varphi$, and state formulas $\psi_1$ and $\psi_2$:

$s \models tt$ if $q \in [s]$

$s \models \neg \psi_1$ if $s \not\models \psi_1$

$s \models \psi_1 \lor \psi_2$ if $s \models \psi_1$ or $s \models \psi_2$

$s \models \exists^{\text{all}}(\varphi)$ if $\exists \sigma \in \Sigma. \text{Outc}(s, \sigma) \subseteq [\varphi]$

$s \models \forall^{\text{all}}(\varphi)$ if $\forall \sigma \in \Sigma. \text{Outc}(s, \sigma) \subseteq [\varphi]$

$s \models \exists^{t}(\varphi)$ if $\exists \sigma \in \Sigma. \text{Pr}_{s}^{\sigma}([\varphi]) = 1$

$s \models \forall^{t}(\varphi)$ if $\forall \sigma \in \Sigma. \text{Pr}_{s}^{\sigma}([\varphi]) = 1$

$s \models \exists^{>0}(\varphi)$ if $\exists \sigma \in \Sigma. \text{Pr}_{s}^{\sigma}([\varphi]) > 0$

$s \models \forall^{>0}(\varphi)$ if $\forall \sigma \in \Sigma. \text{Pr}_{s}^{\sigma}([\varphi]) > 0$

$s \models \exists^{\text{some}}(\varphi)$ if $\exists \sigma \in \Sigma. \text{Outc}(s, \sigma) \cap [\varphi] \neq \emptyset$

$s \models \forall^{\text{some}}(\varphi)$ if $\forall \sigma \in \Sigma. \text{Outc}(s, \sigma) \cap [\varphi] \neq \emptyset$

$s \models \langle 1 \rangle (\varphi)$ if $\exists \sigma \in \Sigma. \forall \pi \in \Pi. \text{Outc}(s, \sigma, \pi) \subseteq [\varphi]$

$s \models \langle p \rangle (\varphi)$ if $\exists \pi \in \Pi. \forall \sigma \in \Sigma. \text{Outc}(s, \sigma, \pi) \subseteq [\varphi]$

$s \models \langle 1, p \rangle (\varphi)$ if $\exists \sigma \in \Sigma. \exists \pi \in \Pi. \text{Outc}(s, \sigma, \pi) \subseteq [\varphi]$

$s \models \langle \emptyset \rangle (\varphi)$ if $\forall \sigma \in \Sigma. \forall \pi \in \Pi. \text{Outc}(s, \sigma, \pi) \subseteq [\varphi]$.

Given an ATL$^*$ or Qrctl$^*$ formula $\varphi$ and an MDP $G = (S, A, \Gamma, \delta, [\cdot])$, we denote by $[\psi]_{G} = \{ s \in S \mid s \models \varphi \}$ the set of states that satisfy the state formula $\psi$, and we omit
the subscript $G$ when obvious from the context. For all path formulas $\varphi$ of $\mathcal{QRCTL}$, the following dualities hold:

$$
\begin{align*}
\exists^{all} \varphi &= \neg (\forall^{some} (\neg \varphi)) \\
\exists^{some} \varphi &= \neg (\forall^{all} (\neg \varphi)) \\
\exists^{>0} \varphi &= \neg (\forall^{1} (\neg \varphi)) \\
\exists^{1} \varphi &= \neg (\forall^{>0} (\neg \varphi)) \quad \text{(2.1)}
\end{align*}
$$

We now present a simple example to illustrate the difference between the satisfaction of a path formula with probability 1 and for all paths.

**Example 2.1.** Consider the simple Markov chain shown in Figure 1. Let the propositions true at states $s$ and $t$ be $q$ and $r$, respectively. Let us consider the starting state as $s$, and the formula $\Diamond r$ (eventually $r$). The formula holds at state $s$ with probability 1, since the only closed recurrent set of states in the Markov chain is the state $t$ (labeled with proposition $r$). Hence $\Diamond r$ holds in state $s$ with probability 1. However, there is a path (namely, $s^\omega$) that violates the property eventually $r$, but the probability measure for the set $\{s^\omega\}$ of paths is 0. Thus the state $s$ does not satisfy that all on all paths we have eventually $r$, though it satisfies the property eventually $r$ with probability 1. If we consider the property eventually $q$, then for all paths starting from $s$ the property holds (hence the property also holds with probability 1).

The following lemma establishes a relationship between $\mathcal{QRCTL}$ and $\mathcal{ATL}$, proving that the $\mathcal{QRCTL}$ quantifiers with superscript $all$ and $some$ are equivalent to the $\mathcal{ATL}$ quantifiers.

**Lemma 2.2.** For all path formulas $\varphi$, the following equivalences hold.

$$
\begin{align*}
\langle 1 \rangle \varphi &= \exists^{all} \varphi \\
\langle 1, p \rangle \varphi &= \exists^{some} \varphi \\
\langle p \rangle \varphi &= \forall^{some} \varphi \\
\langle \emptyset \rangle \varphi &= \forall^{all} \varphi
\end{align*}
$$

**Proof.** Let $G = (S, A, \Gamma, \delta, [\cdot])$ be an MDP and let $s \in S$. We prove the first statement. Assume $s \models \langle 1 \rangle \varphi$. By definition, there exists $\sigma^* \in \Sigma$ such that:

$$
\forall \pi \in \Pi. \text{Outc}(s, \sigma^*, \pi) \subseteq [\varphi].
$$

Let $\pi^* \in \Pi$ be the strategy of player $p$ that chooses the next state according to $\delta$ (i.e., the natural strategy of player $p$ in $G$). We have:

$$
\text{Outc}(s, \sigma^*) = \text{Outc}(s, \sigma^*, \pi^*) \subseteq [\varphi]. \quad \text{(2.2)}
$$

Therefore, $s \models \exists^{all} \varphi$.

Conversely, assume $s \models \exists^{all} \varphi$. Then, there exists $\sigma^* \in \Sigma$ such that (2.2) holds. Let $\pi$ be any strategy of player $p$. We have that $\text{Outc}(s, \sigma^*, \pi) \subseteq \text{Outc}(s, \sigma^*, \pi^*)$, because $\pi^*$ is...
the most liberal strategy for player $p$, i.e., no player-$p$ strategy can ever choose a successor state that is not among those that are chosen by $\pi^*$. Therefore, $\text{Outc}(s, \sigma^*, \pi) \subseteq [\varphi]$ and $s = \langle 1 \rangle \varphi$.

Next, we prove the second statement. The remaining statements follow by duality. Assume $s = \langle 1, p \rangle \varphi$. Then, there exist $\sigma^* \in \Sigma$ and $\pi^* \in \Pi$ such that $\text{Outc}(s, \sigma^*, \pi^*) \subseteq [\varphi]$. Let $\pi^*$ be the natural strategy for player $p$ in $G$. By the previous argument, $\text{Outc}(s, \sigma^*, \pi^*) \subseteq \text{Outc}(s, \sigma^*, \pi^*)$. Therefore, $\text{Outc}(s, \sigma^*, \pi^*) \cap [\varphi] \neq \emptyset$ and $s = \exists \text{some} \varphi$.

Finally, assume $s = \exists \text{some} \varphi$. By definition, there exists $\sigma^* \in \Sigma$ such that $\text{Outc}(s, \sigma^*, \pi^*) \cap [\varphi] \neq \emptyset$, where $\pi^*$ is the natural strategy for player $p$ in $G$. Let $\bar{\omega}$ be a play in $\text{Outc}(s, \sigma^*, \pi^*) \cap [\varphi]$. Define $\sigma^*$ and $\pi^*$ as the deterministic strategies that give as only outcome $\bar{\omega}$. We have:

$$\text{Outc}(s, \sigma^*, \pi^*) = \{ \bar{\omega} \} \subseteq [\varphi].$$

Therefore, $s = \langle 1, p \rangle \varphi$. $\blacksquare$

Finally, the following lemma proves the equivalence of some QRCTL formulas.

**Lemma 2.3.** For all atomic propositions $q, r$, and for all MDPs, we have:

$$\begin{align*}
\exists^{0} \bigcirc q &= \exists^{\text{some}} \bigcirc q \\
\exists^{I} \bigcirc q &= \exists^{\text{all}} \bigcirc q \\
\exists^{0} q U r &= \exists^{\text{some}} q U r \\
\exists^{I} q W r &= \exists^{\text{all}} q W r.
\end{align*}$$  \hspace{1cm} (2.3)

**Proof.** The first two statements are obvious by definition. The third statement follows by noting that $s = \exists^{\text{some}} q U r$ iff there is a finite path in $(S, E)$ from $s$ to an $r$-state, and all states of the path, except possibly the last, are $q$-states. If such a path exists, there is certainly a strategy of player 1 that follows it with positive probability.

For the last statement, the “$\supseteq$” inclusion is obvious by definition. For the other inclusion, assume by contradiction that $s \in [\exists^{I} q W r]$, but all strategies of player 1 ensuring $q W r$ with probability one also exhibit a path violating it. Then, $s \in [\forall^{\text{some}} \neg (q W r)] = [\forall^{\text{some}} \neg r U \neg q]$. Following an argument similar to the one for the third statement, we obtain that $s \in [\forall^{>0} \neg r U \neg q] = [\forall^{>0} \neg (q W r)]$, which is a contradiction. $\blacksquare$

### 2.3. Equivalence Relations

Given an MDP $G = (S, A, \Gamma, \delta, [\cdot])$, we consider the equivalence relations induced over its state space by various syntactic subsets of the logics QRCTL and ATL. Define the following fragments of QRCTL:

- $\text{QRCTL}^{>0}$ is the syntactic fragment of QRCTL containing only the path quantifiers $\exists^{>0}$ and $\forall^{>0}$.
- $\text{QRCTL}^{\text{all}}$ is the syntactic fragment of QRCTL containing only the path quantifiers $\exists^{\text{all}}$ and $\forall^{\text{all}}$.

Note that, because of the dualities (2.1), we do not need to consider the fragments for $\forall^{I}$, $\exists^{I}$, $\forall^{\text{some}}$, $\exists^{\text{some}}$. The relations induced by $\text{QRCTL}^{>0}$ and $\text{QRCTL}^{\text{all}}$ provide us with a notion of qualitative equivalence between states.

$$\begin{align*}
\simeq^{>0} &= \{(s, s') \in S \times S \mid \forall \psi \in \text{QRCTL}^{>0}, s \models \psi \text{ iff } s' \models \psi \} \\
\simeq^{\text{all}} &= \{(s, s') \in S \times S \mid \forall \psi \in \text{QRCTL}^{\text{all}}, s \models \psi \text{ iff } s' \models \psi \}.
\end{align*}$$
Figure 2: Relationship between equivalence relations for AMDPs.

We denote by $\approx_{>0,\circ}$ the equivalence relation defined by $\text{QRCTL}_{>0}^\circ$, with $\circ$ as the only temporal operator. We also define the equivalences $\approx_{>0}^*$ and $\approx_{all}^*$ as the QRCTL$^*$-version of $\approx_{>0}$ and $\approx_{all}$, respectively.

The syntactic subset of $\text{Atl}$ which uses only the path quantifiers $\langle 1, p \rangle$ and $\langle \emptyset \rangle$ induces the usual notion of bisimulation [Mil90]: indeed, quantifiers $\langle 1, p \rangle$ and $\langle \emptyset \rangle$ correspond to quantifiers $\exists$ and $\forall$ of $\text{Ctl}$ [CE81], respectively. The syntactic subset of $\text{Atl}$ which uses only the path quantifiers $\langle 1 \rangle$ and $\langle p \rangle$ induces alternating bisimulation [AHKV98]. We have:

$\approx_{\text{TS}} = \{(s, s') \in S \times S \mid \text{for all } \text{Atl formulas } \psi \text{ with } \langle 1, p \rangle, \langle \emptyset \rangle \text{ as path quantifiers, } s \models \psi \text{ iff } s' \models \psi \}$;

$\approx_{\text{Game}} = \{(s, s') \in S \times S \mid \text{for all } \text{Atl formulas } \psi \text{ with } \langle 1 \rangle, \langle p \rangle \text{ as path quantifiers, } s \models \psi \text{ iff } s' \models \psi \}$;

$\approx_{\text{ATL}} = \{(s, s') \in S \times S \mid \text{for all } \text{Atl formulas } \psi, s \models \psi \text{ iff } s' \models \psi \}$;

where TS is the short form for transition systems. In the relation $\approx_{\text{Game}}$, nondeterministic and probabilistic choice represent the two players of a game. In the relation $\approx_{\text{TS}}$, nondeterminism and probability always cooperate as a single player. Finally, the relation $\approx_{\text{ATL}}$ arises from the full logic ATL, where nondeterminism and probability can be either antagonistic or cooperative. The relations $\approx_{\text{TS}}$, $\approx_{\text{Game}}$, and $\approx_{\text{ATL}}$ can be computed in polynomial time via well-known partition-refinement algorithms [Mil90] [AHKV98].

Figure 2 (resp. Figure 3) summarizes the relationships between different equivalence relations on alternating MDPs (resp. general MDPs) that we will show in this paper. An arrow from relation $A$ to relation $B$ indicates that $A$ implies $B$, i.e., that $A$ is finer than $B$.

3. Model Checking $\text{QRCTL}$

In order to characterize the equivalence relations for $\text{QRCTL}$, it is useful to present first the algorithms for $\text{QRCTL}$ model checking. The algorithms are based on the results of [dA97a, dA97b, dAH00]; see also [CdAH04]. As usual, we present only the algorithms for formulas containing one path quantifier, as nested formulas can be model-checked by
recursively iterating the algorithms. As a consequence of dualities (2.1), we need to provide algorithms only for the operators $\exists \circlearrowleft$, $\exists U$, and $\exists W$, and for the modalities $\textbf{all}$, $1$, $> 0$, and $\textit{some}$. The algorithms use the following predecessor operators, for $X,Y \subseteq S$:

\begin{align*}
\text{Pre}(X) &= \{ s \in S \mid \exists a \in \Gamma(s) . \text{Dest}(s,a) \cap X \neq \emptyset \} \\
\text{Cpre}(X) &= \{ s \in S \mid \exists a \in \Gamma(s) . \text{Dest}(s,a) \subseteq X \} \\
Apre(Y,X) &= \{ s \in S \mid \exists a \in \Gamma(s) . \text{Dest}(s,a) \subseteq Y \land \text{Dest}(s,a) \cap X \neq \emptyset \}.
\end{align*}

The operators $\text{Pre}$ and $\text{Cpre}$ are classical; the operator $Apre$ is from [dAHK98]. We write the algorithms in $\mu$-calculus notation [Koz83]. Given an MDP $G = (S,A,\Gamma,\delta,[\cdot])$, the interpretation $[\psi]$ of a $\mu$-calculus formula $\psi$ is a subset of states. In particular, for a propositional symbol $q \in AP$, we have $[q] = \{ s \in S \mid q \in [s] \}$ and $[-q] = \{ s \in S \mid q \notin [s] \}$. The operators $\cup$, $\cap$, and the above predecessor operators are interpreted as the corresponding operations on sets of states, and $\mu$ and $\nu$ indicate the least and greatest fixpoint, respectively. The following result directly leads to model-checking algorithms for Qrctl.

**Theorem 3.1.** For atomic propositions $q$ and $r$, and for all MDPs, the following equalities hold:

\begin{align*}
[\exists^I \circlearrowleft q] &= [\exists^{\textbf{all}} \circlearrowleft q] = \text{Cpre}([q]) \\
[\exists^{>0} \circlearrowleft q] &= [\exists^\textit{some} \circlearrowleft q] = \text{Pre}([q]) \\
[\exists^{\textbf{all}} qU r] &= \mu X. ([r] \cup ([q] \cap \text{Cpre}(X))) \\
[\exists^{>0} qU r] &= [\exists^\textit{some} qU r] = \mu X. ([r] \cup ([q] \cap \text{Pre}(X))) \\
[\exists^{\textbf{all}} qW r] &= [\exists^I qW r] = \nu Y. ([r] \cup ([q] \cap \text{Cpre}(Y))) \\
[\exists^\textit{some} qW r] &= \nu Y. ([r] \cup ([q] \cap \text{Pre}(Y)))
\end{align*}

If the MDP is finite, the following equalities also hold:

\begin{align*}
[\exists^I qU r] &= \nu Y. \mu X. ([r] \cup ([q] \cap Apre(Y,X))) \\
[\exists^{>0} qW r] &= [\exists^{>0} qU ((r \land q) \lor \exists^{\textbf{all}} q)]
\end{align*}
The formulas involving the all and some modalities (i.e., statements (3.1) to (3.6)) are derived by the corresponding classical game algorithms, thanks to Lemma 2.2 and Lemma 2.3. Formula (3.7) is from [AAMK98]. Formula (3.8) can be understood as follows. A closed component is a subset of states \( T \subseteq S \) such that, for all \( s \in T \), there is at least one \( a \in \Gamma(s) \) such that \( \text{Dest}(s,a) \subseteq T \). Using the relation \( q\text{Wr} \equiv (q\text{U}(r \land q)) \lor \Box q \) [MP91], we have for \( s \in S \) that \( s \models \exists \geq 0 q\text{Wr} \) iff (i) \( s \models \exists \geq 0 q\text{U}(q \land r) \), or (ii) there is a closed component \( T \) composed only of \( q \)-states, and a path \( s_0, s_1, \ldots, s_n \) in \( (S,E) \) composed of \( q \)-states, with \( s_0 = s \) and \( s_n \in T \) (see, e.g., [dA97a]). Formula (3.8) encodes the disjunction of (i) and (ii).

Note that, even though (3.8) is not a \( \mu \)-calculus formula, it can be readily translated into the \( \mu \)-calculus via (3.4) and (3.5). Also observe the \( \mu \)-calculus formulas corresponding to Qrctl are either alternation free or contain one quantifier alternation between the \( \mu \) and \( \nu \) operator. Thus, from the complexity of evaluating \( \mu \)-calculus formulas we obtain the following result.

Theorem 3.2. Given a finite MDP \( G = (S,A,\Gamma,\delta,[\cdot]) \) and a Qrctl formula \( \psi \), the set \( [\psi]_G \) can be computed in \( O(|S| \cdot |\delta| \cdot \ell) \) time, where \( |\delta| = \sum_{s \in S} \sum_{a \in \Gamma(s)} |\text{Dest}(s,a)| \) and \( \ell \) denotes the length of \( \psi \).

Proof. We first consider the computation of \( \text{Pre}(X) \), \( \text{Cpre}(X) \), and \( \text{Apr}(Y,X) \) for \( X, Y \subseteq S \). To decide whether \( s \in \text{Pre}(X) \) we check if there exists \( a \in \Gamma(s) \) such that \( \text{Dest}(s,a) \cap X \neq \emptyset \). Similarly, to decide whether \( s \in \text{Cpre}(X) \) (resp. \( \text{Apr}(Y,X) \)) we check if there exists \( a \in \Gamma(s) \) such that \( \text{Dest}(s,a) \subseteq X \) (resp. \( \text{Dest}(s,a) \subseteq Y \) and \( \text{Dest}(s,a) \cap X \neq \emptyset \)). It follows that given sets \( X \) and \( Y \), the sets \( \text{Pre}(X) \), \( \text{Cpre}(X) \), and \( \text{Apr}(Y,X) \) can be computed in time \( O(\sum_{s \in S} \sum_{a \in A} |\text{Dest}(s,a)|) \). Given a formula \( \psi \) in Qrctl, with all of its subformulas already evaluated, it follows from Theorem 3.1 that the computation of \( [\psi] \) can be obtained by computing a \( \mu \)-calculus formula of constant length with at most one quantifier alternation of \( \mu \) and \( \nu \). Using the monotonicity property of \( \text{Pre}, \text{Cpre} \) and \( \text{Apr} \), and the computation of \( \text{Pre}, \text{Cpre} \) and \( \text{Apr} \), it follows that each inner iteration of the \( \mu \)-calculus formula can be computed in time \( O(\sum_{s \in S} \sum_{a \in A} |\text{Dest}(s,a)|) \). Since the outer iteration of the \( \mu \)-calculus formula converges in \( |S| \) iterations, it follows that \( [\psi] \) can be computed in time \( O(|S| \sum_{s \in S} \sum_{a \in A} |\text{Dest}(s,a)|) \). By a bottom-up algorithm that evaluates subformulas of a formula first, we obtain the desired bound for the algorithm.

4. Relationship between Qrctl and ATL Equivalences

In this section, we compare the relations induced by Qrctl and ATL. These comparisons will then be used in Section 5 to derive algorithms to compute \( \approx^{\text{all}} \) and \( \approx^{>0} \).

We first compare \( \approx^{\text{all}} \) with the relations induced by ATL. As a first result, we show that the relations induced by ATL coincide on alternating MDPs (AMDPs). This result follows from the fact that the turn is visible to the logic.

Proposition 4.1. On AMDPs, we have \( \approx_{\text{Game}} = \approx_{\text{TS}} \).

Proof. Since the turn is observable (via the truth-value of the predicate \( \text{turn} \)), both \( \approx_{\text{Game}} \) and \( \approx_{\text{TS}} \) can relate only states where the same player (1 or \( p \)) can choose the next move. Based on this observation, the equality of the relations can be proved straightforwardly by induction.
Corollary 4.2. On AMDPs, we have $\approx_{\text{ATL}} = \approx_{\text{Game}} = \approx_{\text{TS}}$.

An immediate consequence of Lemma 2.2 is that $\approx^{\text{all}}$ and $\approx_{\text{ATL}}$ coincide. This enables the computation of $\approx^{\text{all}}$ via the algorithms for alternating bisimulation [AHKV98].

Proposition 4.3. For all MDPs, $\approx^{\text{all}} = \approx_{\text{ATL}}$.

Next, we examine the relationship between $\approx^{>0}$ and $\approx_{\text{ATL}}$. On finitely-branching MDPs, $\approx^{>0}$ is finer than $\approx_{\text{ATL}}$; the result cannot be extended to infinitely-branching MDPs.

Theorem 4.4. The following assertions hold:

1. On finitely-branching MDPs we have $\approx^{>0} \subseteq \approx_{\text{ATL}}$.
2. There is an infinitely-branching AMDP on which $\approx^{>0} \not\subseteq \approx_{\text{ATL}}$.

Proof. Assertion 1. For $n > 0$, we consider the $n$-step approximation $\approx_{\text{ATL}}^{n}$ of $\approx_{\text{ATL}}$. In finite MDPs, we have $\approx_{\text{ATL}}^{n} = \approx_{\text{ATL}}$ for $n = |S|$; in finitely-branching MDPs, we have $\approx_{\text{ATL}} = \cap_{n=0}^{\infty} \approx_{\text{ATL}}^{n}$, and this does not extend to MDPs that are not finitely-branching. We define a sequence $\Psi_0, \Psi_1, \Psi_2, \ldots$ of sets of formulas such that, for all $s, t \in S$, we have $s \approx_{\text{ATL}}^{n} t$ iff $s$ and $t$ satisfy the same formulas in $\Psi_n$. To this end, given a finite set $\Psi$ of formulas, we denote by $\text{BoolC}(\Psi)$ the set of all formulas that consist in disjunctions of conjunctions of formulas in $\{\psi, \neg\psi \mid \psi \in \Psi\}$. We assume that each conjunction (resp. disjunction) in $\text{BoolC}(\Psi)$ does not contain repeated elements, so that from the finiteness of $\Psi$ follows the one of $\text{BoolC}(\Psi)$. We let $\Psi_0 = \text{BoolC}(\text{AP})$ and, for $k \geq 0$, we let $\Psi_{k+1} = \text{BoolC}(\Psi_k \cup \exists^{>0} \bigcirc \psi, \exists^{\text{all}} \bigcirc \psi \mid \psi \in \Psi_k)$. The formulas in $\text{BoolC}(\Psi_0), \text{BoolC}(\Psi_1), \ldots, \text{BoolC}(\Psi_n)$ provide witnesses that $\approx^{>0} \subseteq \approx_{\text{ATL}}^{n}$. Thus for all $n$, we have $\approx^{>0} \subseteq \approx_{\text{ATL}}^{n}$, and it follows that $\approx^{>0} \subseteq \approx_{\text{ATL}}$.

Assertion 2. Consider a Markov chain, depicted in Figure 4 with state space $S = \mathbb{N} \cup \{s, s'\}$, with only one predicate symbol $q$, such that $[0] = \{q\}$, and $[t] = \emptyset$ for all $t \in S \setminus \{0\}$. There is a transition from $s$ to every $i \in \mathbb{N}$ with probability $1/2^{i+1}$. There is a transition from $s'$ to $s'$ with probability $1/2$, and from $s'$ to every $i \in \mathbb{N}$ with probability $1/2^{i+2}$. There is a transition from $i \in \mathbb{N}$ with $i > 0$ to every state in $\{j \in \mathbb{N} \mid j < i\}$, with uniform probability. There is a deterministic transition from 0 to itself. Since this is a Markov chain, the two path quantifiers $\exists$ and $\forall$ are equivalent, and we need only consider formulas of the form $\exists^{>0}$ and $\forall^{0}$. By induction on the length of a QRCTL formula $\varphi$, we can then show that $\varphi$ cannot distinguish between states in the set $\{i \in \mathbb{N} \mid i > |\varphi|\}$ and $\{s, s'\}$. Hence, $s \not\approx_{\text{ATL}}^{>0} s'$. On the other hand, we have $s \not\approx_{\text{ATL}} s'$, since $s \not\models \langle \langle p \rangle \rangle \square \neg q$ and $s' \models \langle \langle p \rangle \rangle \square \neg q$. ■
To obtain a partial converse of this theorem, we need to translate all QrCTL formulas into ATL. For finite MDPs, Lemmas 2.2 and 2.3 enable us to translate all QrCTL formulas, except for formulas of the type $\exists^f U$ and $\exists^0 W$. For the latter type, from (3.8) together with Lemmas 2.2 and 2.3, we obtain the following result.

**Lemma 4.5.** For finite MDPs, and for all atomic propositions $q, r$, we have

$$[\exists^0 q \circ W r] = [\langle \langle 1, p \rangle \rangle (q U ((q \land r) \lor \langle \langle 1 \rangle \rangle \Box q))].$$

Regarding formulas of the type $\exists^f U$, they can be model-checked using the $\mu$-calculus expression (3.7). To obtain a translation into ATL, which will be given in proof of Theorem 4.7, we first translate into ATL the operator $Apre$. To this end, for ATL formulas $\varphi, \psi$, define

$$F_{Apre}(\varphi, \psi) = (\langle \langle 1 \rangle \rangle \lor (\varphi \land \psi)) \lor (\langle \langle 0 \rangle \rangle \lor \varphi \land (\langle \langle p \rangle \rangle \lor \psi)).$$

**Lemma 4.6.** For AMDPs, and for all ATL formulas $\varphi, \psi$, we have $[F_{Apre}(\varphi, \psi)] = Apre([\varphi], [\psi]).$

**Proof.** We consider the following characterization of the $Apre$ operator, valid for AMDPs: for sets $X$ and $Y$, and a state $s$ we have $s \in Apre(Y, X)$ iff the following conditions hold:

1. if $s \in S_1$, then there exists $a \in \Gamma(s)$ such that $\delta(s, a) \in X \cap Y$; and
2. if $s \in S_p$, then for the unique action $a \in \Gamma(s)$, we have $Dest(s, a) \subseteq Y$ and $Dest(s, a) \cap X \neq \emptyset$. The definition of $F_{Apre}$ captures the above two conditions. The result follows.

Note that the lemma holds only for alternating MDPs: indeed, we will show that, on non-alternating MDPs, the operator $Apre$ is not translatable into ATL.

Using these lemmas, we can show that on finite AMDPs, we have $\approx_{ATL} \subseteq \approx^{>0}$. This result is tight: we cannot relax the assumption that the MDP is finite, nor the assumption that it is alternating.

**Theorem 4.7.** The following assertions hold:

1. On finite AMDPs, we have $\approx_{ATL} \subseteq \approx^{>0}$.
2. There is a finite MDP on which $\approx_{ATL} \nsubseteq \approx^{>0}$.
3. There is an infinite, but finitely-branching, AMDP on which $\approx_{ATL} \nsubseteq \approx^{>0}$.

**Proof.** Assertion 1. We prove that on a finite, alternating MDP, the counterpositive holds: if $s \not\approx^{>0} t$, then $s \not\approx_{ATL} t$. Let $s$ and $t$ be two states such that $s \not\approx^{>0} t$. Then, there must be a formula $\varphi$ in QrCTL$^{>0}$ that distinguishes $s$ from $t$. From this formula, we derive a formula $f(\varphi)$ in ATL that distinguishes $s$ from $t$.

We proceed by structural induction on $\varphi$, starting from the inner part of the formula and replacing successive parts that are in the scope of a path quantifier by their ATL version. The cases where $\varphi$ is an atomic proposition, or a boolean combination of formulas are trivial. Using (2.1), we reduce QrCTL$^{>0}$-formulas that involve a $\forall$ operator to formulas that only involve the $\exists$ operator. Lemma 2.3 provides translations for all such formulas, except those of type $\exists^f(\varphi U \psi)$. For instance, (2.3) leads to $f(\exists^0 \varphi U \psi) = \langle \langle 1, p \rangle \rangle f(\varphi) U f(\psi)$. In order to translate a formula of the form $\gamma = \exists^f(\varphi U \psi)$, we translate the evaluation of the nested $\mu$-calculus formula (3.7) into the evaluation of a nested ATL formula, as follows. Define the set of formulas $\{\alpha_{i,j} \mid 0 \leq i, j \leq n\}$, where $n = |S|$ is the number of states of the AMDP,
via the following clauses:

\[
\forall i \in [0..n] : \quad \alpha_{i,0} = ff \\
\forall j \in [1..n] : \quad \alpha_{0,j} = tt \\
\forall i \in [1..n], \forall j \in [0..n - 1] : \quad \\
\alpha_{i,j+1} = f(\psi) \vee (f(\varphi) \land Apre(\alpha_{i-1,n}, \alpha_{i,j})) .
\]

From Lemma 4.6, the above set of formulas encodes the iterative evaluation of the nested fixpoint \(3.7\), so that we have \(\alpha_{n,n} = [\gamma]\), and we can define \(f(\gamma) = \alpha_{n,n}\). This concludes the translation.

**Assertion 2.** Consider the MDP shown in Figure 5. The states \(s\) and \(t\) are such that \((s,t) \in \approx_{\text{ATL}}\). However, \(s \models \exists^f (\odot q)\) (consider the strategy that plays always \(a\)), whereas \(t \not\models \exists^f (\odot q)\).

**Assertion 3.** Consider the infinite AMDP shown in Figure 6. All states are probabilistic states, i.e. \(S_1 = \emptyset\). For all \(i > 0\), we set \(x_i = \frac{1}{2}\) and \(y_i = 2^{-\frac{1}{2^i}}\), so that \(\prod_{i>0} x_i = 0\) and \(\prod_{i>0} y_i = \frac{1}{2}\). It is easy to see that \(s \approx_{\text{ATL}} t\). However, \(s \models \exists^{>0} (\Box q)\) and \(t \not\models \exists^{>0} (\Box q)\).

The example in Figure 5 also shows that on non-alternating MDPs, unlike on alternating ones (see Lemma 4.6), the \(Apre\) operator cannot be encoded in \(\text{ATL}\). If we were able to encode \(Apre\) in \(\text{ATL}\), by proceeding as in the proof of the first assertion, given two states \(s\), \(t\) with \(s \not\approx^{>0} t\), we could construct an \(\text{ATL}\) formula distinguishing \(s\) from \(t\).

As a corollary to Theorems 4.4 and 4.7 we have that on finite, alternating MDPs, the equivalences induced by \(\text{ATL}\) and \(\text{QRCTL}\) coincide. Thus the discrete graph theoretic algorithms to compute equivalences for \(\text{ATL}\) can be used to compute the \(\text{QRCTL}\) equivalences for finite AMDPs.

**Corollary 4.8.** For finite AMDPs, we have \(\approx^{>0} = \approx_{\text{ATL}}\).
5. Computing QRCTL Equivalences

In this section, we take advantage of the results obtained in Section 4 to derive algorithms to compute $\approx > 0$ and $\approx^{all}$ for AMDPs. We also provide an algorithm to compute those relations on non-alternating MDPs.

5.1. Alternating MDPs

Corollary 4.8 immediately provides an algorithm for the computation of the QRCTL equivalences on AMDPs, via the computation of the ATL equivalences (interpreting nondeterminism and probability as the two players). In particular, the partition-refinement algorithms presented in [AHK02] can be directly applied to the problem. This yields the following result.

**Theorem 5.1.** The two problems of computing $\approx > 0$ and $\approx^{all}$ on finite AMDPs are PTIME-complete.

**Proof.** Consider a turn-based game and consider the AMDP obtained from the game assigning uniform transition probabilities to all outgoing edges from a player 2 state. Then the 2-player game interpretation of the AMDP coincides with the original turn-based game. The result then follows from Corollary 4.8 and from the PTIME-completeness of ATL model checking and computing $\approx_{ATL}$ [AHK02].

5.2. Non-Altering MDPs

For the general case of non-altering MDPs, on the other hand, the situation is not nearly as simple. First, let us dispel the belief that, in order to compute $\approx > 0$ on a non-altering MDP, we can convert the MDP into an alternating one, compute $\approx > 0$ via $\approx_{ATL}$ (using Corollary 4.8) on the alternating one, and then somehow obtain $\approx > 0$ on the original non-altering MDP. The following example shows that this, in general, is not possible.

**Example 5.2.** Consider the MDP depicted in Figure 7(a), where the set of predicates is $AP = \{q, r\}$. We have $s \approx > 0 s'$. Indeed, the only difference between $s$ and $s'$ is that at state $s'$ the action $c$ is available: since $c$ is a convex combination of $a$ and $b$, $s$ and $s'$ are probabilistically bisimilar in the sense of [SL94], and thus also related by $\approx > 0$. We transform this MDP into an alternating one by adding, for each state $s$ and each $a \in \Gamma(s)$, a state.
⟨s,a⟩ which represents the decision of choosing a at s; the result is depicted in Figure 7(b).

In this AMDP, however, the state ⟨s′,c⟩ has no equivalent, as it satisfies both $\exists^0 q$ and $\exists^0 r$. Therefore, on this AMDP we have $s \not\approx^0 s'$, as witnessed by the formula $\exists^{all} ((\exists^0 q) \land (\exists^0 r))$.

As the example illustrates, the problem is that once nondeterminism and probability are separated into different states, the distinguishing power of $\approx^0$ increases, so that computing $\approx^0$ on the resulting alternating MDP does not help to compute $\approx^0$ on the original non-alternating one.

**Failure of local partition refinement.** Simulation and bisimulation relations can be computed via partition refinement algorithms that consider, at each step, the 1-neighbourhood of each state: that is, the set of states reachable from a given state in one step [Mil90]. We call such algorithms 1-neighbourhood partition refinements. Here, we show a general result: no 1-neighbourhood partition refinement algorithm exists for $\approx^0$ on non-alternating MDPs.

We make this notion precise as follows. Consider an MDP $G = (S,A,\Gamma,\delta,\cdot)$, together with an equivalence relation $\sim$ on $S$. Intuitively, two states are 1-neighbourhood isomorphic up to $\sim$ if their 1-step future looks identical, up to the equivalence $\sim$. Formally, we say that two states $s,t \in S$ are 1-neighbourhood isomorphic up to $\sim$, written $s \overset{1}{\sim} t$, iff $s \sim t$, and if there is a bijection $R$ between $E(s)$ and $E(t)$, and a bijection $\hat{R}$ between $\Gamma(s)$ and $\Gamma(t)$, which preserve $\sim$ and the transition probabilities. Precisely, we require that:

- if $s' \in E(s)$ and $t' \in E(t)$ with $s' R t'$, then $s' \sim t'$;
- if $a \in \Gamma(s)$ and $b \in \Gamma(t)$ with $a \hat{R} b$, then for all $s' \in E(s)$ and $t' \in E(t)$ with $s' R t'$, we have $\delta(s,a)(s') = \delta(t,b)(t')$.

Let $\text{Part}S$ be the set of equivalence relations on $S$. A partition refinement operator $f : \text{Part}S \mapsto \text{Part}S$ is an operator such that, for all $\sim \in \text{Part}S$, we have $f(\sim)$ is finer than $\sim$. We say that a partition operator computes a relation $\approx$ if we have $\approx = \lim_{n \to \infty} f^n(\approx_{\text{pred}})$, where $f^n$ denotes $n$ repeated applications of $f$ and $s \approx_{\text{pred}} t$ iff $[s] = [t]$.

We say that a partition refinement operator $f$ is 1-neighbourhood if it refines an equivalence relation $\sim$ on the basis of the 1-neighbourhood of the states, treating in the same fashion states whose 1-neighbourhoods are isomorphic up to $\sim$. Precisely, $f$ is 1-neighbourhood if, for all $\sim \in \text{Part}S$ and for all $s,s',t,t' \in S$ with $s \overset{1}{\sim} s'$, $t \overset{1}{\sim} t'$, we have either $(s,t),(s',t') \in f(\sim)$, or $(s,t),(s',t') \not\in f(\sim)$. We can now state the non-existence of 1-neighbourhood refinement operators for $\approx^0$ as follows.

![Figure 8: MDP showing the lack of 1-neighbourhood refinement operators.](image-url)
Theorem 5.3. There is no 1-neighbourhood partition refinement operator which computes $\approx_{>0}$ on all MDPs.

Proof. Consider the states $s_1, s_2, s_3, s_4$ of the MDP depicted in Figure 5 and take $\sim = \sim_{pred}$. Let $f$ be any 1-neighbourhood partition refinement operator. From $s_1 \sim s_2 \sim s_3 \sim s_4$, we can see that $s_2 \not\sim s_3 \not\sim s_4$. Let $\sim' = f(\sim)$. Considering the pairs $(s_1, s_2), (s_1, s_3),$ and $(s_1, s_4)$ in the definition of 1-neighbourhood partition refinement operator, we have that $\sim'$ satisfies one of the following two cases:

1. $s_1 \not\sim' s_2$ and $s_1 \not\sim' s_3$ and $s_1 \not\sim' s_4$,
2. $s_1 \sim' s_2$ and $s_1 \sim' s_3$ and $s_1 \sim' s_4$.

In the first case, the partition refinement terminates with a relation $\sim''$ such that $s_1 \not\sim'' s_2$. This is incorrect, since we can prove by induction on the length of QRctl formulas that no such formula distinguishes $s_1$ from $s_2$, so that $s_1 \approx_{>0} s_2$. In the second case, the partition refinement terminates with a relation $\sim''$ such that $s_1 \sim'' s_3$. This is also incorrect, since the formula $\exists \cdot \phi_r$ is a witness to $s_1 \not\approx_{>0} s_3$. We conclude that a 1-neighbourhood partition refinement operator cannot compute $\approx_{>0}$.

To give an algorithm for the computation of $\approx_{>0}$, given two sets of states $C_1$ and $C_2$, let:

$$U(C_1, C_2) = \{ (s_0, s_1, \ldots) \mid \exists j \geq 0. s_j \in C_2 \text{ and } \forall 0 \leq i < j. s_i \in C_1 \}$$

$$EU^1(C_1, C_2) = \{ s \in S \mid \exists \sigma \in \Sigma. \Pr_s^\sigma(U(C_1, C_2)) = 1 \}.$$ Intuitively, if $C_1 = \lbrack \varphi_1 \rbrack$ and $C_2 = \lbrack \varphi_2 \rbrack$ for two QRctl formulas $\varphi_1$ and $\varphi_2$, then $EU^1(C_1, C_2)$ is $\lbrack \exists \cdot (\varphi_1 \cup \varphi_2) \rbrack$.

We say that an equivalence relation $\simeq$ is 1, $p$, EU-stable if, for all unions $C_1, C_2$ of equivalence classes with respect to $\simeq$, and for all $s, t \in S$ with $s \simeq t$, we have:

1. $s \in \Pr(C_1)$ iff $t \in \Pr(C_1)$;
2. $s \in \Cpre(C_1)$ iff $t \in \Cpre(C_1)$;
3. $s \in EU^1(C_1, C_2)$ iff $t \in EU^1(C_1, C_2)$.

Let $\approx_{ATL}^{EU}$ be the coarsest equivalence relation that is 1, $p$, EU-stable. We show that $\approx_{ATL}^{EU}$ coincides with $\approx_{>0}$.

Theorem 5.4. For all finite MDPs, we have $\approx_{ATL}^{EU} = \approx_{>0}$.

Proof. We prove containment in the two directions.

$\approx_{ATL}^{EU} \subseteq \approx_{>0}$. This statement is equivalent to saying that for all formulas $\varphi$ in QRctl, $\lbrack \varphi \rbrack$ is the union of classes in $S/\approx_{ATL}^{EU}$. Let $s$ and $t$ be two states such that $s \not\approx_{>0} t$, and let $\varphi$ be a formula from QRctl such that $s \models \varphi$ and $t \not\models \varphi$. We show by structural induction on $\varphi$ that $s \not\approx_{ATL}^{EU} t$. The cases where $\varphi$ is a proposition, or the boolean combination of formulas are trivial. All other cases follow as in the proof of the first part of Theorem 4.7, except for the case $\varphi = \exists \cdot (\varphi_1 \cup \varphi_2)$. For $\varphi = \exists \cdot (\varphi_1 \cup \varphi_2)$, we have $s \in EU^1(\lbrack \varphi_1 \rbrack, \lbrack \varphi_2 \rbrack)$, while $t \not\in EU^1(\lbrack \varphi_1 \rbrack, \lbrack \varphi_2 \rbrack)$. By inductive hypothesis, we can assume that $\lbrack \varphi_1 \rbrack$ and $\lbrack \varphi_2 \rbrack$ are unions of classes in $S/\approx_{ATL}^{EU}$. So, $(s, t) \not\in \approx_{ATL}^{EU}$.

$\approx_{>0} \subseteq \approx_{ATL}^{EU}$. The proof follows the same idea of the proof of the first part of Theorem 4.4. The only modification needed is in the inductive definition of the set of formulas: we take here $\Psi_{k+1} = \BoolC(\Psi_k \cup \{ \exists >0 \circ \psi, \exists \text{all} \circ \psi, \exists \cdot (\psi \cup \psi') \mid \psi, \psi' \in \Psi_k \})$. \qed
The following theorem provides an upper bound for the complexity of computing $\approx^{>0}$ on MDPs. The PTIME-completeness of ordinary simulation [ABGS91] provides a lower bound, but no tight lower bound is known.

**Theorem 5.5.** The problem of deciding whether $s \approx^{>0} t$ for two states $s$ and $t$ of an MDP is in co-NP.

**Proof.** We show that the problem of deciding $s \not\approx^{>0} t$ is in NP. To this end, we have to show that there is a certificate for $s \not\approx^{>0} t$ that has polynomial size, and is polynomially checkable. Consider the usual partition-refinement method for computing $\approx^{ATL}$ [Mil90, AHKV98]. The method starts with an equivalence relation $\simeq$ that reflects propositional equivalence. Then, $\simeq$ is refined at most $m = |S|$ times. At each refinement step, some state-pairs are removed from $\simeq$. A certificate for the removal of a pair from $\simeq$ is simply a $\text{Cpre}$ or $\text{Pre}$ or $\text{EU}^1$ operator, along with a union of equivalence classes; it is thus of size polynomial in $m$. Since at most $m^2$ pairs can be removed from $\simeq$, the total size of these state-pair removal certificates is polynomial in $m$. This yields a polynomial-size and polynomially-checkable certificate for $s \not\approx^{>0} t$.

6. The Roles of Until and Wait-For

In this section we study the roles of the until and the wait-for operator, and the relationship between the equivalences induced by $\text{Qrctl}$ and $\text{Qrctl}^*$.

It is well known that in the standard branching logics $\text{Ctl}$ and $\text{Ctl}^*$, as well as in $\text{ATL}$, the next-time operator $\bigcirc$ is the only temporal operator needed for characterizing bisimulation. For $\text{Qrctl}$, this is not the case: the operators $U$ and $W$ can increase the distinguishing power of the logics, as the following theorem indicates.

**Theorem 6.1.** The following assertions hold:

1. On finitely-branching MDPs, we have $\approx^{>0,\bigcirc} = \approx^{ATL}$.
2. For all MDPs, we have $\approx^{>0} \subseteq \approx^{>0,\bigcirc}$.
3. For finite AMDPs, we have $\approx^{>0,\bigcirc} \subseteq \approx^{>0}$.
4. There is a finitely-branching, infinite AMDP on which $\approx^{>0,\bigcirc} \not\subseteq \approx^{>0}$.
5. There is a finite, (non-alternating) MDP on which $\approx^{>0,\bigcirc} \not\subseteq \approx^{>0}$.

**Proof.** Assertion 1. The inclusion $\approx^{>0,\bigcirc} \subseteq \approx^{ATL}$ follows from the fact that formulas used in the first part of the proof of Theorem 4.4 make use only of the $\bigcirc$ temporal operator, and from $\approx^{ATL} = \approx^{\bigcirc^{ATL}}$. To prove the inclusion $\approx^{ATL} \subseteq \approx^{>0,\bigcirc}$, consider two states $s, t \in S$ such that $s \not\approx^{>0,\bigcirc} t$. Then, there is a $\text{Qrctl}^{>0}$ formula $\varphi$ that distinguishes them. From this formula we derive an $\text{ATL}$ formula $f(\varphi)$ that also distinguishes them. We proceed by structural induction. The result is obvious for boolean operators and atomic propositions. The cases $\varphi = \exists^t \bigcirc \varphi_1$ and $\varphi = \exists^{>0} \bigcirc \varphi_1$ are an easy consequence of Lemma 2.3.

Assertion 2. Immediate, as the set of $\text{Qrctl}^{>0}$ formulas without $U$ and $W$ is a subset of the set of all $\text{Qrctl}^{>0}$ formulas.

Assertion 3. The result is derived as follows: $\approx^{>0,\bigcirc} \subseteq \approx^{ATL} = \approx^{>0}$. The inclusion $\approx^{>0,\bigcirc} \subseteq \approx^{ATL}$ is a consequence of Assertion 1 of this theorem. The equality $\approx^{\text{Game}} = \approx^{>0}$ follows by combining Assertion 1 of Theorem 4.4 and Assertion 1 of Theorem 4.7.
Assertion 4. The result follows by considering again the infinite AMDP of Figure 6. Reasoning as in the proof of Theorem 4.7 it holds \((s,t) \in \approx^{0},\varnothing\), but \((s,t) \not\in \approx^{0}\); indeed, note that \(s \models \exists \approx^{0}(\varnothing q)\) and \(t \not\models \exists \approx^{0}(\varnothing q)\).

Assertion 5. The result is a consequence of Theorem 4.7, Assertion 2, and of the present theorem, Assertion 1; the same MDP used to show \(\approx_{\text{ATL}} \not\subseteq \approx^{0}\), depicted in Figure 5, also shows \(\approx^{0},\varnothing \not\subseteq \approx^{0}\).

7. Linear Time Nesting

The logics CTL and CTL* induce the same equivalence, namely, bisimulation. Similarly, ATL and ATL* both induce alternating bisimulation. We show here that QRCTL and QRCTL* induce the same equivalences on finite, alternating MDPs, but we show that for infinite, or non-alternating, MDPs, QRCTL* induces finer relations than QRCTL. These results are summarized by the following theorem.

**Theorem 7.1.** The following assertions hold:

1. For all MDPs, we have \(\approx^{0}_{\text{s}} \subseteq \approx^{0}\).
2. For all finite AMDPs, we have \(\approx^{0}_{\text{s}} = \approx^{0}\).
3. There is a finitely-branching, infinite AMDP, on which \(\approx^{0} \not\subseteq \approx^{0}_{\text{s}}\).
4. There is a finite MDP on which \(\approx^{0} \not\subseteq \approx^{0}_{\text{s}}\).

Before presenting the proof of this result, it is useful to recall some facts about Rabin automata, Markov decision processes, and probabilistic verification.

**Rabin automata and temporal logic.** An *infinite-word automaton over AP* is a tuple \(A = (L, L_{\text{init}}, r, \cdot, \Delta)\), where \(L\) is a finite set of locations, \(L_{\text{init}} \subseteq L\) is the set of initial locations, \(r : L \to 2^{AP}\) is a labeling function that associates with each location \(l \in L\) the set \(r(l) \subseteq AP\) of predicates that are true at \(l\), and \(\Delta : L \to 2^{L}\) is the transition relation. The automaton \(A\) is deterministic if the following conditions hold:

- for all \(\eta \subseteq AP\), there is a unique \(l \in L_{\text{init}}\) with \(r(l) = \eta\);
- for all \(l \in L\) and all \(\eta \subseteq AP\), there is \(l' \in \Delta(l)\) with \(r(l') = \eta\);
- for all \(l, l', l'' \in L\), we have that \(l', l'' \in \Delta(l)\) and \(l' \neq l''\) implies \(r(l') \neq r(l'')\).

The set of paths of a language is \(\text{Paths}(A) = \{l_0, l_1, l_2, \ldots \mid l_0 \in L_{\text{init}}, \forall k \geq 0, l_{k+1} \in \Delta(l_k)\}\). A Rabin acceptance condition over a set \(L\) is a set of pairs \(F = \{(P_1, R_1), (P_2, R_2), \ldots, (P_m, R_m)\}\) where, for \(1 \leq i \leq m\), we have \(P_i, R_i \subseteq L\). The acceptance condition \(F\) defines a set of paths over \(L\). For a path \(\tau = s_0, s_1, s_2, \ldots \in L^\omega\), we define \(\text{Inf}(\tau)\) to be the set of locations that occur infinitely often along \(\tau\). We define \(\text{Paths}(F) = \{\tau \in L^\omega \mid \exists i \in [1..m] . (\text{Inf}(\tau) \cap P_i = \emptyset \land \text{Inf}(\tau) \cap R_i = \emptyset)\}\). A Rabin automaton \((A, F)\) is an infinite-word automaton \(A\) with set of locations \(L\), together with a Rabin acceptance condition \(F\) on \(L\); we associate with it the set of paths \(\text{Paths}(A, F) = \text{Paths}(A) \cap \text{Paths}(F)\).

Given a set of predicates \(AP\), a trace \(\rho \in (2^{AP})^\omega\) over \(AP\) is an infinite sequence of interpretations of \(AP\); we indicate with \(\text{Traces}(AP) = (2^{AP})^\omega\) the set of all traces over \(AP\). A Rabin automaton \((A, F)\) with \(A = (L, L_{\text{init}}, r, \cdot, \Delta)\) induces the set of traces \(\text{Traces}(A, F) = \{r(l_0), r(l_1), r(l_2), \ldots \mid l_0, l_1, l_2, \ldots \in \text{Paths}(A, F)\}\). An LTL formula \(\varphi\) over the set of propositions \(AP\) induces the set of traces \(\text{Traces}(\varphi) \subseteq \text{Traces}(AP)\), defined as
usual (see, e.g., [MP91]). From [VW86] it is known that for an LTL formula $\varphi$ we can construct a deterministic Rabin automaton $(A, F)$ such that $\text{Traces}(A, F) = \text{Traces}(\varphi)$.

We can now proceed to prove Theorem 7.1.

**Proof of Theorem 7.1.**

*Proof.* The first assertion is obvious. For the other assertions, we proceed as follows.

**Assertion 2.** Let $G = (S, A, \Gamma, \delta, [\cdot])$ be a finite, alternating MDP. Since Qrctl is a fragment of Qrctl*, it follows that $\approx^0 \subseteq \approx^>$. To prove $\approx^> \subseteq \approx^0_1$, we show that if there exists a Qrctl* formula that distinguishes two states $s$ and $t$, then there also exists a Qrctl formula that distinguishes $s$ and $t$. We focus on formulas of the type $\exists^0 \varphi$ and $\exists^! \varphi$, where $\varphi$ is an LTL formula. The generalization to the complete logic follows by structural induction and duality. Thus, assume that there are two states $s^*, t^* \in S$ and $\alpha \in \{1, > \}$ such that $s^* \models \exists^0 \varphi$ and $t^* \not\models \exists^0 \varphi$. Let $(A, F)$ be a deterministic Rabin automaton such that $\text{Traces}(A, F) = \text{Traces}(\varphi)$, and assume that $A = (L, L_{\init}, \cdot, \cdot, \Delta)$ and $F = \{(P_1, R_1), \ldots, (P_m, R_m)\}$. Let $G' = G \times A = (S', A', \Gamma', [\cdot])$ be the MDP resulting from the usual synchronous product of $G$ and $A$. In detail, we have:

- $S' = \{(s, l) \in S \times L \mid [s] = \lceil \Gamma \rceil\}$;
- $\Gamma'(s, l) = \Gamma(s)$ for all $(s, l) \in S'$;
- for all $(s_1, l_1), (s_2, l_2) \in S'$ and $a \in A$, we have $\delta'(((s_1, l_1), a)(s_2, l_2) = \delta(s_1, a)(s_2)$ if $l_2 \in \Delta(l_1)$, and $\delta'((s_1, l_1), a)(s_2, l_2) = 0$ otherwise;
- $\left\{(s, l) = \lceil \Gamma \rceil, \text{ for all } (s, l) \in S'\right\}$.

Let $F'$ be the Rabin acceptance condition of $G'$, defined by $F' = \{(P'_1, R'_1), \ldots, (P'_m, R'_m)\}$, where each $P'_i, R'_i \subseteq S'$ is defined as follows: $P'_i = \{(s, l) \in S' \mid l \in P_i\}$ and $R'_i = \{(s, l) \in S' \mid l \in R_i\}$. For every $s \in S$, denote with $l_{\init}(s)$ the unique $l \in L_{\init}$ such that $[s] = \lceil \Gamma \rceil$. Using the results of [DA97a, DA98, DAH04] on the model-checking of MDPs with respect to probabilistic temporal-logic properties, we can construct $\mu$-calculus formulas to distinguish $(s^*, l_{\init}(s^*))$ and $(t^*, l_{\init}(t^*))$. Define, first of all, the following abbreviations:

\[
\hat{\psi}^{\text{all}} = \bigcup_{i=1}^{m} \nu Y. \mu X. [P'_i \cap (Cpre(X) \cup (R'_i \cap Cpre(Y)))]
\]

\[
\hat{\psi}^{I} = \bigcup_{i=1}^{m} \nu Y. \mu X. [P'_i \cap (Apre(Y, X) \cup (R'_i \cap Cpre(Y)))]
\]

\[
\hat{\psi}^{\text{some}} = \bigcup_{i=1}^{m} \nu Y. \mu X. [P'_i \cap (Pre(X) \cup (R'_i \cap Pre(Y)))]
\]

On the basis of the above formulas, define:

$\psi^{\text{all}} = \mu W. (\hat{\psi}^{\text{all}} \cup Cpre(W))$

$\psi^{I} = \nu Z. \mu W. (Apre(Z, W) \cup \hat{\psi}^{I})$

$\psi^{>0} = \mu W. (\hat{\psi}^{I} \cup Pre(W))$

$\psi^{\text{some}} = \mu W. (\hat{\psi}^{\text{some}} \cup Pre(W))$.

For $\alpha \in \{\text{all}, 1, >, \text{some}\}$ and $s \in S$, we have:

$(s, l_{\init}(s)) \in [[\psi^{\alpha}]]_{G'}$ iff $s \models \exists^\alpha \varphi$
so that, in particular, \((s^*, l_{\text{init}}(s^*)) \in [\psi^o]_G\) and \((t^*, l_{\text{init}}(t^*)) \notin [\psi^o]_G\). Hence, the formula \(\psi^o\) is a \(\mu\)-calculus witness, on \(G\), of the distinction between \(s^*\) and \(t^*\). We now show how to transform \(\psi^o\), first into a \(\mu\)-calculus formula to be evaluated on \(G\), and then into a QCTL formula to be evaluated on \(G\). This will show that \(s^* \not \equiv^0 t^*\), as required.

To obtain a \(\mu\)-calculus formula on \(G\), from \(\psi^o\) we construct a \(\mu\)-calculus formula \(\gamma^o\) with the following property: for all \(s \in S\), we have \(s \in [\gamma^o]_G\) if \((s, l_{\text{init}}(s)) \notin [\psi^o]_G\). The idea, taken from [dAHM01], is as follows.

First, \(\psi^o\) can be rewritten in equational form [BC96], as a sequence of blocks \(B'_1, \ldots, B'_k\), where \(B'_i\) is the innermost block and \(B'_k\) the outermost block. Each block \(B'_j\), for \(1 \leq j \leq k\), has the form \(v_j = \lambda e_j\), where \(\lambda \in \{\mu, \nu\}\), and where \(e_j\) is an expression not containing \(\mu\), \(\nu\), in which all the occurrences of the variables \(v_1, \ldots, v_k\) have positive polarity [BC96]; the output variable is \(v_k\).

From this formula, we obtain another formula \(\gamma^o\), also in equational form, with sets of variables \(\{v'_i \mid 1 \leq i \leq k \land l \in L\} \cup \{v_{k+1}\}\). Formula \(\gamma^o\) simulates on \(G\) the evaluation of \(\psi^o\) on \(G\): for each variable \(v_i\), with \(1 \leq i \leq k\), formula \(\gamma^o\) contains the set of variables \(\{v'_i \mid l \in L\}\), where the value of \(v_i\) at location \(l \in L\) is encoded as the value of \(v'_i\) at \(s\). The formula \(\psi\) consists of the blocks \(B_1, \ldots, B_k\), plus an additional block \(B_{k+1}\). For \(1 \leq i \leq k\), the block \(B_i\) contains the equations for the variables \(\{v'_i \mid l \in L\}\). The equation for \(v'_i\) is obtained from the equation for \(v_i\) as follows:

- replace each variable \(v_i\) on the left-hand side with the variable \(v'_i\);
- replace \(P_j\) (resp. \(R_j\)), for \(1 \leq j \leq m\), with \(S\) if \(l \in P_j\) (resp. \(l \in R_j\)), and with \(\emptyset\) if \(l \notin P_j\) (resp. \(l \notin R_j\));
- replace \(C_{\text{pre}}(v_h)\), for variable \(1 \leq h \leq k\), with \(C_{\text{pre}}(\bigcup_{l' \in \Delta(l)} v'^{l'}_h)\);
- intersect the right-hand side with \(\bigcap_{q \in \overline{T \cap T^*}} \bigcup_{l \in S} q \cap \bigcap_{q \in \overline{AP \setminus T \cap T^*}} q\).

The block \(B_{k+1}\) consists of only one equation \(v_{k+1} = \bigcup_{l \in \text{Init}} v'^{l}_k\), and can be either a \(\mu\) or a \(\nu\)-block. The output variable is \(v_{k+1}\).

The result of the above transformation is a \(\mu\)-calculus formula \(\gamma^o\) on \(G\) containing only the operators \(C_{\text{pre}}\) and \(A_{\text{pre}}\). By (3.1) and Lemma 4.6 both operators can be encoded in QCTL. Then, proceeding as in the first part of the proof of Theorem 4.7, we can “unroll” the computation of the fixpoints of the \(\mu\)-calculus formulas, since we know that each fixpoint converges in at most \(|S|\) iterations. The result of these two transformations is a QCTL formula \(\lambda^o\), such that \(s^* \models \lambda^o\) and \(t^* \not \models \lambda^o\), as required.

**Assertion 3.** Consider the AMDP \(G\) with state space \(S = (\{1, 2, 3\} \times \mathbb{N}) \cup \{0\}\). The only successor of 0 is 0 itself. States of the type \((i, 2n)\), for \(i \in \{1, 2, 3\}\) (i.e., *even states*) belong to player 1, while odd states belong to player \(p\). For all \(n \geq 0\) we have: \(\Gamma((1, 2n)) = \Gamma((3, 2n)) = \{a, b\}\) and \(\Gamma((2, 2n)) = \{a, b, c\}\), where, for all \(i \in \{1, 2, 3\}\):

\[
\text{Dest}(i, 2n) = \{\langle i, 2n \rangle\}
\]
\[
\text{Dest}(i, 2n, b) = \{\langle i, 2n + 1 \rangle\}
\]
\[
\text{Dest}(2, 2n, c) = \{\langle 3, 2n + 1 \rangle\}.
\]

Player \(p\) states starting with 1 or 2 lead to the next state in their chain and to the sink state 0 with equal probability. Formally, \(\Gamma((i, 2n + 1)) = \{x\}\) and

\[
\begin{align*}
\delta(1, 2n + 1, x)(1, 2n + 2) &= \delta(1, 2n + 1, x)(0) = \\
\delta(2, 2n + 1, x)(2, 2n + 2) &= \delta(2, 2n + 1, x)(0) = 1/2.
\end{align*}
\]
Figure 9: An MDP where \( s \approx^> 0 s' \) and \( s \not\approx^* > 0 s' \).

Finally, states starting with \( 3 \) obey the following distribution.

\[
\delta(\langle 3, 2n + 1 \rangle, x)(\langle 2, 2n + 2 \rangle) = \exp(-1/2^n) \\
\delta(\langle 3, 2n + 1 \rangle, x)(0) = 1 - \exp(-1/2^n).
\]

Observe that \( G \) is a finitely-branching, infinite AMDP. We take \( AP = \{ q \} \), and we ask that the predicate \( q \) be true at all odd states. Then, by induction on the structure of a QCTL formula, it is not hard to see that \( \langle 1, 0 \rangle \approx^> 0 \langle 2, 0 \rangle \). On the other hand, we have \( \langle 2, 0 \rangle \models \exists 0 \Box q \) and \( \langle 1, 0 \rangle \not\models \exists 0 \Box q \).

Assertion 4. Consider the MDP depicted in Figure 9. By induction on the structure of a QCTL formula, it is not hard to see that \( s \approx^> 0 s' \). On the other hand, for \( \varphi = \exists 1 (\Diamond q \wedge \Box \exists^0 \Diamond q) \) we have \( s \models \varphi, s' \not\models \varphi \).

We do not provide an algorithm for computing \( \approx^* > 0 \) on non-alternating MDPs. Identifying such an algorithm is an open problem.
