ABSTRACT

Medaka is a model organism in medicine, genetics, developmental biology and population genetics. Lab stocks composed of more than 100 wild local populations are available for research in these fields. Thus, medaka represents a potentially excellent bioresource for screening disease-risk- and adaptation-related genes in genome-wide association studies. Although the genetic population structure should be known before performing such an analysis, a comprehensive study on the genome-wide diversity of wild medaka populations has not been performed. Here, we performed genotyping-by-sequencing (GBS) for 81 and 12 medakas captured from a bioresource and the wild, respectively. Based on the GBS data, we evaluated the genetic population structure and estimated the demographic parameters using an approximate Bayesian computation (ABC) framework. The genome-wide data confirmed that there were substantial differences between local populations and supported our previously proposed hypothesis on medaka dispersal based on mitochondrial genome (mtDNA) data. A new finding was that a local group that was thought to be a hybrid between the northern and the southern Japanese groups was actually an origin of the northern Japanese group. Thus, this paper presents the first population-genomic study of medaka and reveals its population structure and history based on chromosomal genetic diversity.

KEYWORDS

local population freshwater fish demography RAD-seq bioresource

Medaka (Oryzias latipes) is a small fresh-water fish native to East Asia that has attracted attention as a vertebrate model for population genetics (Oota and Mitani 2011; Spivakov et al. 2014). Wild medaka populations have been maintained in certain universities and research institutes as a bioresource (hereafter, wild lab stocks) with funding from the Japanese government since 1985 (Shima et al. 1985). These populations consist of more than 100 local-wild populations that have various phenotypic traits (Watanabe-Asaka et al. 2014; Igarashi et al. 2017) and abundant genetic diversity (Kasahara et al. 2007). Geographical features affect the population structure of organisms. Seas and mountains restrict the movement of terrestrial animals and freshwater fish, and the climate also changes the breeding timing and foraging environment. Particularly, noticeable climate differences are observed within island groups, such as the Japanese archipelago, where a large latitudinal difference exists between the southern and northern ends. Therefore, animals are exposed to various selective pressures according to the geographic environment. The local populations have differentiated into local groups by genetic drift, resulting in genetically divergent groups. Medakas stocked as a bioresource are thought to have retained the genetically adapted traits they acquired from various environments of the Japanese archipelago.

Our ultimate goal in exploiting medaka characteristics is to establish an experimental system for testing the functional differences between alleles detected by, for instance, genome-wide association studies. Once genetic polymorphisms related to phenotypic traits in medaka are detected, in vivo experiments, such as genome editing experiments (Ansai and Kinoshita 2014), can be conducted to understand the functions of the genetic variants (Shimmura et al. 2017). Revealing the
functional difference between alleles in wild populations allows us to infer the role of genetic polymorphisms in human homologous genes (Igarashi et al. 2017; Shimmura et al. 2017).

Most previous analyses of medaka genetic diversity and population structure have been conducted using mitochondrial DNA (mtDNA). Medaka is divided into four mitochondrial groups: the northern Japanese (N.JPN), southern Japanese (S.JPN), eastern Korean (E.KOR) and western Korean/Chinese groups (W.KOR) (Sakaizumi et al. 1980; 1983; Sakaizumi 1986; Katsumura et al. 2009). There is a claim that N.JPN and S.JPN are different species because of slightly different morphological characteristics (Asai et al. 2011) and deep divergence time based on mtDNA sequences (Setiamarga et al. 2009). However, it is still controversial, because the divergence time (approximately 18 MYA) is able to change using the different calibration points (Miya et al. 2013; Broughton et al. 2013), N.JPN and S.JPN have no reproductive isolation (Sakaizumi et al. 1992), and fertile when mating even in wild environment (Iguchi et al. 2018), strongly suggesting that N.JPN and S.JPN are geographical subspecies. Furthermore, although previous allozyme-based studies show that an ambiguous group exists in the geographic boundary region known as Tajima-Tango area (see also Figures 1 and S1), between N.JPN and S.JPN, which is thought to be a hybridization of the two groups (Sakaizumi 1984; Takehana et al. 2016), the process has not been fully verified. Further investigation of the local population structures of medaka in Japan and east Asia would provide evidences for more precise and deep understanding of natural history of medaka in the Japanese archipelago.

Based on mtDNA cytochrome b gene sequences, N.JPN and S.JPN are composed of 3 and 11 subgroups, respectively (Takehana et al. 2003). Each subgroup is composed of local populations, and the between-population genetic diversities are greater than the within-population genetic diversities, indicating substantial genetic differentiation between local populations (Katsumura et al. 2009). Their habitat environments are also largely different. For instance, there is a large amount of snowfall in the habitats of N.JPN, where the breeding season is short. The habitat of S.JPN is wider than that of N.JPN, and its climate environment is also diverse; e.g., the differences of the annual average temperature and rainfall between the south end (Nago in Okinawa) and north end (Ichinoseki in Iwate) inhabited by S.JPN were 11.6°C and 988 mm in 2017, respectively (http://www.jma.go.jp/jma/indexe.html). The phylogenetic data from these studies also suggested that N.JPN and S.JPN have been spreading in the Japanese archipelago at different times. Particularly, the origin of S.JPN, which has the largest habitat, has been suggested to be the northern part of Kyushu Island based on mtDNA ("Out of Northern Kyushu" hypothesis) (Katsumura et al. 2012). However, mtDNA is insufficient to describe the population structure and history because of its single locus. Genetic diversity based on chromosomes is essential to understand the medaka population structure, but the comprehensive data of chromosomes are still limited.

An inference of the population structure and history induced by genome-wide information is more robust than that induced by single loci. To unravel the population structure based on chromosomes, we comprehensively performed a population-genetic analysis based on chromosomal single-nucleotide polymorphisms (SNPs) using all 81 local populations maintained as wild lab stocks at the University of Tokyo. We examined an individual sampled from each population stock and...
12 wild individuals captured from the northern part of Kyushu Island, where (Katsumura et al. 2012) the medakas currently distributed along the entire Pacific side of the Japanese archipelago originated, to estimate each population’s time of expansion from Northern Kyushu. To obtain SNP data, we conducted genotyping-by-sequencing (GBS) (Elshire et al. 2011; Narum et al. 2013) using a high-throughput sequencer. This method, which allowed us to cost-effectively genotype tens of thousands of SNPs (Andrews et al. 2016), resulted in an accurate enhancement of the population-genetic estimates because the variance in the demographic parameter estimates decreased when we used many SNPs. Eventually, we obtained more than ten thousand SNPs from eighty-one wild lab stocks and twelve wild-captured medakas. Here, we re-evaluated the medaka genetic diversity and population structures based on these SNPs and reconstructed the population history by assessing three demographic events. These data redefine the medaka local groups and provide a basis of the population history for discussing the role of phenotype-associated alleles in the context of adaptation.

**MATERIALS AND METHODS**

**Samples**

We sampled 81 male medakas from 81 wild lab stocks (14 from N. JPN, 56 from S.JPN, 5 from Tajima-Tango in the geographic boundary region between N.JPN and S.JPN, 3 from E.KOR, and 3 from W.KOR; note that these groupings come from previous mtDNA sequences and allozyme patterns) at the University of Tokyo in 2014. The lab stocks originated from geographically distinct populations in East Asia and have been maintained since 1985 (Shima et al. 1985) as closed colonies in the Graduate School of Frontier Sciences, the University of Tokyo, Kashiwa City (Figure 1). These lab stocks maintain the genetic diversity originating from their habitat (Katsumura et al. 2014; Igarashi et al. 2017) and show less diversity within populations than between populations (Katsumura et al. 2009). Because of these characteristics, we considered that one individual sampled from the lab stock would be adequate to represent its originating population. In addition, we used two wild-captured medaka populations from the Saga Prefecture in the northern part of Kyushu, Japan. One population was the Ogi (SO: Saga Ogi) population from Southern Saga (S.Saga), and the other population was the Umejirio (US: Umejirio in Saga) population from Northern Saga (N.Saga), both of which were captured in September 2010 (see Katsumura et al. 2012). Six of 48 medakas from each wild-captured population were selected randomly and analyzed via GBS.

**DNA extraction and genotyping-by-sequencing**

One-third of the medaka body was dissolved in a 600 μl lysis buffer containing 1.24% SDS, 0.124 M EDTA and 0.062 mg/ml proteinase K (final concentrations). The total genomic DNA was extracted and purified using phenol-chloroform and isopropanol precipitation. After a 70% EtOH wash, an isolated DNA pellet was resuspended in 100 μl TE buffer and then treated with RNase A (final conc. 1 mg/ml) for 1 hr at room temperature. Then, the DNA was purified again using phenol-chloroform and isopropanol precipitation. For ninety-three samples, the GBS process was outsourced to Macrogen Japan in Kyoto. The procedures for constructing libraries and performing Illumina HiSeq 2000 single-end sequencing were the same as those described by Poland et al. (Poland et al. 2012) except for the use of the restriction enzyme ApeKI instead of EcoRI–MspI. The sequence lengths were 51 bp and included each individual in-line barcode (4–9 bp) for the individual sample. The data have been submitted to the DDBJ Sequence Read Archive (DRA) database under project accession ID: DRA006353.

**Quality filtering and SNP extraction**

Our single-end reads were filtered using FASTQ Quality Filter in FASTX-Toolkit version 0.0.13 (http://hannonlab.cshl.edu/fastx_toolkit/download.html) using the following options: -Q 33 -v -x -q 30 -p 90. The draft genome of the medaka sequenced by the PacBio sequencer (Medaka-Hd-rP-chicbio_version2.0.fasta; http://utgenome.org/medaka_v2/#/Assembly.md) was used to align the reads using BWA backtrac 0.7.12-r1039 (Li and Durbin 2009) using the “-n 0.06” option. After the mapping process, the multi-mapped reads were removed using Samtools v1.2 (Li et al. 2009) and the “-S 20” option. Following this pipeline, sequencing of the ApeKI-digested GBS libraries generated an average of 3.06 million reads per individual before any quality filtering. The read numbers ranged from 1.89 to 4.10 million reads per individual. After quality filtering, 2.76 million (90.2%) sequences per individual on average were retained, and 0.30 million (9.8%) sequences were eliminated. The retained sequences presented a mean quality score of 38.7 and a GC content of 47.8%. An average of 1.84 million of the retained sequences (66.7%) aligned to the medaka chromosomal genome, and 0.92 million sequences (33.3%) were not aligned and discarded because they mapped to non-chromosomal loci (mitochondrial genome and unanchored contigs) and multiple loci.

The Stacks pipeline (version 1.35) and the Stacks workflow (https://github.com/enormandeau/stacks_workflow) were used to generate SNPs and sequences for each individual separately (Catchen et al. 2011; 2013). The selected Stacks parameters were as follows: minimum stack depth (-m), 3; and number of mismatches when building the catalog (-n), 1. In the ‘rx’ step of Stacks, we used the bounded SNP model set to 0.1, the e upper bound set to 0.1 and the log likelihood set to 10. Following this pipeline, five datasets were constructed using the population program in Stacks.

The first was the “PopStat” dataset, which was generated using the “-p 5 -r 0.66” options and mitochondrial grouping (N.JPN, Tajima-Tango, S.JPN, E.KOR, W.KOR; see also Figure 1) to calculate the population-genetic statistics (Table 1) using the loci shared across all groups and sequenced in one or more populations in each group.

The second was the “Global” dataset, which was generated using the “-p 58 -r 1.00” option and without the mitochondrial grouping, to examine the phylogenetic relationships between the geographic populations and the population structure within the species. Additionally, nucleotide diversity in each individual were calculated using this data set to compare genetic diversity between lab-stocks and wild-captured medaka.

The third and the fourth were the “HZ-1” and “HZ-2” datasets (“HZ” is the abbreviation of “Hybrid zone”), respectively, including the 15 boundary populations (N.JPN: Kaga, Maiduru, Miyadu, Ohama, and Sabae; Tajima-Tango: Amino, Hamasaka, Kinosaki, Kumihama, and Toyooka; and Honshu: Ayabe, Iwami, Kasumi, Matsue, and Tottori) with or without the Kyushu populations (Kyushu: Fukue, Hiwaki, Izumi, Kadusa, and Kikai). These datasets were generated using the “-p 3 -r 0.70” (without Kyushu) and the “-p 4 -r 0.70” (with Kyushu) option, respectively, to assess the genetic population structure and the history of the boundary population for the Tajima-Tango group.

The fifth was the “Local” dataset, including two Kyushu deme samples: one was Umejirio (US), which was sampled in the northern part of
Table 1 Summary genetic statistics for five populations using “PopStat” dataset. These statistics include the mean number of individuals genotyped at each locus, the number of variable sites in five populations (Variants), the number of polymorphic sites in each population (Polymorphic) and the number of variable sites unique to each population (Private). The number in parenthesis is Standard Error.

| Group          | Number of Individual | Total length of GBS loci (bp) | Variant | Polymorphic | Private | Major Allele Frequency | Observed Heterozygosity | Nucleotide Diversity |
|----------------|----------------------|-------------------------------|---------|-------------|---------|------------------------|------------------------|----------------------|
| N.JPN(nJPN)    | 11.5 (+/−0.03)       | 45968                         | 2453    | 256         | 136     | 0.983 (+/−0.0014)      | 0.023 (+/−0.0022)      | 0.0014 (+/−0.0001)   |
| Tajima-Tango   | 4.4 (+/−0.01)        | 44011                         | 2453    | 199         | 71      | 0.980 (+/−0.0016)      | 0.024 (+/−0.0022)      | 0.0017 (+/−0.0001)   |
| S.JPN          | 41.6 (+/−0.08)       | 45968                         | 2453    | 1448        | 1231    | 0.958 (+/−0.0017)      | 0.029 (+/−0.0016)      | 0.0036 (+/−0.0001)   |
| W.KOR          | 2.4 (+/−0.01)        | 44990                         | 2453    | 467         | 342     | 0.940 (+/−0.0027)      | 0.054 (+/−0.0032)      | 0.0053 (+/−0.0003)   |
| E.KOR          | 2.4 (+/−0.01)        | 44011                         | 2453    | 346         | 203     | 0.953 (+/−0.0025)      | 0.041 (+/−0.0030)      | 0.0042 (+/−0.0002)   |

The Saga prefecture, and the other was Ogi (SO), which was sampled in the southern part of the Saga prefecture. These samples were used to estimate the time of Honshu’s population divergence from Kyushu to infer the timing of the “Out of Northern Kyushu” event (Katsumura et al. 2012).

Note that we define the terms “deme samples” and “non-deme samples” as “samples from the local-wild population” and “samples from the wild lab stocks”, respectively (see details in Katsumura et al. 2009).

Against those datasets (except “PopStat” and “HZ-1”), the SNPs with strong linkage disequilibrium were randomly removed, one from each pair of SNPs with $r^2 > 0.2$, using Plink1.9 (Chang et al. 2015) and the “-indep-pairwise 12.5 0.2—autosome-num 24” option. These values were set based on a medaka population genomics study (Spivakov et al. 2014). Finally, the “Global”, “HZ-2” and “Local” datasets contained 8,361 SNPs out of 13,177 SNPs, 1,014 SNPs out of 2,661 SNPs and 698 SNPs out of 2,246 SNPs, respectively.

Genetic clustering analysis

To obtain a genetic overview of the relationship of medaka geographic populations, we performed a principal component analysis (PCA) of the “Global” dataset as implemented in the SNPRelate program (Zheng et al. 2012) in R version 3.2.2. Additionally, to examine the genetic relationships between medakas in the Japanese archipelago, we used the subdataset without the E/W.KOR and Chinese populations, which were run, which provided approximately one million simulations for each scenario.

Reconstructing the phylogenetic tree using the maximum likelihood method

We considered an individual as representative of a population and generated the individual sequences using the population program with the “-p 58 -r 1.00—phylip_all” option in the Stacks pipeline. The dataset included 4,638 partitions and 217,986 bp of nucleotide sequences to compensate for the loci that could not be sequenced by invariable sites across all samples and “N” at the variable site. The dataset including 4,638 partitions and 217,986 bp nucleotide sequences was analyzed via the IQ-TREE program (Nguyen et al. 2015) to reconstruct a maximum likelihood tree with model selection for each partition (Chernomor et al. 2016) and 1,000 SH-aLRT/ultrafast-bootstrapping (Guindon et al. 2010; Minh et al. 2013). Then, we used the FigTree program (http://tree.bio.ed.ac.uk/software/figtree/) to visualize the phylogenetic tree.

Inference of demographic parameters of the populations in and around Tajima-Tango and the time of “Out of Northern Kyushu” based on the ABC framework

Using the HZ-2 dataset, which added five Kyushu populations to 15 boundary populations of the HZ-1 data set, the population history, including the possibility that the Tajima-Tango group occurred by the admixture of N.JPN and S.JPN, was inferred from 1,014 SNPs using DIYABC ver2.1.0 (Cornuet et al. 2014). We tested four evolutionary scenarios in which N.JPN and S.JPN diverged from an ancestral population at time $t$: (I) Tajima-Tango originated in N.JPN; Honshu and Kyushu diverged at time $t$, and then Tajima-Tango diverged from N.JPN at time $t_1$ (Takehana et al. 2016); (II) Admixture of N.JPN and Honshu: Honshu and Kyushu diverged at time $t_2$, and then Tajima-Tango diverged from N.JPN at time $t_3$; (III) N.JPN originated in Tajima-Tango: Honshu and Kyushu diverged at time $t_2$, and then N.JPN diverged from Tajima-Tango at time $t_3$; and (IV) Honshu diverged from Kyushu and then Tajima-Tango occurred by an admixture with Honshu of rate $r$. For simplicity, all populations were assumed to have constant effective sizes in each lineage (i.e., no bottleneck and expansion). The same prior parameters were defined for four scenarios based on previous studies, and the prior distribution of each parameter is presented in Table 2. In addition, we set the conditional constraint as follows: $t_3 > t_2$, $t_3 > t_1$ and $t_2 > t_1$. In total, four million simulations were run, which provided approximately one million simulations for each scenario.

The summary statistics for all SNP loci included the proportion of loci with null gene diversity, mean gene diversity across polymorphic loci, proportion of loci with null Nei’s distance between the two samples, variance across loci of non-null Nei’s distances between two samples, proportion of loci with null admixture estimates, mean across loci of non-null admixture estimates and mean across all locus admixture estimates. The $1\%$ simulated datasets closest to the observed dataset were used to estimate the posterior parameter distributions through a weighted local linear regression procedure (Beaumont et al. 2002). Scenarios were compared by estimating their posterior probabilities using the direct estimation and logistic regression methods implemented in DIYABC (Cornuet et al. 2014). We also estimated the time for “Out of Northern Kyushu” using the Local dataset that included 698 SNPs from DIYABC. We inferred the following time-based simple evolutionary scenario: N.Saga diverged from S.Saga at time $t$ because this divergence event was consistent with the “Out of Northern Kyushu” event (Katsumura et al. 2012).
Table 2 Demographic parameters estimated by DIYABC under three scenarios. Performance of each estimation was evaluated by RRMISE (the square Root of the Relative Mean Integrated Square Error), RMeanAD (the Relative Mean Absolute Deviation) and RRMSE (the square Root of the Relative Mean Square Error), which are output from DIYABC option “Compute bias and mean square error.” The numbers with or without parentheses in the columns “Performances for estimating posterior distributions of parameters” are those of the statistics computed from the prior or posterior distribution of parameters, respectively.

| Scenario | Parameters | Type | Prior distribution | Posterior parameter estimates | Performances for estimating posterior distributions of parameters |
|----------|------------|------|--------------------|------------------------------|---------------------------------------------------------------|
|          |            |      |                    |                               | RRMISE            | RMeanAD           | RRMSE            |

In this case, all populations were assumed to have unchangeable effective sizes in each lineage.

The prior distribution of each parameter is presented in Table 2, and the 1% simulated datasets closest to the observed dataset were used to estimate the posterior parameter distributions. We evaluated the accuracy of the demographic parameter estimation by calculating accuracy indicators (Bias and mean square error option) in DIYABC and accepted the parameters that were non-scaled and scaled by the mean effective population size for the HZ-2 and Local datasets, respectively. Using the infinite-sites model in the Wright-Fisher populations of a constant size, a rough value of \( N_e \) was estimated using the relationship \( \pi = 4N_e \mu \) (Tajima 1983), where \( \pi \) is genome-wide nucleotide diversity and \( \mu \) is the mutation rate per site per generation (Osada 2015). We calculated \( N_e \) using the above formula with the following values: \( \mu = 10^{-9}/\text{site/generation}; \text{generation} = 1 \text{ year}, \) which resulted in a mean effective population size from all presented deles in northern Kyushu of 1,275,000.

**Reconstruction of the phylogenetic tree for the partial mitochondrial DNA sequence**

To examine the mitochondrial introgression in the tested samples, we generated and analyzed the mitochondrial DNA (mtDNA) partial sequences from the GBS-read data. We mapped the reads to the complete mtDNA sequence of “Clade C” (Matsuda et al. 1997; Takehana et al. 2003), which diverged genetically from S.JPN and N.JPN, to eliminate the mapping bias that occurs when genetically distant sequences are used as a reference. The genomic DNA of “Clade C” was extracted in Katsumura et al. (2009). The complete mtDNA sequence was determined as follows. Using PCR, five DNA fragments of mitochondrial DNA were amplified: fragment 1—4,556 bp; fragment 2—4,527 bp; fragment 3—1,458 bp; fragment 2—4,504 bp; and fragment 4—4,546 bp (Figure S3). Table S1 describes the primers, which were designed based on the inbred strain Hdr-r complete mtDNA sequence (accession number: AP08938). Approximately 20 ng of the genomic DNA was used as a template for the PCR assay in a 50 μl solution containing dNTP at 0.2 mM, 0.2 μM of each of primer, 0.75 U of EX Taq polymerase HS (TaKaRa Shuzo Co.), and the reaction buffer attached to the polymerase. The reactions were conducted in a TaKaRa PCR Thermal Cycler Dice (TaKaRa Shuzo Co.) using the following protocol: an initial denaturing step at 95° for 2 min, 40 cycles of denaturation at 95° for 30 sec, annealing at 60° for 30 sec, extension at 72° for 300 sec, and a final extension step at 72° for 5 min. The PCR products were diluted 20-fold and used as templates in the sequencing reaction (following the commercial protocol) with thirty-three primers (Table S1 and Figure S3) and then analyzed in an ABI 3500xL Genetic Analyzer (Life Technologies). The complete mtDNA sequence of “Clade C” was reconstructed using SeqMan Pro 10.1.2.20 (DNASTAR) and deposited into the international DNA database DDBJ/EMBL/GenBank (accession number: LC335803).

The “Clade C” complete mtDNA sequence was used to align the reads using BWA backtrack 0.7.12-r1039 (Li and Durbin 2009) using the “-n 5” option. After the mapping process, to remove the multi-mapped reads, we used Samtools v1.2 (Li et al. 2009) using the “-Sq 20” option. Then, we used Stacks with the “-m 3” option for minimum stack depth (Catchen et al. 2011; 2013) and then obtained the 322 bp nucleotide sequences. The loci where the sequence was missing were filled in with “N”. In addition, the nucleotide position showing the multi-allelic state was replaced by “N”. Phylogenetic trees were constructed using the neighbor-joining (NJ) method (Saitou and Néi 1987) with the program MEGAS (Tamura et al. 2011). The evolutionary distances were calculated using the Jukes-Cantor method (Jukes and Cantor 1969). The analysis also involved 13 nucleotide sequences from the DNA database (See Figure S4). All ambiguous positions were removed for each sequence pair. The reliability of the tree was evaluated using 1000 bootstrap replicates (Felsenstein 1985).

**Data availability**

Wild lab-stocks are available upon request (e-mail to Hiroshi Mitani: mitani@edu.k.u-tokyo.ac.jp). GBS data are available at DDBJ Sequence Read Archive (DRA) database with the accession number: DRA006353. The complete mtDNA sequence is available at the international DNA database DDBJ/EMBL/GenBank with the accession number: LC33580. Supplemental material available at Figshare: https://doi.org/10.25387/g3.7358042.

**RESULTS**

**Genome-wide genetic diversity of five groups of Oryzias latipes**

To assess the genetic diversity based on chromosomal SNPs within known mitochondrial groups—the northern Japanese (N.JPN), southern Japanese (S.JPN), eastern Korean (E.KOR) and western Korean/Chinese (W.KOR) groups—and hybridization group which is Tajima-Tango group, their population-genetic summary statistics were calculated using the “PopStat” dataset that included the alignment regions across all groups and contained approximately 45 kb of sequences and 2,453 SNPs (Table 1). All groups showed major allele frequencies and heterozygosities of 0.940–0.983 and 0.023–0.054, respectively, indicating many rare alleles and homozygous sites in our wild lab-stocks. W.KOR showed the highest nucleotide diversity (0.0053 ± 0.0003) in all lab-stocks originated from East Asia. S.JPN showed the highest nucleotide diversity (0.0036 ± 0.0001) and N.JPN the lowest in the Japanese archipelago (Table 1), which is consistent with the diversity based on mtDNA (Katsumura et al. 2009). To evaluate the influence for had been maintained as closed colony, we calculated the nucleotide diversity in each individual (that is mean heterozygosity per site). Comparing these lab stocks with wild-captured medakas (Ogi and Umejirio populations) by nucleotide diversity, lab-stocks, excluding Yongcheon and Shanghai, showed the lower values than wild ones (Figure S5).

**Genetic clustering based on genome-wide SNPs inferring medaka population structure**

To reveal the medaka population structure based on the chromosomal SNPs, we performed genetic clustering analyses using the “Global” dataset. First, we investigated the genetic relationship by a principle component analysis (PCA) using 8,361 SNPs on 24 chromosomes. The PCA showed that the wild lab-stocks were divided into two clusters, N.JPN/Tajima-Tango and S.JPN and others from E/W.KOR, which is similar to the grouping based on the mtDNA data (Takehana et al. 2003; Katsumura et al. 2009) (Figures 2A and S6). E.W.KOR individuals were plotted dispersedly compared with other clusters, and Yongcheon (E.KOR) was close to N.JPN/Tajima-Tango. As the third principal component (PC3) was divided into E.KOR and W.KOR, the chromosomess in these mtDNA groups were differentiated into each other. Although Tajima-Tango was considered to be a hybridization group between N.JPN and S.JPN (Sakaiuzumi 2004), all individuals from Tajima-Tango were plotted with those from N.JPN as a cluster (Figure 2A). Next, for a fine-scale mapping of Japanese medaka, we performed the PCA based on 7,126 SNPs, excluding E.W.KOR individuals (Figure 2B). The PCA showed that the Kyushu populations (Kudamatsu, Ogi, Izumi, Hiwaki, Kikai, Nago, Gushikami, Hisayama, Umejirio, Ashibe,
Arita, Kusu and Nobeoka) in S.JPN were dispersed along the PC2 axis (Figure S7), while that Tajima-Tango overlapped with N.JPN again, even though we used up to PC5 (Figure S6). This result indicated that Tajima-Tango was not considerably differentiated from N.JPN on chromosomes, suggesting that S.JPN was differentiated within the groups and the genetic diversity was especially high among the Kyushu populations (Figure 2B).

To examine the phylogenetic relationship among 83 populations, we constructed a maximum likelihood (ML) tree based on 4,638 short fragment sequences (comparative nucleotide sequence length: 217,986 bp) using IQ-TREE. The maximum likelihood tree showed relatively high bootstrap values on each branch and almost the same topology as previous trees based on mtDNA (Takehana et al. 2003; Katsumura et al. 2009), except for Yongcheon (Figures 3 and S8; see also Discussion). Medakas from the Korean peninsula were genetically close to each other in both groups, whereas those from Shanghai, which have been classified into W.KOR based on mtDNA studies, diverged from the other individuals from W.KOR. The medakas in the Japanese archipelago were divided into two major clusters similar to mtDNA. One was the N.JPN/Tajima-Tango, and the other was S.JPN. The N.JPN/Tajima-Tango cluster was further divided into two submajor clusters with a 100% bootstrapping value in the ML tree based on concatenated sequences obtained from GBS, although N.JPN and Tajima-Tango overlapped in PCA, which reduced SNP information, i.e., N.JPN and Tajima-Tango diverged on the whole chromosomal sequenced regions. S.JPN was further divided into two sub-major clusters: Kyushu-only and Kyushu & others, which included 14 Kyushu populations, represented in Figure 3 by an open and a closed red circle, respectively. While the Kyushu-only cluster diverged into the northern and the southern Kyushu, the Kyushu & others cluster diverged to the Pacific side of eastern and the northern Honshu (main-island Japan), which included several clusters supported by high bootstrapping value (SH-aLRT ≥ 80% and UFboot ≥ 95%, Figure S8). Finally, we characterized the S.JPN ancestry in the context of East Asian genetic diversity of medaka by performing an ADMIXTURE analysis, which is a model-based unsupervised genetic clustering method. With the optimal number of ancestral components (K = 4), S.JPN medakas were assigned to two distinct ancestries (Figures 3 and S2). In suboptimal runs with more ancestral components (K = 5, 6), only S.JPN in Honshu (main-island Japan) was assigned to the other ancestral components found in the northern Kyushu populations. This analysis indicated that genetic diversities in the northern Kyushu populations were the highest among S.JPN. Thus, the genetic clustering analyses based on genome-wide SNP data strongly suggested that S.JPN spread from northern Kyushu to Honshu.

**Boundary population genomes similar to that of the northern Japanese group**

To explore hybridization signatures on chromosomes, we examined allele-sharing between boundary populations and surrounding populations using the “HZ-1” dataset (see Materials and Methods). We classified the fixed alleles between the groups into three states: shared by N.JPN and Tajima-Tango, shared by S.JPN and Tajima-Tango, and shared by N.JPN and S.JPN. Then, we summarized each state’s total numbers, as shown in table in Figure 4. We found 1,380 out of 4,661 SNPs that were common alleles between two of the three groups (Figure 4). Regarding those alleles, the majority (81.4%) were common alleles between Tajima-Tango and S.JPN, which was a much higher frequency than that between Tajima-Tango and S.JPN (11.2%). The rest of them were common alleles between N.JPN and S.JPN (7.5%), i.e., specific alleles in Tajima-Tango. These proportions are near those of a previous study based on 96 genomic regions (4 loci for each chromosome) (Takehana et al. 2016). Although the regions with neighboring common alleles between Tajima-Tango and S.JPN were observed for certain chromosomes, alleles on the Tajima-Tango genome were mostly shared with N.JPN, suggesting that Tajima-Tango is a subgroup of N.JPN with a short divergence time.

To investigate the mitochondrial introgression in boundary populations, we reconstructed the phylogenetic tree based on partial mtDNA sequences generated by mapping short reads from the GBS of the complete mitochondrial genome (Figure S4). The mtDNA sequences from Toyooka and Kinosaki in Tajima-Tango were clustered and closely related to those from Kaga, which was a root population in N.JPN. Considering that Tajima-Tango was a subgroup of N.JPN, which we inferred from the ML tree based on chromosomal sequences, these phylogenetic positions on the mtDNA tree would have also reflected an evolutionary history in which N.JPN diverged from the Tajima-Tango group. We confirmed that Amino, Kumihama and Hamasaka in Tajima-Tango had the mitochondrial genomes of phylogenetically distant populations classified into S.JPN (Figure S4). Additionally, the mitochondrial genome of Ayabe in S.JPN was classified into N.JPN but diverged from Tajima-Tango. These results suggest that mitochondrial genome introgressions occurred.
independently, meaning that they occurred not only from S.JPN to Tajima-Tango but also from N.JPN to S.JPN.

Inferring medaka demographic parameters
To infer the demographic parameters, effective population size ($N_e$), time ($T$), and proportion of the admixture ($r$), we analyzed the “HZ-2” dataset based on the coalescent theory using an approximate Bayesian computation (ABC) framework. We performed the model selection to identify the best explanation scenario for the observed data from the four scenarios; (I) Tajima-Tango originated in N.JPN, (II) Admixture of N.JPN and Honshu, (III) N.JPN originated in Tajima-Tango, and (IV) Admixture of Tajima-Tango and Honshu (Figure 5A).

DIYABC has two different approaches (directional and logistic) for model selection. Based on each criterion, scenario III (Honshu diverged from Kyushu and then N.JPN diverged from the Tajima-Tango group without admixture with Honshu) and scenario IV (Honshu diverged from Kyushu and then Tajima-Tango occurred by an admixture with Honshu at r rate) were supported by the directional (posterior probability: 0.4720, 95% CI: 0.0344–0.9096) and logistic (posterior probability: 0.4477, 95% CI: 0.4313–0.4641) approaches, respectively (Figure S9). Our data could not distinguish between scenarios III and IV (see the Discussion section).

The posterior parameter estimates of scenarios III and IV shown in Table 2, and Figures 5C and 5D were not scaled because various measures of accuracy (RRMISE, RMeanAD, and RMSE in the DIYABC output) indicated that non-scaled parameters fit the observed data better than scaled parameters. These estimates showed that the time to the most common ancestor (TMRCA) between S.JPN and N.JPN in scenarios III and IV were dated to 4,560,000 (95% CI: 2,820,000–6,810,000) and 5,160,000 (95% CI: 3,080,000–7,780,000) years ago, respectively. However, although we inferred the TMRCA at three divergence events (Figure 5), these times might be overestimated because the dataset for this estimation consisted of non-deme samples, i.e., polymorphisms within populations were underestimated, and the random-mating assumption could not be satisfied. Therefore, we estimated the timing of the “Out of Northern Kyushu” event using the “Local” dataset composed of the two deme samples (S.Saga and N. Saga), which were split at first on the S.JPN lineage (Figure 3). Based on a simple hypothesis, constant population size and no migration, we obtained the estimated time (510,000 years ago, 95% CI: 337,875–679,575) for the ancestral divergence of the two deme samples (Table 2 and Figure 5E), which was calculated from a scaled parameter by the mean effective population size because various accuracy measures indicated that scaled parameters fit the observed data better than non-scaled parameters. Thus, our population-genetic estimate using ABC suggests that medakas diverged and dispersed throughout Pacific-side Japan approximately 510 kyr ago.

DISCUSSION
Redefined subgroups in Japanese archipelago based on the population structure inferred from genome-wide single-nucleotide polymorphisms
*Oryzias latipes* can be divided into five groups (N.JPN, S.JPN, E.KOR, W.KOR and Tajima-Tango) by mtDNA sequences and allozymic
electrophoresis patterns (Sakaizumi 1984; Takehana et al. 2003). In this study, based on chromosomal SNPs, the genetic clustering analysis showed that ”K = 4” was the most supportive because it presented the lowest fivefold cross-validation error, indicating that N.JPN and S.JPN were divided into three ancestral clusters. When the K values increased, only S.JPN divided into more subgroups, which suggests that the S.JPN group was composed of more divergent groups than the other groups. Considering together with the results of the ML tree analysis, it is possible to redefine subgroups composed of each major group for our wild lab-stocks originated from the Japanese archipelago as follows. First, Tajima-Tango, which had been considered a hybridization group, should be included under the N.JPN group because it shows almost the same ancestral component as N.JPN, for which we propose the name “ancestral northern Japanese (aN.JPN).” Then, the group called N.JPN should be assigned to a subgroup, for which we propose the name “derived northern Japanese (dN.JPN).” These two subgroups, aN.JPN and dN.JPN, compose the N.JPN group (Figure S8). Second, S.JPN can be divided into several subgroups, San-in, San-yo/ Shikoku/Kinki and the Pacific Ocean side of Northeastern Honshu (PO.NEH), because the Kyushu & others cluster was subdivided into three sub-clusters composed of geographically neighboring populations. Adding the two Kyushu subgroups: Northern and Southern Kyushu (Figure 3), S.JPN is composed of five subgroups. Thus, medaka in Japanese archipelago could also be composed of the seven distinct subgroups based on chromosomal genetic diversity (Figure S8).

S.JPN can be divided into finer subgroups based on the mitochondrial genome (Takehana et al. 2003), likely because the effective population size of mtDNA is one quarter that of a nuclear gene. This causes the intermingled branch pattern of the mtDNA tree, which is not associated with geographic distance. Although this intermingled branch pattern has been also observed our wild lab-stocks in a previous study based on mtDNA (Katsumura et al. 2009), it has been sometimes interpreted as artificial migrations accompanied by recent human activities (Takehana et al. 2003). If the branching pattern was formed by human activities, various ancestral components should appear independent of geographic relatedness in the result of the ADMIXTURE analysis based on chromosomal SNPs. However, no signal of recent migration was found in the ADMIXTURE result. Rather, the chromosomal SNP data support another hypothetical scenario in which the mtDNA tree topology reflects ancestral polymorphisms only and their local fixation is caused by a small effective population size (Katsumura et al. 2009). This result indicates that arguing the geographical origins of medaka based only on mtDNA may lead to false conclusions.

From our data, it may be difficult to accurately evaluate the genetic diversities in E/W.KOR groups because the number of populations examined in each group was small. Therefore, though care must be taken in the interpretation, W.KOR showed the highest nucleotide diversity and E.KOR the second highest among the four major mitochondrial groups (Table 1). The W.KOR group included the Chinese medaka in Shanghai, which could have elevated its value, while the latter group did not include any geographically distant populations. The clustering analysis showed that Shanghai from W.KOR and Yongcheon from E. KOR had an ancestry component from N.JPN (Figure 3). Additionally, Shanghai and Yongcheon showed higher nucleotide diversities than

**Figure 4** Shared allele distribution among boundary populations. The gray rectangle represents the total length of each medaka chromosome. The table in the figure shows the number of alleles shared between the groups observed on each chromosome. Mark represents the state whose group shares that allele. *1 and 2 are the total number from chromosomes 1 to 12 and from chromosomes 13 to 24, respectively.
other lab stocks and wild-captured medaka. These suggest two possibilities: one is that the N.JPN ancestor was derived from the E/W.KOR ancestor, and the other is that contamination occurred through the maintained wild lab stocks (the latter possibility may be slightly high because the nucleotide diversities of Shanghai and Yongcheon were higher than those of wild-captured medakas). To investigate these possibilities and the origin of *O. latipes*, a population-based genome wide analysis must be conducted to increase the population numbers of E/W.KOR from other wild lab-stocks or wild medaka in Korean, and include the sister species *O. curvinotus* and *O. luzonensis*.

Reconstruction of the medaka population history in the Japanese archipelago

Our genome-wide analysis shows that medakas in N.JPN and S.JPN are deeply divergent and dispersed over the Japanese archipelago from different locations at different times. In particular, our ABC analysis indicates that dN.JPN originated in and diverged from aN.JPN. This inference about the history of N.JPN after divergence from S.JPN is not consistent with previous inferences from the allozyme, mtDNA and limited chromosomal SNP analyses, which have suggested that aN.JPN is a hybridization group between dN.JPN and S.JPN, or aN.JPN is a subgroup derived from dN.JPN. Our GBS data show that (i) the nucleotide diversity in aN.JPN is higher than that in dN.JPN (Table 1), (ii) S.JPN is genetically more closely related to aN.JPN than to dN.JPN based on the number of shared alleles (table in Figure 4), and (iii) the aN.JPN branch is the root in the N.JPN clade of the phylogenetic tree based on partial mtDNA sequences (Figure S4), which is also shown by the whole mitochondrial genome analysis (Hirayama et al. 2010). These data suggest that aN.JPN forms an outgroup to all present-day dN.JPN and it spread along the Sea of Japan side. Furthermore, the ABC framework’s estimation supports our scenario, although the analysis does not statistically distinguish between scenario III and scenario IV. Even if the admixture occurred, the inferred ratio of the admixture is too low (Figure 5D). However, we have to recognize the problem and limitation which derived from the use these lab-stocks in this estimation by ABC approach. The nucleotide diversity showed the low in lab stocks, indicating that the lab stocks experienced genetic bottlenecks or selection under the laboratory condition. This would affect the estimation of population history (especially in demographic events, admixture rate might be underestimated) by the ABC approach. We would have to sample the wild-capture medaka for more highly accurately estimation.

Our findings strongly support the “Out of northern Kyushu” model of S.JPN proposed in Katsumura et al. (2012) and have revealed the dispersal route of dN.JPN / aN.JPN in N.JPN. The genetic clustering analyses and phylogenetic tree based on the GBS data elucidate medaka history better than previous mitochondrial DNA analyses. In particular, the ADMIXTURE analysis shows that the two ancestry components (yellow and blue in Figure 3) were observed in northern Kyushu, suggesting that S.JPN dispersed in three different directions after dispersing out of Northern Kyushu. Geographically, Shikoku, San-jo, and Kinki are separated by sea, but medakas in the three local lands share the same ancestral component (blue in Figure 6; see also Figure S1 for geographic information). Medaka is a freshwater fish, but survival and reproductive even in seawater (Inoue and Takei 2002). Because most of the rivers in the Japanese archipelago are steep and short, the rivers tend to flood after heavy rain. Although medakas are highly likely to drift to

![Figure 5](image_url)
the sea on each occasion, medakas can have survived even in the sea and may have returned to the river because of their saltwater tolerance. Thus, the possibility of moving from river to river through the sea cannot be also ignored, although there were several subsidings of sea level during the Pleistocene. The results of this study suggest a history in which medakas migrated throughout the Japanese archipelago through the sea.

The different branching patterns of chromosomal and mtDNA trees suggest that the mtDNA introgression occurred not only from S.JPN to anJPN but also from dN.JPN to S.JPN. The Tajima-Tango region is surrounded by mountains (Figure S1); however, it contains the lowest watershed (sea level 95.45 m) in the Japanese archipelago. The medaka has possibly moved in both directions across the watershed. From the above, the most plausible scenario is as follows (Figure 6). Ancestral S.JPN and N.JPN diverged first and independently reached their current habitats in the Japanese archipelago. After S.JPN, which is an ancestor of San-in, San-yo/Shikoku/Kinki and PO.NEH, dispersed from northern Kyushu approximately 510 kyr ago, dN.JPN diverged from anJPN in N.JPN. Then, their descendant populations spread rapidly to northern Honshu on the Sea of Japan side. Meanwhile, S.JPN dispersed in as many as three different directions and then spread rapidly northeastward from the western part of Fossa Magna. In the process of dispersing across the main island of Japan, certain S.JPN populations infiltrated the Tajima-Tango region from the west and the south, and the resulting mtDNA introgression occurred independently.

Conclusion

Our genome-wide SNP analysis reconstructed the detailed population structure and reliable history of medaka that evolved in the Japanese archipelago. Since the distribution of the subgroups was highly consistent with the geographical features, several adaptive traits could have evolved in each subgroup. Furthermore, the boundary populations were not caused by a hybridization event but instead were the origin of the populations dispersed to a northeastern part of the Japanese archipelago on the Sea of Japan side. A better understanding of the population structure and history of medaka will support association studies for phenotypes and genotypes related to environmental adaptation.

ACKNOWLEDGMENTS

We thank Mrs. Shizuko Chiba, Mrs. Sumiko Tomizuka, Dr. Atsuko Shimada and Prof. Emeritus Akihiro Shima (the University of Tokyo) for maintaining the medaka stocks from wild populations. This study was supported in part by grants-in-aid for Young Scientists (B), no. 16K21352 to T.K., and by a grant-in-aid for Scientific Research (A) nos. 26251050, 25251046, 17H01453, 18H03590, and Scientific Research (B) no 17H03738 to H.O. T.K. was also supported by a grant-in-aid from JSPS Research Fellowships (16f07227).
