Abstract

Introduction: Slow coronary flow (SCF) is an angiographic phenomenon characterized by delayed opacification of epicardial coronary arteries without an obstructive coronary disease. Serum soluble urokinase-type plasminogen activator receptor (suPAR) levels seem closely related to atherosclerosis due to increased inflammation and prothrombotic state. We studied whether circulating suPAR is related to SCF.

Material and methods: The present study was cross-sectional and observational. It included 75 individuals who underwent coronary angiography with suspected CAD and had angiographically normal coronary arteries of varying coronary flow rates. The relationship between suPAR, C-reactive protein (CRP) and SCF was investigated. Forty patients with isolated SCF (mean age: 46.0 ±4.14 years) and 35 age- and gender-matched control participants with normal coronary flow (NCF) and normal coronary arteries (NCA) (mean age: 46.0 ±5.7 years) were included in the study. We used logistic regression analysis to determine the predictors of SCF.

Results: The clinical characteristics were not statistically significantly different between SCF and NCA groups. Serum suPAR level was significantly higher in the SCF group than the control group (2.5–5.4 ng/ml vs. 0.1–1.4 ng/ml; \(p<0.001\)). Also the serum CRP level was higher in the CSF group than the control group (1.57 ±0.43 mg/l vs. 0.53 ±0.23 mg/l; \(p<0.001\)).

Conclusions: This study revealed significantly increased serum suPAR levels in patients with SCF. Although we cannot draw conclusions on the underlying pathological process of SCF, we believe that these findings may be pioneering for further studies investigating the specific roles of circulating suPAR in the SCF phenomenon in the coronary vasculature.

Key words: coronary slow flow, suPAR, high-sensitivity C-reactive protein, coronary angiography, regression analysis.
et al. [1], there have been many reports with the aim of describing the precise pathophysiological mechanisms such as small vessel disease, microvascular vasomotor dysfunction, diffuse atherosclerosis, and endothelial dysfunction [3–6]. Occlusive disease of the small coronary arteries, which may be a form of early-phase atherosclerosis, has also been suggested as a cause [7]. Also, it is reported that SCF may cause transient myocardial hypoperfusion in patients with angina and normal coronary arteries, and these patients have a higher chance of significant coronary artery disease and an apparently worse prognosis [8].

suPAR is a novel proinflammatory biomarker and chemotactic agent [9] that is released by cleavage of the membrane-bound urokinase type plasminogen activator receptor (uPAR). suPAR is ubiquitous in body fluids including the plasma, urine, and cerebrospinal fluid, is involved in the inflammatory processes and promotes the body’s immune response. Up-regulation of uPAR is manifested by raised blood suPAR levels and has been observed in many conditions such as rheumatologic conditions, malignancies, infections, sepsis and cardiovascular diseases [10–20]. suPAR is also thought to be involved in atherosclerotic processes such as endothelial dysfunction, macrophage-mediated inflammation and immune dysregulation [21]. The physiological role and pathophysiological importance of suPAR in SCF are unclear. Since SCF seems to be an early form of atherosclerosis and low-grade inflammation plays a major role in the atherosclerotic vascular processes, suPAR-related inflammation may also be involved in SCF as well.

The aim of this study was to investigate whether suPAR level and high-sensitivity C-reactive protein (hs-CRP) levels are higher in patients with SCF compared to patients with angiographically normal coronary arteries. We also evaluated the potential relationship between these markers and Thrombolysis in Myocardial Infarction (TIMI) frame count.

Material and methods

Study design and patient population

The present study was cross-sectional and observational. We randomly selected a total of 75 individuals from patients who underwent coronary angiography with suspicion of CAD, between March 2015 and October 2015, at our institute’s outpatient clinic, and had angiographically normal coronary arteries (NCA) of varying coronary flow rates without any atherosclerotic lesions. They were enrolled in the study. All patients had chest pain or angina equivalent symptoms with either positive treadmill test or myocardial perfusion study. Clinical characteristics, which consisted of multiple descriptors from each patient’s history and physical examination, were collected by physicians from the cardiology clinic of each patient at the time of cardiac catheterization and were stored in the database of coronary angiography laboratory at our institution. Patients with known coronary or peripheral vascular disease, ectatic coronary arteries, non-ischemic dilated cardiomyopathy, renal and hepatic dysfunction, evidence of ongoing infection or inflammation, hematological disorders, and known malignancy were excluded from the study. None of the participants in the study was on any vasoactive drugs.

The study was performed in accordance with the principles stated in the Declaration of Helsinki and approved by the local Ethics Committee of Marmara University, Faculty of Medicine. Informed consent was obtained from all patients prior to the study.

Biochemical measurements

Blood samples were drawn by venipuncture to measure routine blood chemistry parameters after fasting for at least 8 h. Fasting blood glucose, serum creatinine, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, and triglyceride levels were recorded. Glucose, creatinine, and lipid profile were determined by standard methods. Serum CRP was analyzed using a nephelometric technique (Beckman Coulter Immage 800; Fullerton, CA, USA; normal range 0–0.8 mg/dl). Blood samples for suPAR were drawn after coronary angiography and serum, isolated by centrifugation within 1 h at 2500 g for 10 min, and stored at –80°C. Serum levels of suPAR were measured using commercially available kits according to the manufacturer’s instructions (suPARnostic kit; ViroGates, Copenhagen, Denmark) Minimum detectable high-sensitivity C-reactive protein (hs-CRP) and suPAR were 0.1 mg/l and 0.1 ng/ml, respectively.

Coronary angiography and determination of SCF

Coronary angiography was performed by the femoral approach using the standard Judkins technique. Coronary angiograms were recorded in right and left oblique planes using cranial and caudal angulations, with a rate of 30 frames/s. During coronary angiography, iopromide (Ultravist 370, Schering AG, Berlin, Germany) was used as the contrast agent in all patients and control participants. TIMI frame count was derived from the number of cine-frames recorded from the first entrance of contrast to its arrival at the distal end of the left anterior descending artery (LAD), the circumflex artery (Cx), or the right coronary artery (RCA) [22]. It is a quantitative, simple, objective and re-
Increased circulating soluble urokinase-type plasminogen activator receptor (suPAR) levels in patients with slow coronary flow

Clinical and laboratory characteristics of the patients with SCF and the control group are presented in Table I. There were no statistically significant differences between the two groups with respect to age, gender, body mass index, smoking, systolic and diastolic blood pressures, heart rate, ejection fraction and levels of glucose, creatinine, total cholesterol, triglyceride, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, or white blood cells. The TIMI frame count for all the epicardial coronary arteries and the mean TIMI frame count were significantly higher in the SCF group than the control group.

Serum suPAR levels and hs-CRP levels in SCF

Serum suPAR levels were significantly higher among patients with SCF than controls (3.71 ng/ml; 2.5–5.4 ng/ml vs. 0.75 ng/ml; 0.1–1.4 ng/ml respectively; \( p < 0.001 \)). Serum hs-CRP levels were significantly higher among patients with SCF than controls (1.57 ±0.43 vs. 0.53 ±0.23 mg/l respectively; \( p < 0.001 \)).

Relationship between serum suPAR levels and TIMI frame count

In linear regression analysis, when suPAR levels were taken as the dependent variable with other study variables which are potential confounders such as age, gender, BMI, smoking, glucose and cholesterol levels, serum suPAR levels were only independently correlated with mean TIMI frame count (\( \beta = 0.60, 95\% \text{ CI: 4.23–8.56, } p < 0.001 \)) (Figure 1 A). When serum hs-CRP levels were taken as the dependent variable with other study variables which are potential confounders such as age, gender, BMI, smoking, glucose and cholesterol levels, serum hs-CRP levels were only independently correlated with mean TIMI frame count (\( \beta = 0.29, 95\% \text{ CI: 0.68–3.78, } p = 0.003 \)) (Figure 1 B).

Discussion

In this study, we found that suPAR and hs-CRP levels were significantly higher in patients with SCF than in control subjects. We also found a significant association of suPAR and hs-CRP levels with TIMI frame count. Several mechanisms have been proposed for the etiology of SCF, including occlusion of small vessels, increased microvascular resistance, and diffuse atherosclerosis \([1, 4, 5, 7]\). However, the exact underlying pathophysiological mechanisms, as well as the clinical importance of this angiographic phenomenon, are not fully understood at present. Inflammation has been reported to play a major contributing factor to many cardiovascular events, and demonstrated to be associated with different clinical settings of coronary artery disease \([21, 23]\).

Recently, inflammation has been suggested to play a role in the pathogenesis of SCF. Li et al.
**Table I. Clinical and laboratory characteristics of patients with CSF and control group**

| Variables                        | CSF group (n = 40) | Control group (n = 35) | P-value |
|----------------------------------|--------------------|------------------------|---------|
| Age [years]                      | 46.0 ±4.14         | 46 ±5.7                | 0.98    |
| Male gender (%)                  | 25 (62.5)          | 23 (65.7)              | 0.772   |
| Current smoking (%)              | 29 (72.5)          | 25 (71.5)              | 0.918   |
| Family history of CAD (%)        | 7 (17.5)           | 7 (20)                 | 0.782   |
| **Baseline hemodynamic data:**   |                    |                        |         |

| Mean                             | 33.3 (30–38)       | 13.9 (12–17.3)         | < 0.001 |

CSF – coronary slow flow; CAD – coronary artery disease, SBP – systolic blood pressure, DBP – diastolic blood pressure, EF – ejection fraction, LDL – low-density lipoprotein, HDL – high-density lipoprotein, WBC – white blood cells, hs-CRP – high-sensitivity C-reactive protein, suPAR – circulating soluble urokinase-type plasminogen activator receptor, TIMI – Thrombolysis in Myocardial Infarction, LAD – left anterior descending artery, LCX – left circumflex artery, RCA – right coronary artery.

**Figure 1.** A – Serum suPAR levels were significantly higher among patients with SCF than controls. B – Serum hs-CRP levels were significantly higher among patients with SCF than controls.
found that plasma levels of inflammatory factors, hs-CRP and IL-6 in patients with SCF were significantly higher than those of control subjects [23]. Varol et al. found higher levels of neopterin, which is thought to be a marker of immune activation and macrophage activity, in the CSF group than the normal coronary flow group [24]. Selçuk et al. reported that serum concentrations of adiponectin, a modulator of the inflammatory response in the vascular wall, were decreased in patients with SCF and inversely correlated with mean TIMI frame count [25]. Durakoğluğil et al. reported significantly increased serum levels of sCD40, which is a proinflammatory agent, in patients with SCF [26]. Yıldırım et al. observed that levels of thrombin activatable fibrinolysis inhibitor (TAFI), also a proinflammatory factor, were higher in patients with SCF [27]. Aksan et al. reported that patients with CSF had elevated levels of neutrophil gelatinase-associated lipocalin (NGAL), which is released in response to active inflammation [28]. Çalış et al. found that increased levels of resistin, an inflammatory modulator, were associated with CSF [29]. Also, Çakmak et al. reported that visfatin, which is a novel adipokine and plays a role in inflammatory modulation, was associated with CSF [30].

Urokinase plasminogen activator (uPA) is a serine protease that, on binding its receptor, urokinase plasminogen activator receptor (uPAR), leads to the generation of plasmin [31]. uPA is produced by vascular endothelial cells, smooth muscle cells, monocytes, macrophages, fibroblasts and epithelial cells [32]. uPAR plays a role in development of atherosclerosis by orchestrating cellular adhesion, migration, and proliferation [31, 33], and plasma suPAR likely reflects cellular shedding of a section of uPAR from either inflammatory or endothelial cells. suPAR is present in low concentrations in healthy individuals, where it has a role in neutrophil trafficking and stem cell mobilization [34]. Serum concentrations are elevated in infectious diseases induced by various pathogenic species [13, 35, 36]. suPAR levels are also elevated in patients with inflammatory disorders, including arthritis [14] and inflammatory bowel disease [37]. On the basis of these data, suPAR has been considered a marker of (low-grade) activation of the immune system [38].

In the general population, individuals with high suPAR concentrations are at an increased risk for cardiovascular events, independent of Framingham risk factors [39, 40]. Eapen et al. found that suPAR level is an independent predictor of the presence and severity of coronary artery disease and of future adverse events [41]. In patients with non-ST elevation acute coronary syndrome, as well as in patients with ST-elevation myocardial infarction (MI), suPAR predicts all-cause mortality and recurrent MI [18, 19]. suPAR was associated with subclinical organ damage independently of traditional risk factors [42]. One small study confirmed the relationship between the levels of suPAR in plasma and carotid plaques and the presence of symptoms [43]. They concluded that plaque suPAR levels were associated with the vulnerable plaque phenotype. This, however, contradicted an earlier study suggesting that suPAR levels did not predict atherosclerotic plaque vulnerability [44]. The association between coronary microvascular dysfunction and inflammatory markers has been previously reported [45, 46]. Recently Mekonnen et al. found that plasma suPAR level was an independent predictor of coronary microvascular function [47]. However, the relation between SCF and suPAR levels has not been investigated previously. To the best of our knowledge, this is the first study investigating serum suPAR levels in patients with SCF and the relationship with TIMI frame count.

Some limitations of this study should be noted. The first is the small number of patients. Another limitation is that the analysis was based on a simple baseline determination that may not reflect the patient status over long periods.

In conclusion, we found that suPAR and hs-CRP levels were significantly elevated in patients with SCF compared with control subjects. This study shows that low-grade, chronic inflammation may be involved in the pathogenesis of SCF. Further prospective studies with a larger sample size are required to establish the pathophysiological and clinical significance of increased suPAR levels in patients with SCF.
