(Dated: November 12, 2018)

We theoretically explore the crossover from three dimensions (3D) to two (2D) in a strongly interacting atomic Fermi superfluid through confining the transverse spatial dimension. Using the gaussian pair fluctuation theory, we determine the zero-temperature equation of state and Landau critical velocity as functions of the spatial extent of the transverse dimension and interaction strength. In the presence of strong interactions, we map out a dimensional crossover diagram from the location of maximum critical velocity, which exhibits distinct dependence on the transverse dimension from 2D to quasi-2D, and to 3D. We calculate the dynamic structure factor to characterize the low-energy excitations of the system and propose that the intermediate quasi-2D regime can be experimentally probed using Bragg spectroscopy.

Recent breakthroughs in understanding strongly interacting ultracold atomic Fermi gases at the crossover from Bose-Einstein condensates (BEC) to Bardeen-Cooper-Schrieffer (BCS) superfluids [1–4] have attracted enormous attention from diverse fields of physics [5–7]. Due to the unprecedented accuracy in controlling the dimensionality and interatomic interaction [8–10], significant progress has been made to realize systems in the 2D limit [11–20]. It thus provides a new paradigm to explore a number of intriguing low-dimensional phenomena, including the absence of a true long-range order at nonzero temperature [21, 22], the existence of quasi-condensates due to the Berezinskii-Kosterlitz-Thouless mechanism [23–25], the disruptive role of pair fluctuations around the mean-field (MF) [26–30], and the possible observation of exotic imbalanced superfluidity [31–33]. These unusual features lie at the heart of many technologically interesting materials such as high-temperature superconductors [34], where the dimensional crossover from 3D to 2D is dictated by the ratio of the Cooper pair size to the thickness of the superconducting layer.

Despite rapid experimental advances, the fundamental criteria for reaching the strict 2D regime at the BEC-BCS crossover are still not well understood. Experimentally, a 2D Fermi gas is realized by freezing the atomic motion in the transverse direction using a single highly-oblate harmonic trap [13, 24] or a tight one-dimensional optical lattice [10, 11, 15, 16, 17, 19]. In the absence of interactions, the 2D condition is easy to clarify within the single-particle picture: the chemical potential $\mu$ and temperature $k_B T$ of the system should be smaller than the characteristic energy scale $\hbar \omega_z$ along the transverse direction, so that all atoms stay in the lowest transverse mode [13]. With strong interactions, the situation is less clear. Indeed, a recent measurement of time-of-flight expansion indicates that it is difficult to display the strict 2D kinematics when the interaction becomes stronger [22]. Theoretically, the dimensional crossover of a strongly interacting Fermi gas from 3D to 2D is challenging due to the strong correlations [15].

To date, an interacting quasi-2D Fermi gas has only been studied in the highly imbalanced polaron limit [16] or by using mean-field approach that is known to break down in the 2D limit [17, 43].

In this Letter, we determine the dimensional crossover diagram (see Fig. 1), by considering a uniform strongly interacting quasi-2D Fermi gas with periodic boundary condition (PBC) in the tightly confined transverse direction. This configuration is motivated by the recent successful production of a box trapping potential that leads to a uniform Bose or Fermi gas in bulk [39, 50].

Figure 1: (color online). The dimensional crossover diagram, tuned by the dimension parameter $\eta$ (in logarithmic scale) and the value of the interaction strength, $(l_z/a_{3D})_{v_{\text{max}}}$, at which the Landau critical velocity peaks. The red solid line (with circles) and blue dashed line show $(l_z/a_{3D})_{v_{\text{max}}}^\text{predicted by the GPF and MF theories, respectively. Their distinct dependences on $\eta$ enables us to identify the 2D and 3D regimes, and the quasi-2D regime in between. The inset shows the dimensional crossover diagram in the non-interacting case, determined from the free Fermi gas number equation (see text).
apply a gaussian pair fluctuation (GPF) theory to obtain the zero-temperature equation of state (Fig. 2) and Landau critical velocity (Fig. 3) at the dimensional crossover. For a given dimensional parameter \( \eta \equiv k_F^{3D} l_z \), where \( l_z \) is the periodic length of the confining potential in the transverse direction and \( k_F^{3D} \equiv (3\pi^2 n)^{1/3} \) is the three-dimensional (3D) Fermi momentum of the gas with density \( n \), we determine the interaction strength at which there is a maximum of the Landau critical velocity \( \xi_f \), \( (l_z/a_{3D})_{\max} \), where \( a_{3D} \) is the 3D s-wave scattering length. A Fermi superfluid is most robust to external excitations at this maximum, which is found, in 3D, close to unitarity \[52\] [54]. We obtain a regime where the maximum of the critical velocity in the BEC-BCS crossover depends on the logarithm of \( \eta \) for \( \eta < 2 \), denoting a 2D regime (i.e., the long-dashed line in Fig. 1). Also, \( (l_z/a_{3D})_{\max} \) depends linearly on \( \eta \) for \( \eta > 8 \), denoting a 3D regime. The region that links these regimes is defined as quasi-2D and has properties distinct to the 2D and 3D limits.

**Theoretical framework.** — We start by defining various Fermi momenta. We consider a s-wave two-component Fermi gas at zero temperature where the transverse direction is confined with periodic length \( l_z \), implying the discretization of momentum in the \( z \)-direction, \( k_z = 2\pi n_z/l_z \), for any integer \( n_z \). The Fermi momentum \( k_F \) of the dimensional crossover system can then be defined as the maximally allowed momentum in the axial direction:

\[
n = \frac{1}{2\pi l_z} \sum_{n_z=-n_{\max}}^{n_{\max}} \left[ k_F^2 - \left( \frac{2\pi n_z}{l_z} \right)^2 \right],
\]

where \( n_{\max} \) is the largest integer smaller than \( k_F l_z / (2\pi) \). It is useful to first examine the dimensional crossover diagram for an ideal Fermi gas, as shown in the inset of Fig. 1. At large \( l_z \) (or \( \eta \)), \( k_F \) approaches the 3D Fermi momentum \( k_F^{3D} \), as anticipated. In the limit of small \( l_z \) instead, \( k_F \) coincides with a 2D Fermi momentum \( k_F^{2D} \equiv \sqrt{2\pi n_{2D}} = \sqrt{2\pi n / (3\pi)} k_F^{3D} \), where the column density \( n_{2D} \equiv n l_z \). An ideal 2D Fermi gas is thus realized when \( k_F = k_F^{2D} \) or \( \eta < \sqrt{6\pi} \approx 5.7 \), for which only the lowest transverse mode is occupied. This simple 2D condition is not applicable in the presence of strong interactions, a situation that we shall consider below. A strongly interacting Fermi gas with contact interactions between unlike fermions can be described by a single-channel Hamiltonian density \[52\] [33] [55] [56],

\[
\mathcal{H} = \sum_{\sigma=\uparrow,\downarrow} \bar{\psi}_\sigma(r) \mathcal{H}_0 \psi_\sigma(r) - g \bar{\psi}_\uparrow(r) \bar{\psi}_\downarrow(r) \psi_\uparrow(r) \psi_\downarrow(r),
\]

where \( \psi_\sigma(r) \) are the annihilation operators for each spin state, \( \mathcal{H}_0 = -\hbar^2 \nabla^2 / (2M) - \mu \) is the free Hamiltonian with atomic mass \( M \), \( \mu \) is the chemical potential, and \( g > 0 \) denotes the bare interaction strength. The contact potential is a convenient choice of interaction, however it needs to be regularized and related to a physical observable of the system. We achieve this by relating the bare interaction strength \( g \) to the bound state energy \( B_0 \) [57],

\[
\frac{1}{g} = \sum_{\mathbf{k},k_z} \frac{1}{2(\epsilon_\mathbf{k} + \epsilon_{k_z}) + B_0},
\]

where \( \epsilon_\mathbf{k} = \hbar^2 k^2 / (2M) \) and the sums on \( (\mathbf{k},k_z) \) carry a volume factor that goes to \( (2\pi)^2 l_z \) at the thermodynamic limit. In order to recover the 3D limit, we require the two-body T-matrix in the dimensional crossover be equivalent to its 3D counterpart in the limit \( l_z \to \infty \). This implies that the binding energy, \( B_0 \), can be analytically related to the 3D scattering length \( a_{3D} \), according to \[57\] [58],

\[
B_0 = 4 \left( \frac{\hbar^2}{M l_z^2} \right) \arcsinh^2 \left[ \frac{c_0^2 / (2a_{3D})}{2} \right].
\]

It is also possible to define a 2D binding energy, \( \epsilon_B^{2D} = \hbar^2 / (Ma_{2D}^2) \), find the equivalence between the scattering T-matrix and the 2D T-matrix as \( l_z \to 0 \), and show analytically that \( B_0 = \epsilon_B^{2D} \) in the 2D limit.

We solve the many-body Hamiltonian Eq. (2) by using the zero-temperature GPF theory, which provides reasonable quantitative predictions for equation of state in both 2D [38] and 3D [59] [60]. The theory takes into account strong pair fluctuations at the gaussian level on top of mean-field solutions [53] [56] and hence we separate the thermodynamic potential into two parts: \( \Omega = \Omega_{\text{MF}} + \Omega_{\text{GF}} \). The mean-field part is [38],

\[
\Omega_{\text{MF}} = \frac{\Delta}{g} + \sum_{\mathbf{k},k_z} \left( \xi_{\mathbf{k},k_z} - E_{\mathbf{k},k_z} \right),
\]

where \( \xi_{\mathbf{k},k_z} = \epsilon_\mathbf{k} + \epsilon_{k_z} - \mu, E_{\mathbf{k},k_z} = \sqrt{\epsilon_\mathbf{k}^2 + \Delta^2} \), and the order parameter \( \Delta \) is determined self-consistently using the mean-field gap equation, \( \Delta \sum_{\mathbf{k},k_z} \{ (\epsilon_\mathbf{k} + \epsilon_{k_z} + B_0 / 2)^{-1} - E_{\mathbf{k},k_z}^{-1} \} = 0 \), ensuring the gapless Goldstone mode [52]. The pair fluctuation part is given by \( \Omega_{\text{GF}} \equiv \sum_{\mathbf{q},\mathbf{q}_0} \int_0^{\infty} d\omega \ln \left[ \frac{M_{11}(Q) M_{11}(-Q) - M_{12}(Q)}{M_{11}(Q) M_{11}(-Q)} \right], \)

with the matrix elements,

\[
M_{11}(Q) = \frac{1}{g} + \sum_{\mathbf{k},k_z} \left( \frac{u_+^2 u_-^2}{\omega - E_+ + E_-} - \frac{v_+^2 v_-^2}{\omega + E_+ + E_-} \right),
\]

\[
M_{12}(Q) = \sum_{\mathbf{k},k_z} \left( \frac{-u_+ u_- v_+ v_-}{\omega - E_+ + E_-} + \frac{u_+ u_- v_+ v_-}{\omega + E_+ + E_-} \right),
\]

\[
M_{11}^C(Q) = \frac{1}{g} + \sum_{\mathbf{k},k_z} \frac{u_+^2 u_-^2}{\omega - E_+ + E_-}.
\]

Here, we use the notations \( E_\pm \equiv E_{\mathbf{k}\pm\mathbf{q}/2,k_z\pm q_z/2} \), \( u_\pm^2 = (1 + \xi_{\mathbf{k}\pm\mathbf{q}/2,k_z\pm q_z/2} / E_{\mathbf{k}\pm\mathbf{q}/2,k_z\pm q_z/2}) / 2 \) and \( v_\pm^2 = 1 - u_\pm^2 \).
The chemical potential is found by solving the number equation, \( n = -\partial N/\partial \mu \).

**Equation of state.** — In Fig. 2(a), we report the dimensionless shifted chemical potential \( (\mu + B_0/2)/\varepsilon_F \), as a function of \( l_z/a_{3D} \) at various dimension parameters \( \eta = 1 \sim 6 \), from the quasi-2D to 2D regime. The inset shows the order parameter \( \Delta/\varepsilon_F \). (b) The chemical potential near the 2D limit, replotted as a function of \( \ln((\sqrt{B_0/(2\varepsilon_F)}) \), showing the order parameter \( \Delta/\varepsilon_F \), as a function of \( k^D/\varepsilon_F \). (c) The chemical potential near the 3D limit in units of \( \varepsilon_F \) as a function of \( 1/(k^D_{3D} a_{3D}) \).

**Figure 2:** (color online). (a) The dimensionless shifted chemical potential, \( (\mu + B_0/2)/\varepsilon_F \), as a function of \( l_z/a_{3D} \) at various dimension parameters \( \eta = 1 \sim 6 \), from the quasi-2D to 2D regime. The inset shows the order parameter \( \Delta/\varepsilon_F \). (b) The chemical potential near the 2D limit, replotted as a function of \( \ln((\sqrt{B_0/(2\varepsilon_F)}) \), showing the order parameter \( \Delta/\varepsilon_F \), as a function of \( k^D/\varepsilon_F \). (c) The chemical potential near the 3D limit in units of \( \varepsilon_F \) as a function of \( 1/(k^D_{3D} a_{3D}) \).

\[ \text{Figure 3: (color online). Landau critical velocity } v_c \text{ compared with the speed of sound } c_s \text{ across the BEC-BCS crossover, as a function of } l_z/a_{3D} \text{ at different values of } \eta \text{. The theoretical values at large } \eta \text{ may be compared with the experimental results of the critical velocity, obtained by Weimer et al. [64] for a 3D trapped Fermi gas with } \varepsilon^D/F = \frac{\sqrt{B_0/(M\omega_z)}}{M} = 2.9 \text{. Here, } v_c^D = \frac{\hbar k^D/M}{2} \text{ is the 3D Fermi velocity.} \]

\[ \text{Landau critical velocity.} \quad \text{— Within the GPF theory, we can calculate the critical velocity of the superfluid through both the BEC-BCS and dimensional crossover. Once we know the dispersion of in-plane } (q_z = 0) \text{ collective modes } \omega_0(q = |q|), \text{ which corresponds to the poles of } |M_{11}(Q)M_{11}(-Q) - M_{12}(Q)|^{-1}, \text{ for a given set of the parameters } \eta \text{ and } l_z/a_{3D}, \text{ we compute the speed of sound of the superfluid, } c_s = \lim_{q \to 0} \omega(q)/q, \text{ and the pair-breaking velocity } v_{pb} = [\hbar^2(\Delta^2 + \mu^2 - \mu)]/M^{1/2}. \]

\[ v_c = \min \left\{ \frac{\omega_0(q)}{q} \right\} = \min \{c_s, v_{pb}\}. \] (8)

**Figure 3:** (color online). Landau critical velocity \( v_c \) compared with the speed of sound \( c_s \) across the BEC-BCS crossover, as a function of \( l_z/a_{3D} \) at different values of \( \eta \). The theoretical values at large \( \eta \) may be compared with the experimental results of the critical velocity, obtained by Weimer et al. [64] for a 3D trapped Fermi gas with \( \varepsilon^D/F = \frac{\sqrt{B_0/(M\omega_z)}}{M} = 2.9 \). Here, \( v_c^D = \frac{\hbar k^D/M}{2} \) is the 3D Fermi velocity.

\[ \text{Figure 3: (color online). Landau critical velocity } v_c \text{ compared with the speed of sound } c_s \text{ across the BEC-BCS crossover, as a function of } l_z/a_{3D} \text{ at different values of } \eta \text{. The theoretical values at large } \eta \text{ may be compared with the experimental results of the critical velocity, obtained by Weimer et al. [64] for a 3D trapped Fermi gas with } \varepsilon^D/F = \frac{\sqrt{B_0/(M\omega_z)}}{M} = 2.9 \). Here, \( v_c^D = \frac{\hbar k^D/M}{2} \) is the 3D Fermi velocity. \]

\[ v_c = \min \left\{ \frac{\omega_0(q)}{q} \right\} = \min \{c_s, v_{pb}\}. \] (8)

\[ \text{In Fig. 3, we present the speeds of sound } c_s \text{ and critical velocities } v_c \text{ for dimensions } \eta = 1 \sim 4 \text{ as a function of the interaction strength } l_z/a_{3D}. \text{ The critical velocity of a 3D Fermi superfluid at the BEC-BCS crossover has been experimentally measured in a harmonic trap [54, 61] and can be compared with our results using the transverse harmonic oscillator length, } l_{HO} = \sqrt{\hbar/(M\omega_z)}, \text{ as input to determine } \eta. \text{ In Ref. [61], the 3D regime is approximately reached with } \varepsilon^D/F = \frac{\sqrt{B_0/(M\omega_z)}}{M} \gtrsim 4.2 \text{ that corresponds to } \eta \approx 2.9 \text{ and the data match qualitatively well with the predicted Landau critical velocity (i.e., } \eta = 3). \]

\[ \text{In 3D the BCS regime displays a large speed of sound and a smaller pair-breaking velocity that limits the critical velocity [52, 53]. On the BEC side, close to the 3D} \]
unitarity, the pair-breaking velocity becomes equal to the speed of sound, which is referred to as the most robust configuration of the BEC-BCS crossover [52]. Beyond this point the speed of sound becomes the critical velocity, marking the system undergoing macroscopic condensation. The 2D and quasi-2D critical velocities behave similarly to the 3D case. However, the tuning point of the BEC-BCS crossover \( l_z / a_{3D} \to \text{max} \) – at which the critical velocity peaks – shows a non-trivial dependence on the dimensional parameter \( \eta \). This enables us to characterize the dimensional crossover diagram in the presence of strong interactions, as shown in Fig. 1. In the region \( 0 < \eta < 2 \), the 2D regime, we see the logarithmic dependence of the critical velocity maximum with respect to \( \eta \), with the peak of the critical velocity in 2D at \( \ln(k_F a_{2D}) \approx 1.08 \) [51, 52]. Moreover, a linear behavior is observed in the nearly 3D regime with \( \eta > 8 \) placing the peak of the critical velocity in 3D at \( 1/(k_F a_{3D}) \approx 0.056 \) [51, 52]. In between \( (2 < \eta < 8) \), the maximum of the critical velocity lies in the interval \(-1 < l_z / a_{3D} < 0.67 \) and \( (l_z / a_{3D})_{\text{max}} \) varies non-monotonically with \( \eta \). We identify this as the quasi-2D regime, consolidating the previous conclusion made from equation of state.

Probing the quasi-2D regime. — A practical way to measure both the speed of sound, \( c_s \), and the order parameter, \( \Delta \), is via Bragg spectroscopy. The spectroscopic response probes the dynamic structure factor [63, 65], which in the case of a Fermi superfluid exhibits a peak corresponding to the Bogoliubov-Anderson phonon mode and a continuum of particle-hole excitations [52]. Due to the presence of a pairing gap in the excitation spectrum, an external excitation of momentum \( Q_r \) is collective if it does not break pairs when it excites states with energy below the threshold,

\[
\omega_{th}(Q_r) = \begin{cases} 
\frac{2 \Delta}{2 \sqrt{\mu Q_r} + \Delta^2} & \mu > 0 \text{ and } \hbar^2 Q_r^2 \leq 8M \mu \\
0 & \text{otherwise} \end{cases}
\]

with the peak of the critical velocity in 2D at \( \eta > 0.8 \) [51, 62]. Moreover, a linear behavior is observed in the nearly 3D regime with \( \eta > 8 \) placing the peak of the critical velocity in 3D at \( 1/(k_F a_{3D}) \approx 0.056 \) [51, 52]. In between \( (2 < \eta < 8) \), the maximum of the critical velocity lies in the interval \(-1 < l_z / a_{3D} < 0.67 \) and \( (l_z/a_{3D})_{\text{max}} \) varies non-monotonically with \( \eta \). We identify this as the quasi-2D regime, consolidating the previous conclusion made from equation of state.

The dynamic response of the system, for a transverse recoil momentum \( Q_r = (q_r, q_z) \), a combination of an in-plane momentum \( q_r \), and a transverse excitation, \( q_z = 2\pi n_z / l_z \) for fixed integer \( n_z \). We note that the calculation of the dynamic structure factor \( S(Q_r, \omega) \) within the GPF theory is notoriously difficult [60], so we instead use the random phase approximation within the mean-field framework [67].

In Fig. 4 we plot the dynamic structure factor in the quasi-2D regime at \( \eta = 4 \), normalized by the number of particles \( N \) and recoil energy \( \omega_r = \hbar Q_r^2 / (2M) \) for three different recoil momenta, (a) \( Q_r = (3.2k_F , 0) \), (b) \( Q_r = (0.6k_F , 0) \) and (c) \( Q_r = (0, 2\pi / l_z) \). One observes in Figs. 4(a)-(b) that the response is similar to the 3D case [67], showing the characteristic peaks in the continuum spectrum for \( \omega > \omega_{th} \), and the presence of the phonon mode. We note the appearance of a second peak, marked by \( \omega_{th}(q_r, 4\pi / l_z) \) (green dashed in Fig. 4(a), corresponding to the generation of a transverse excitation. The response at \( \omega_{th}(q_r, 2\pi / l_z) \) is absent, due to the need of the system to excite two modes along \( z \) with opposite momenta, in order to conserve the total momentum. The same structure, present in Fig. 4(b), is not resolved due to the energy required at this momentum.

The dynamic response of the system, for a transverse recoil momentum \( Q_r = (0, 2\pi / l_z) \), is shown in Fig. 4(c), and has a specific structure due to the quasi-2D regime. Conservation of total momentum forces in-plane excitations to place the second continuum peak at \( \omega_{th}(4\pi / l_z, 2\pi / l_z) \) and gives no response at \( \omega_{th}(2\pi / l_z, 2\pi / l_z) \), which would break momentum conservation. We expect this to be a signature of the quasi-2D regime, as in 3D the pairing gap between box modes, \( 2\pi / l_z \), goes to zero and the isolated peaks merge in a continuous structure, while in 2D, the peak \( \omega_{th}(4\pi / l_z, 2\pi / l_z) \) moves too far away from the main spectrum.

Conclusions. — In summary, we have examined the role of dimension in a strongly interacting Fermi superfluid by treating the transverse confinement with PBC. We have mapped out a dimensional crossover diagram from the zero-temperature equation of state and have

Figure 4: (color online). The density dynamic structure factor \( S(Q_r, \omega) \) scaled by the ratio \( \omega_r / N \), where \( \omega_r \) is the recoil energy and \( N \) the particle number, in the quasi-2D regime for \( \eta = 4 \) at various interaction strengths \( l_z / a_{3D} \), with the in-plane recoil momentum \( Q_r = (3.2k_F , 0) \) (a), \( Q_r = (0.6k_F , 0) \) (b) and transverse recoil momentum \( Q_r = (0, 2\pi / l_z) \) (c). The spectral width of the Bogoliubov-Anderson phonon peak is illustrated by the height of the delta function.
quantitatively determined the boundaries between 2D, quasi-2D, and 3D from the location of maximum Landau critical velocity. This sets a framework for characterizing the BCS-BEC crossover in quasi-2D, where the different regimes of the superfluid can be experimentally probed using Bragg spectroscopy. Our results are directly applicable to an interacting dimensional crossover Fermi gas realized by imposing a box trapping potential in the tight confinement direction [50], and we expect our findings to be qualitatively similar under harmonic transverse confinement.

Supplemental Material for
“Dimensional crossover in a strongly interacting ultracold atomic Fermi gas”

I. ALTERNATIVE CHARACTERIZATIONS OF THE DIMENSIONAL CROSSOVER

The dimensional crossover is tuned by the quasi-2D BCS-BEC crossover parameter, \( l_z/a_{3D} \), computed at the position where the Landau critical velocity has a maximum. Here, we present alternative characterizations by using the ratio between the pairing order parameter \( \Delta \) and the chemical potential \( \mu \), or the ratio between the pairing order parameter and the Fermi energy \( \epsilon_F \).

![Figure S1: The evolution of the tuning parameter \( l_z/a_{3D} \), computed at different conditions, as a function of the dimensional parameter \( \eta \) (in logarithmic scale). \( l_z/a_{3D} \) is computed (i) when the Landau critical velocity has a maximum (red line with circles), (ii) when the ratio between the order parameter \( \Delta \) and the chemical potential \( \mu \) reproduces the 3D typical values \( \Delta_0^{3D}/\mu_0^{3D} \) (purple dot-dashed line), and (iii) when \( \Delta = \epsilon_F \) (solid line at the top right).](image)

In Fig. S1 we plot the critical values of \( l_z/a_{3D} \), across the dimensional crossover, when, (i) the Landau critical velocity has a maximum (circles), (ii) the ratio \( \Delta/\mu \) is equal to the 3D case (dashed-dotted) and (iii) when the order parameter, \( \Delta \), is equal to the Fermi energy, \( \epsilon_F \). We observe that as expected, the ratio \( \Delta/\mu \) approaches the 3D limit.
II. LANDAU CRITICAL VELOCITY IN THE 3D AND 2D LIMITS

A. The 3D limit

We observe that, for a 3D Fermi gas, the MF theory predicts the critical velocity to be slightly on the BEC side at approximately $1/(k_F^3 a_{3D}) \approx 0.07$ [2]. Figure 1 is expected to predict this behaviour when we restore the 3D limit case for $\eta \to \infty$. We consider the most general choice to describe the BCS-BEC tuning parameter in this limit,

$$\left( \frac{l_z}{a_{3D}} \right)_{v_{c,3D}^\text{max}} = \sum_{n=-\infty}^{\infty} a_n \eta^n.$$ \hfill (S1)

The limit of the proper 3D tuning parameter, $1/(k_F^3 a_{3D})$, is then given by

$$\lim_{\eta \to \infty} \left( \frac{l_z}{a_{3D}} \right)_{v_{c,3D}^\text{max}} \frac{1}{\eta} = \sum_{n=-\infty}^{\infty} a_n \eta^{n-1}.$$ \hfill (S2)

Every coefficient $a_n$ for $n < 1$ is negligible when $\eta$ is large enough, while each term $a_n \neq 0$, for $n > 1$, would lead to a divergence in the definition of the 3D peak for the critical velocity and it is therefore discarded. We fit the far right hand side of Fig. 1 via a linear function,

$$\left( \frac{l_z}{a_{3D}} \right)_{v_{c,3D}^\text{max}} \big|_{\eta \geq 8} = a_0 + a_1 \eta,$$ \hfill (S3)

and we included the $a_0$ term due to the proximity of data to the quasi-2D regime when $\eta \approx 8$. This leads to

$$\left( \frac{1}{k_F^3 a_{3D}} \right)_{v_{c,3D}^\text{max}} = a_1 \simeq 0.056.$$ \hfill (S4)

The behaviour in the 3D regime is shown in Fig. S2(a) that provides the same results of Fig. 1 with a change of scale in the vertical axis from $l_z/a_{3D}$ to $1/(k_F^3 a_{3D})$. 
B. The 2D limit

In the 2D limit, we denote that

\[
\frac{l_z}{a_{3D}} = F(\eta),
\] (S5)

where the approximate form of \( F(\eta) \) is to be determined. We observe from Fig. 2(a)-(b) that the proper BCS-BEC crossover tuning parameter becomes \( \ln\left(\sqrt{B_0/(2\epsilon_F)}\right) \), where \( k_F = k_{2D}F \), for \( \eta \leq \pi 6^{1/3} \), and \( \lim_{\eta \to 0} \sqrt{B_0/(2\epsilon_F)} = 1/(k_{2D}F a_{2D}) \). We consider the relation between the 2D and the quasi-2D tuning parameters,

\[
\sqrt{B_0} = \frac{\sqrt{3\pi}}{\eta^{3/2}} \text{arsinh}\left[\frac{1}{2} \exp\left(\frac{l_z}{2a_{3D}}\right)\right].
\] (S6)

It is reasonable to assume that at the position where the Landau critical velocity takes the maximum value, we would have,

\[
\lim_{\eta \to 0} \sqrt{B_0} = A \neq 0.
\] (S7)

By using the above three equations, we find that,

\[
F(\eta) = 2 \ln \left[\sinh\left(\frac{A\eta^{3/2}}{\sqrt{3\pi}}\right)\right] \sim_{\eta \to 0} 2 \ln \left(\frac{2A}{\sqrt{3\pi}}\right) + 3 \ln \eta + \mathcal{O}(\eta^3).
\] (S8)

Therefore, our numerical results in the 2D limit could be fitted with the function

\[
F(\eta) = W + Z \ln \eta.
\] (S9)

We obtain the values \( W = 3.02 \) and \( Z = 2.97 \) from the fitting. The latter value \( Z \approx 3 \) confirms our theoretical anticipation of the 2D limit, within a relative error of a few percents. Using the former value of \( W \), we can compute the position of the Landau critical velocity peak in the 2D limit being,

\[
\lim_{\eta \to 0} \ln \left(\sqrt{B_0} \frac{v_{\text{max}}}{2\epsilon_F}\right) = \ln A = \frac{W}{2} + \ln \frac{\sqrt{3\pi}}{2} \approx -1.08,
\] (S10)

as represented in the dimensional crossover diagram of Fig. S2(b) that provides the same results of Fig. 4 with a change of scale in the vertical axis from \( l_z/a_{3D} \) to \( \ln\left(\sqrt{B_0/(2\epsilon_F)}\right) \). This extracted position of the peak of the Landau critical velocity in the 2D limit is consistent with the position of the peak of the contact, \( \ln(k_{2D}F a_{2D}) \sim 1 \), obtained recently via auxiliary-field Monte Carlo simulations for a 2D interacting Fermi gas \[62\].
