ABSTRACT: When a Poincaré-invariant system spontaneously breaks continuous internal symmetries, Goldstones’ theorem demands the existence of massless, spin-zero excitations in a one-to-one correspondence with the broken symmetry generators. When a system spontaneously breaks Poincaré symmetry, however, the kinds of excitations that satisfy Goldstone’s theorem can be quite unusual. In particular, they may have any spin and need not be particles or even quasiparticles. The standard coset construction used to formulate effective actions of Goldstones, however, is rather restrictive and is incapable of generating the full spectrum of possibilities allowed by Goldstone’s theorem. We propose a (partial) remedy to this problem by postulating a novel coset construction for systems that spontaneously break Poincaré symmetry. This new construction is capable of generating effective actions with a wide range of Goldstone excitations — including fermionic degrees of freedom — even when all symmetries are bosonic. To demonstrate its utility, we focus on constructing effective actions for point particles of various spins. We recover the known result that a particle of spin $s$ requires an $\mathcal{N} = 2s$ supersymmetric worldline reparameterization gauge symmetry, which we implement at the level of the coset construction. In the process, we discover that massless particles require a novel kind of inverse Higgs constraint that bears some resemblance to the dynamical inverse Higgs constraints that appear in certain fermi liquid effective field theories. We then consider particles that, in addition to quantum spin, have finite spatial extent and are free to rotate. We derive a novel action for such particles and find a ‘spin-orbital’ coupling between the intrinsic quantum spin and the physical-rotation degrees of freedom.

1 Introduction

Symmetries are one of the most important physical properties of a system. This fact becomes particularly evident when we are primarily concerned with low-energy dynamics. When continuous symmetries are spontaneously broken, the spectrum of low-energy excitations include gapless Goldstone modes. If only internal symmetries are broken and the underlying physics is Poincaré-invariant, Goldstone’s theorem guarantees the existence of one Goldstone boson for each spontaneously broken symmetry. When Poincaré symmetry is broken, however, no such one-to-one correspondence is guaranteed. At least one gapless excitation must exist, but it need not be describable as a scalar particle. In fact, it could have any spin and need not be a particle — or even a quasiparticle — in any conventional sense. A striking example occurs in fermi liquids at zero temperature, which spontaneously breaks Lorentz boosts. The corresponding gapless excitations that satisfy Goldstone’s theorem are the well-known particle-hole pairs, which evidently have no single-particle interpretation [1].

Oftentimes, the only gapless excitations of a given system are the Goldstones.1 Whenever this is the case, as long as we only concern ourselves with the deep infrared (IR), we can integrate out all gapped excitations, yielding a theory consisting of only Goldstone modes. In practice, we often do not explicitly integrate out the gapped modes. Instead, we use the principles of effective field theory (EFT) to construct an action by writing down a linear combination of all symmetry-invariant terms at any given order in a derivative expansion. The coefficients of this linear combination are phenomenological constants that can be determined experimentally. It is important to note that even when symmetries are spontaneously broken, they remain symmetries of the IR theory of Goldstones; however, their action on the Goldstones is non-linear and as a result can be quite complicated. Therefore, constructing the full set of symmetry-invariant terms can be rather challenging. To facilitate the formulation of Goldstone EFTs, a procedure known as the coset construction has been devised [2–6].

For a Poincaré-invariant system that spontaneously breaks internal symmetries while leaving spacetime symmetries intact, there is no ambiguity or choice in how to formulate an action using the coset construction (except for the numerical values of various coefficients that can be fixed experimentally). This uniqueness is a clear reflection of the strict nature of Goldstone’s theorem when Poincaré symmetry is preserved; in particular Goldstones must be massless, scalar particles that exist in a one-to-one correspondence with the spontaneously broken symmetry generators. When Poincaré symmetry is broken, however, Goldstone’s theorem is not always so restrictive. In particular, the number or type of Goldstones in the EFT is not determined by the spontaneous symmetry-breaking pattern alone [7, 8]. We must supply additional information regarding the spontaneous symmetry-breaking mechanism if we are to uniquely determine the EFT (up to experimentally-determined coefficients) [6].2 Ideally, the coset construction for spontaneously broken spacetime sym-

---

1There can also be gapless excitations associated with conserved currents for finite-temperature systems. But we will focus only on zero-temperature systems in this paper.

2The situation is even more complicated when the system exists at finite temperature, but we will ignore such complications here [9, 10].
metries should reflect this extended set of possibilities. While the last few decades have seen a great effort to understand the coset construction when Poincaré symmetry is spontaneously broken, there remain many kinds of systems that spontaneously break Poincaré symmetry, but whose effective actions cannot be generated with the method of cosets. In this paper, we will extend the coset construction to allow for a wider range of types of Goldstones. In particular, we focus on a simple yet illustrative class of system that have largely evaded descriptions at the level of the coset construction, namely relativistic point particles. This class of EFT is a useful testing-ground for extensions of the coset construction for two main reasons:

- All particles exhibit identical (or almost identical) spontaneous symmetry breaking (SSB) patterns, yet there are infinitely many distinct kinds of particles, each of which exhibits markedly different behavior. In particular, each kind of particle is classified by its spin $s \in \mathbb{Z}/2$ and mass $m$. Massive and massless particles behave quite differently and particles of different spins have qualitatively very different actions.

- Almost all previous attempts at formulating coset constructions for systems without fermionic symmetries have assumed that the Goldstone excitations involve only bosonic fields; however, many Goldstone’s effective actions involve fermionic degrees of freedom. Since point-particles of half-integer spin are fermions, we have a simple testing-ground for fermionic extensions of the coset construction. Thus, an important aim of this paper is to extend the coset construction to account for situations in which the Goldstone excitations involve fermions even when the global symmetry group is purely bosonic (i.e. the symmetry algebra is an ordinary algebra as opposed to a graded algebra).

The structure of this paper is as follows. We begin with a review of the standard coset construction when Poincaré symmetry is spontaneously broken. Next, we outline a new philosophy for the coset construction and comment on the advantages of this novel perspective. As a warm-up we construct the well-known EFT for massive spin-0 point-particles. It turns out that to construct an effective action for a spin $s$ particle, we must impose an $\mathcal{N} = 2s$ super-reparameterization gauge symmetry on the particle wordline. After a brief review of the superspace formalism, we impose this gauged supersymmetry (SUSY) at the level of the coset construction and use it to formulate actions for spin-1/2 particles. We then extend superspace to allow for $\mathcal{N} = 2s$ supercharges and formulate actions for arbitrary-spin particles using the method of cosets. It turns out that for $\mathcal{N} > 1$, the situation becomes complicated and we must supplement the superspace formalism with a multiplet calculus similar to that presented in [13]. To demonstrate that these supersymmetric actions do in fact describe spinning point-particles, we quantize these actions and demonstrate that they have the correct state-spectrum. We find that for massless particles, a new kind of inverse Higgs (IH) constraint, which bears some resemblance to the dynamical IH constraints of [11, 12] is needed to remove Lorentz Goldstones. To further

---

3Notable successful attempts to include fermions are given in [11, 12], but these fermionic degrees of freedom were included by hand as opposed to being generated by the coset itself.
investigate the nature of these novel IH constraints we construct two distinct actions for massless spin-0 particles. Finally, we conclude by commenting on how our new perspective on the coset construction can open up exciting possibilities for future research.

Throughout this paper we use the ‘mostly-plus’ convention for the Minkowski metric, namely $\eta_{\mu\nu} = \text{diag}(-, +, +, +)$.

2 The coset construction: a review

Consider a relativistic quantum field theory with global symmetry group $G$ that is spontaneously broken to the subgroup $H$. We include both internal and spacetime symmetries in $G$ and $H$. Let the symmetry generators be

\begin{align}
\bar{P}_\mu &= \text{unbroken translations,} \\
T_A &= \text{other unbroken generators,} \\
P_{\mu^\prime} &= \text{broken translations,} \\
\tau_\alpha &= \text{other broken generators}
\end{align}

where $\mu$ and $\mu^\prime$ run over complementary subsets of $0, \ldots, D$, and $D + 1$ is the dimension of spacetime. Supposing that $\bar{P}_\mu = 0, \ldots, p$, the above SSB pattern describes a $D_p$-brane running parallel to translations generated by $P_{\bar{\mu}}$. We permit $\tau_\alpha$ and $T_A$ to be some combinations of internal and spacetime generators. Importantly, $\bar{P}_\mu$ need not be the spacetime translation generators, $P_{\bar{\mu}}$, of the Poincaré group. We insist on the existence of unbroken $\bar{P}_\mu$ so that states may be classified by some notion of energy and momentum parallel to the brane. For example, solids spontaneously break spatial translations, but phonons can be classified according to lattice momentum, which is conserved (in the vanishing-Umklapp scattering limit) [10, 14, 15].

Although $\bar{P}_\mu$ and $T_A$ are both unbroken generators, they will play very different roles in the coset construction. As a result, it is helpful to define the subgroup $H_0 \subset H$ that is generated exclusively by $T_A$.

To construct an effective action of only Goldstones, we parameterize the coset of non-linearly realized symmetries by

\begin{equation}
\gamma = e^{ix^\mu \bar{P}_\mu} e^{ix^{\mu^\prime}(x) P_{\mu^\prime}} e^{i\pi^\alpha(x) \tau_\alpha}.
\end{equation}

The coordinates are $x^\mu$ and the Goldstone fields are $X^{\mu^\prime}$ and $\pi^\alpha$, up to normalization. The symmetry transformations act on $\gamma$ by left-multiplication. That is, for constant $U \in G$, we have

\begin{equation}
\gamma \to U \cdot \gamma,
\end{equation}

which can be used to determine the transformation rules for the Goldstones and coordinates [6]. In the world of mathematics, it is a well-known fact that the Maurer-Cartan

---

4Although $\bar{P}_\mu$ are unbroken and hence linearly realized on the fields, they generate shifts (i.e. are non-linearly realized) when acting on the coordinates. As a result, we include these generators in the coset.
form, defined by $\gamma^{-1}d\gamma$, is a Lie algebra-valued one-form. As a result, we may express it as a linear combination of the symmetry generators

$$
\gamma^{-1}\partial\mu\gamma = iE^\mu_\nu \left( \bar{P}_\nu + \nabla_\nu X^\mu P_{\mu'} + \nabla_\nu \pi^\alpha \tau_\alpha + B^A_\nu T_A \right). \quad (2.4)
$$

Under a global symmetry transformation, it can be checked that $E^\mu_\nu$ transforms as a vielbein, $\nabla_\nu \pi^\alpha$ and $\nabla_\nu X^\mu$ transform covariantly, and $B^A_\nu$ transforms as a connection under $H_0$. As a result, we refer to $\nabla_\nu \pi^\alpha (\nabla_\nu X^\mu)$ as the covariant derivative of $\pi^\alpha (X^\mu)$ and to take further covariant derivatives, we may use

$$
\nabla^\mu_\nu \equiv (E^{-1})^\mu_\nu (\partial_\nu + iB^A_\nu). \quad (2.5)
$$

Notice that we have been completely general about the dimension of the symmetry-breaking object; it can be a brane of any dimension. In the simple case of a 0-brane (i.e. a point-particle), we construct our EFT as a one-dimensional field theory on the time coordinate $t \equiv x^0$.

We mentioned earlier that when only internal symmetries are broken, the number of Goldstones exactly matches the number of broken generators. However, when spacetime symmetries are broken, this need not be the case. The removal of extraneous Goldstones can be implemented at the level of the coset construction by way of imposing inverse Higgs (IH) constraints [3–5, 16].

Pragmatically, the rules of the game are as follows: suppose that the commutator between an unbroken translation generator $\bar{P}$ and a broken generator $\tau'$ contains another broken generator $\tau$, that is $[\bar{P}, \tau'] \supset \tau$. Suppose further that $\tau$ and $\tau'$ do not belong to the same irreducible multiplet under $H_0$. Then it turns out that it is consistent with symmetry transformations to set the covariant derivative of the $\tau$-Goldstone in the direction of $\bar{P}$ to zero. This gives a constraint that relates the $\tau'$-Goldstone to derivatives of the $\tau$-Goldstone, allowing the removal of the $\tau'$-Goldstone. The setting of this covariant derivative to zero is known as an inverse Higgs constraint. It turns out that in certain situations, the set of allowed IH constraints is significantly expanded beyond what we have mentioned above [9, 10]. There are two main physical motivations for imposing IH constraints. First, sometimes two Goldstones in the coset will not induce independent fluctuations. Then, we can view IH constraints as convenient gauge-fixing conditions to remove redundant Goldstones. Second, it is often the case that if we do not impose IH constraints, then we find that our EFT has gapped Goldstones. Naturalness arguments often indicate that the gap of such Goldstones is of order the UV cutoff of our EFT. As a result, we must integrate out these gapped degrees of freedom. In such a case, IH constraints correspond to integrating out gapped Goldstones. For further explanations of the origins of IH constraints, consult [6, 16–18] and for more on the coset construction, see [2, 6, 9, 10, 19, 20].

3 Our philosophy

The coset construction derives its name from the broken symmetry coset $G/H$. As explained in the previous section, the coset is parameterized by the Goldstone fields. As a
result, the number of Goldstones that appear in the coset exactly equals the number of spontaneously broken symmetry generators; however, after imposing IH constraints, extraneous Goldstones are removed, meaning that the total number of Goldstones that exist in the EFT may be less than the number of broken generators. This picture is all well and good for a wide range of systems, but we can begin to see issues as soon as we consider the bosonic point particle. In particular, the leading-order effective action is

\[ S = -m \int dt \sqrt{1 - \dot{X}^i \dot{X}^i}, \]  

(3.1)

where \( X^i(t) \) gives the instantaneous position of the particle at time \( t \) and \( m \) is the mass \([6]\). As we will see in the next section, the fields \( X^i(t) \) appear in the coset as Goldstones associated with spontaneously broken spatial translations. If we consider a quantum mechanical particle, however, this is cause for alarm. The energy eigenstates of a free bosonic point particle are labeled by their three-momentum, \(|\vec{p}\rangle\), with corresponding energy \( E_\vec{p} = \sqrt{\vec{p}^2 + m^2} \). Thus the ground state of this system is \(|\vec{0}\rangle\). But notice that such a state spontaneously breaks Lorentz boosts, while preserving spatial rotations and spacetime translations. How is it possible that the field content of our action (3.1) consists of Goldstones corresponding to spatial translations when such translations are not spontaneously broken?

One response is that a classical point-particle has a well-defined position and momentum simultaneously. As a result, the ground state must pick a particular spatial position and hence spontaneously breaks spatial translations. Thus it is natural to suppose that the resulting EFT should have spatial translation Goldstones. But it seems rather odd that in order to describe a quantum particle, we should have to rely so strongly on classical intuition.

It turns out that a similar problem arises when formulating EFTs for finite-temperature systems. For example, the EFT for a fluid consists of Goldstones associated with spacetime translations despite the fact that the equilibrium density matrix spontaneously breaks Lorentz boosts while preserving spatial rotations and spacetime translations (i.e. the same SSB pattern as a quantum point particle). The solution proposed in \([9]\) involves a similar appeal to classical intuition: while the equilibrium density matrix of a fluid may not spontaneously break symmetries, semiclassically the density matrix accounts for a statistical ensemble of highly chaotic micro-states, each of which spontaneously breaks every symmetry, including translations. As a result, the coset should not be parametrized by Goldstones associated with the broken generators alone, but should instead be parameterized by Goldstones as if every symmetry of the theory were broken. We will refer to Goldstones associated with broken symmetries as \textit{broken Goldstones} and those associated with unbroken symmetries as \textit{unbroken Goldstones}. It turns out that broken and unbroken Goldstones behaved rather differently; at the level of the coset this difference manifests as gauge redundancies. In this paper, we will borrow this approach and generalize it. We unfortunately have no first-principles understanding of why the inclusion of unbroken Goldstone fields is necessary for quantum point particles. The intuition employed to justify their existence in the finite-temperature case does not obviously apply to zero-temperature systems of any variety. What is clear, however, is that the inclusion of unbroken Gold-
stones is often necessary. It is our goal to outline the most general rules imaginable for including unbroken Goldstones at the level of the coset construction. Then we will apply this generalized coset construction to formulate actions for relativistic particles with spin.

The approach we take to the cosets is as follows. Let the symmetry generators be given by (2.1), where once again \( \bar{\mu} \) and \( \mu' \) run over complementary subsets of the Lorentz index \( \mu = 0, \ldots, D \), where \( D + 1 \) is the dimension of the spacetime.\(^5\) In general, \( P_\bar{\mu} \) need not be the spacetime translation generators \( P_\mu \); however for all examples considered in this paper they will be. The rules of our new coset construction are the following.

- Instead of constructing the effective action on the spacetime coordinates \( x^\bar{\mu} \), introduce worldvolume (or worldline / worldsheet depending on dimension) coordinates \( \sigma^M \). To keep things completely general, we will allow \( \sigma^M \) to include both bosonic (Grassmann even) and fermionic (Grassmann odd) coordinates. We let \( M = 0, \ldots, p \) for \( p \leq D \) represent bosonic coordinates and \( M = p + 1, \ldots, N + p \) be fermionic coordinates. Importantly, the dimension of the worldvolume need not be the same as that of the physical spacetime. As such the worldvolume coordinates can be thought of as defining a \( D_p \)-brane. In particular, we will construct spinning point-particle actions on manifolds with \( p = 0 \) and \( N = 2s \), where \( s \) is the spin of the particle. Notice that a (classical) \( D_p \)-brane cannot have more than \( p + 1 \) unbroken spacetime translations. As a result, the unbroken translation index runs over \( \bar{\mu} = 0, \ldots, d \leq p \).

- Parameterize the coset with Goldstones associated with every symmetry generator

\[
g(\sigma) = e^{iX^{\bar{\mu}}(\sigma)P_\bar{\mu}} e^{iX^{\mu'}(\sigma)P_{\mu'}} e^{i\alpha(\sigma)\tau_{\alpha}} e^{ib_A(\sigma)T_A}.
\] (3.2)

Notice that at this point, broken and unbroken Goldstones appear on equal footing. Global symmetries act via left-multiplication, so for constant \( U \in \mathcal{G} \), we have \( g \rightarrow U \cdot g \).

- If spacetime translations parallel to the \( D_p \)-brane are unbroken, we may impose some sort of worldvolume-reparameterization symmetry — this could include super-reparameterization — as needed

\[
\sigma^M \rightarrow \sigma^M + \alpha^M(\sigma).
\] (3.3)

This symmetry can be total reparameterization or partial reparameterization. There is a great deal of freedom here. In many of the examples to come, it will be convenient to introduce a worldvolume vielbein as a gauge-field that transforms under these diffeomorphisms. If the translations parallel to the \( D_p \)-brane are broken, (e.g. by a lattice) we may impose a rigid linear symmetry of the coordinates

\[
\sigma^M \rightarrow L^M_N \sigma^N + \alpha^M, \quad L^M_N, \alpha^M = \text{const}.
\] (3.4)

Such rigid symmetries arise in solids and certain phases of liquid crystals [10], though we will consider no such examples in this paper.

\(^5\)E.g. we may have \( \bar{\mu} = 0 \) and \( \mu' = 1, \ldots, D \), but we may not have \( \bar{\mu} = 0, 1 \) and \( \mu' = 1, \ldots, D \).
To distinguish unbroken Goldstones associated with $T_A$ from broken Goldstones associated with $\tau_\alpha$, impose gauge symmetries associated with $T_A$ of the form
\[ g(\sigma) \rightarrow g(\sigma) \cdot e^{i\lambda^A(\sigma)T_A}. \] (3.5)

Just like with the reparameterization invariance, there is a great deal of freedom here. We could allow $\lambda^A(\sigma)$ to be a generic function of $\sigma$, in which case the Goldstones associated with $T_\alpha$ can be gauge-fixed to zero. Alternatively, we can put constraints on the allowed form of $\lambda^\alpha(\sigma)$. Thus, the extent of these gauge symmetries are not strictly determined by the symmetry-breaking pattern. For the broken generators $\tau_\alpha$ we may (though are not required to) impose rigid transformations of the form
\[ g(\sigma) \rightarrow g(\sigma) \cdot e^{i\kappa^\alpha \tau_\alpha}, \quad \kappa^\alpha = \text{const}. \] (3.6)

Such rigid symmetries arise, for example, in superfluids that spontaneously break spatial rotations [15]. Finally, notice that all gauge symmetries act via right-multiplication on $g$ and the physical symmetries act via left-multiplication. As a result the gauge symmetries must commute with the physical symmetries.

The EFT is constructed using invariant building-blocks generated by the Maurer-Cartan form
\[ g^{-1}dg. \] (3.7)

All terms generated by the Maurer-Cartan form that are manifestly invariant under the coordinate reparameterization and gauge symmetries can be used as building-blocks of the EFT.

Inverse Higgs constraints can be imposed whenever there is a set of covariant terms (i.e. they transform linearly under global, reparameterization, and gauge symmetries) that when set to zero, enables the removal of one set of Goldstones from all invariant building-blocks. This includes the rather unusual dynamical IH constraints presented in [11, 12] that enable the removal of certain Goldstones at the price of introducing non-trivial operator-constraints on the remaining fields. We will find that similarly unusual IH constraints can be imposed when considering massless particles.

We allow for a great deal of freedom in this coset construction. The reason for doing so is that we are treating the coset as a pragmatic tool to construct symmetry-invariant actions that satisfy Goldstone’s theorem. In particular, since there are no local gauge symmetries associated with any of the broken generators, Goldstone’s theorem will be satisfied. The terms of the Maurer-Cartan form that arise from this coset construction are automatically invariant under all internal symmetries. Finally, to recover the usual coset construction in which only broken Goldstones appear, one need only choose $\sigma^M$ to be purely bosonic and allow $\sigma^M$ in (3.3) and $\lambda^A$ in (3.5) to be completely general functions of $\sigma$. In this way, we may gauge-fix $\sigma^M = \delta^M_\mu X^\mu$ and $b^A = 0$. 

---

-7-
4 Massive spin-0 point-particles

We will construct the effective action for the spin-0 point-particle in two different ways. First, we employ the usual coset construction techniques to formulate a classical action, reminiscent of the Nambu-Goto action. Next, we use our new philosophy of cosets to formulate a point-particle action in the style of the Polyakov action that can easily be quantized. We let $P_\mu$ generate spacetime translations and $J_{\mu\nu}$ generate Lorentz boosts, which satisfy the usual Poincaré algebra

$$\begin{align*}
i[J_{\mu\nu}, J_{\rho\sigma}] &= \eta_{\nu\rho} J_{\mu\sigma} - \eta_{\nu\mu} J_{\rho\sigma} - \eta_{\sigma\mu} J_{\rho\nu} + \eta_{\sigma\nu} J_{\rho\mu}, \\
i[P_\mu, J_{\rho\sigma}] &= \eta_{\mu\rho} P_\sigma - \eta_{\mu\sigma} P_\rho, \\
i[P_\mu, P_\nu] &= 0.
\end{align*}$$

We will often find it convenient to use the basis of Lorentz generators

$$K_i = J_{0i}, \quad J_i = \frac{1}{2} \epsilon^{ijk} J_{jk}. \quad (4.2)$$

4.1 À la Nambu-Goto

Consider a classical scalar point-particle sitting at rest. The SSB pattern is rather straightforward: Lorentz boosts $K_i$ and spatial translations $P_i$ are spontaneously broken, while spatial rotations $J_i$ and temporal translations $P_0$ are unbroken. As pointed out in the previous section, the fact that $P_i$ are spontaneously broken is a feature of the classical point-particle only; the ground-state of the quantum point-particle breaks boosts alone.

We begin with the coset of non-linearly realized symmetries

$$g(t) = e^{itP_0} e^{iX^i(t) P_i} e^{i\eta^i(t) K_i}. \quad (4.3)$$

The Maurer-Cartan form is then

$$g^{-1}\partial_t g = iE(P_0 + \nabla X^i P_i + \nabla \eta^i K_i + \Omega^i J_i), \quad (4.4)$$

where the einbein $E$, covariant derivatives $\nabla X^i$ and $\nabla \eta^i$, and spin connection $\Omega^i$ are given by

$$\begin{align*}
E &= \Lambda^0_0 + \dot{X}^i \Lambda^i_0, \\
\nabla X^i &= E^{-1}(\Lambda^i_0 + \dot{X}^j \Lambda^i_j), \\
\nabla \eta^i &= E^{-1}(\Lambda^{-1} \partial_t \Lambda)^0_0, \\
\Omega^i &= \frac{E^{-1}}{2} \epsilon^{ijk} (\Lambda^{-1} \partial_t \Lambda)^j k, \quad (4.5)
\end{align*}$$

where $\Lambda^\mu_\nu \equiv (e^{i\eta^i(t) K_i})^\mu_\nu$ and $\dot{X}^i \equiv \partial_t X^i$. We can now impose the IH constraints $\nabla X^i = 0$, which can be solved to give

$$\frac{\eta^i}{\eta} \tanh \eta = \dot{X}^i, \quad (4.6)$$

- 8 -
where $\eta \equiv \sqrt{\vec{\eta}^2}$. These IH constraints imply that $\nabla \eta^i$ and $\Omega^i$ are sub-leading in the derivative expansion, so the only building-block at leading order is $E$, which becomes $E = \sqrt{1 - \dot{X}^i \dot{X}^i}$. Hence the action is

$$S = -m \int dt \sqrt{1 - \dot{X}^i \dot{X}^i}, \quad (4.7)$$

where $m$ is a phenomenological constant that we interpret as the mass. We can see, therefore, that $X^i$ are the only Goldstones that survive the IH constraints.

Finally, it is worth pointing out that the above action can be thought of as a gauge-fixed version of a manifestly-covariant action. Let $\tau$ be the coordinate of the particle’s worldline and let $X^\mu(\tau)$ be the fields. Then we can define the action

$$S = -m \int d\tau \sqrt{-\dot{X}^\mu \dot{X}_\mu}, \quad (4.8)$$

where $\dot{X}^\mu \equiv \partial_\tau X^\mu$. Notice that this action is invariant under reparameterization of the coordinate $\tau \rightarrow \tau'(\tau)$. Thus, we can gauge-fix $\tau = X^0(\tau) \equiv t$, recovering our initial action (4.7).

### 4.2 À la Polyakov

We now throw off the shackles of the ordinary coset construction and proceed with our new philosophy. Begin by parameterizing the full symmetry group

$$g(\tau) = e^{iX^\mu(\tau)P_\mu} e^{i\eta^i(\tau)K_i} e^{i\vartheta^i(\tau)J_i}, \quad (4.9)$$

where $\tau$ is the particle’s worldline coordinate. With our new philosophy, since $P_0$ is unbroken, we have free reign to impose any kind of diffeomorphism (i.e. reparameterization) symmetry on the coordinate $\tau$, and since $J_i$ are unbroken we may impose any gauge symmetries of the form $g \rightarrow g \cdot e^{i\lambda^i(\tau)J_i}$. Evidently, there are many possibilities. On the one hand, the excess of possibilities is a draw-back: one of the most appealing features of the coset construction is that it is so constraining that one need barely think in order to use it effectively. On the other hand, Goldstone’s theorem for spontaneously broken space-time symmetries (unlike its internal symmetry counterpart) can be satisfied in all sorts of unusual and unexpected ways. We should therefore not be disappointed that our novel approach to the coset construction now reflects this diversity of possibilities more fully.

With some foreknowledge of the desired point-particle action, we impose the following gauge symmetries.

- **Reparameterization invariance:** let $e(\tau)$ be the einbein of the particle’s worldline. Then we have

$$\delta \tau = -\xi(\tau), \quad \delta e = \partial_\tau (e \xi),$$

where $\xi$ is an arbitrary infinitesimal function of $\tau$.

- **We do not want any rotational Goldstones $\vartheta^i$ in the EFT, so we impose total rotational gauge symmetry**

$$g \rightarrow g \cdot e^{i\lambda^i(\tau)J_i},$$

where $\lambda^i$ is an arbitrary function of $\tau$. We can use this gauge symmetry to fix $\vartheta^i = 0$. 

- 9 –
With this gauge-fixing condition, our group-element is now
\[ g(\tau) = e^{iX^\mu(\tau)P_\mu e^{i\eta^i(\tau)K_i}}. \] (4.12)

We may compute the Maurer-Cartan form, using \( e \) as the einbein,
\[ g^{-1}\partial_\tau g = ie(\nabla X^\mu P_\mu + \nabla \eta^i K_i + \Omega^i J_i), \] (4.13)
where the covariant derivatives and spin connections are given by
\[ \nabla X^\mu = e^{-1}\tilde{X}^\nu \Lambda_\nu^\mu, \]
\[ \nabla \eta^i = e^{-1}(\Lambda^{-1} \partial_\tau \Lambda)^{ih}, \]
\[ \Omega^i = \frac{1}{2e}e^{ijk}(\Lambda^{-1} \partial_\tau \Lambda)^{jk}, \] (4.14)
such that \( \Lambda_{\mu\nu} \equiv (e^{i\eta^i(\tau)K_i})^{\mu}_{\nu} \) and \( \tilde{X}^\mu \equiv \partial_\tau X^\mu \).

We can impose the IH constraints \( \nabla X^i = 0 \), which can be solved to give
\[ \frac{\eta^i}{\eta} \tanh \eta = \frac{\dot{X}^i}{X^0}. \] (4.15)

These IH constraints ensure that \( \nabla \eta^i \) and \( \Omega^i \) do not contribute to the leading order. Thus, the only leading-order building block is \( \nabla X^0 \), which now becomes
\[ \nabla X^0 = e^{-1}\sqrt{-\dot{X}^\mu \dot{X}_\mu}. \] (4.16)

Thus, our leading-order action is
\[ S = \int d\tau e \left( (\nabla X^0)^2 + m^2 \right) \]
\[ = -\int d\tau \left( \frac{1}{e} \dot{X}^\mu \dot{X}_\mu - cm^2 \right), \] (4.17)
where \( m \) is the mass. We have used the fact that \( \int d\tau e \) is the invariant integration measure.

We have thus recovered the standard effective action for a spin-0 point-particle. Since such an action has an external einbein, it is clear that the ordinary coset construction would not generate it. We therefore see a clear (albeit small) benefit of our new coset construction philosophy. In the following sections, we will see more significant advantages.

5 Worldline SUSY

In order to construct an effective action for spin-1/2 particles, we will need to endow the particle’s worldline with local SUSY. In this section, we review the basics of both global and local SUSY in one dimension. For an in-depth discussion of \( \mathcal{N} = 1 \) SUSY, consult [21].

We begin by considering global worldline SUSY. There are many possible starting-points for a discussion of SUSY, but for our purposes, it is most convenient to work in superspace. Superspace is essentially a mathematical trick to make SUSY manifest. Suppose that our coordinates are \( \sigma^M = (\tau, \theta)^M \), where \( \tau \) is a standard, bosonic (i.e. commuting,
or Grassmann even) coordinate and $\theta$ is a fermionic (i.e. anti-commuting, or Grassmann odd) coordinate. In other words, $\theta^2 = 0$. It is sometimes convenient to use the notation $\sigma^0 = \tau$ and $\sigma^1 = \theta$. Suppose we have a field defined on these coordinates, $X(\tau, \theta)$. Then, because $\theta^2 = 0$, Taylor expanding to linear order in $\theta$ gives an exact result,

$$X(\tau, \theta) = X(\tau) + i\theta\psi(\tau), \quad (5.1)$$

where $X$ is a real-valued field and $\psi$ is a Grassman-odd field. Thus, $X$ is a Grassmann-even field.

We define integration and differentiation with respect to $\theta$ as equivalent operations, given by

$$\int d\theta X = \partial_\theta X = i\psi. \quad (5.2)$$

The global SUSY and worldline translation transformations act on the coordinates by

$$(\tau, \theta) \rightarrow (\tau', \theta') = (\tau - \xi - i\theta \varepsilon, \theta - \varepsilon), \quad (5.3)$$

where $\xi$ is a constant real number and $\varepsilon$ is a Grassmann-odd constant. It is straightforward to check that there are two linear combinations of the partial derivatives $\partial_\tau$ and $\partial_\theta$ that do not transform under SUSY, namely

$$D_0 \equiv \partial_\tau, \quad D_1 \equiv \partial_\theta + i\theta\partial_\tau. \quad (5.4)$$

Additionally, it can be checked that $D_1^2 = D_0$. Often $D_1$ is referred to as the covariant derivative (not to be confused with the covariant derivatives in the coset construction).

We now define the (flat) SUSY zweibein $E^A_M$ for $A, M = 1, 2$ as the $2 \times 2$ matrix

$$E^A_M = \begin{pmatrix} 1 & 0 \\ -i\theta & 1 \end{pmatrix}, \quad (5.5)$$

With this definition, we can succinctly express both SUSY derivatives as the components of $D_A \equiv E^A_M \partial_M$, where $\partial_M \equiv (\partial_\tau, \partial_\theta)_M$ and $E^A_M$ is the inverse of $E^A_M$. We now promote SUSY to the full reparameterization invariance of the superspace, namely

$$\sigma^M \rightarrow \sigma^M - \alpha^M(\sigma), \quad (5.6)$$

where $\alpha^M$ is a generic infinitesimal function of $\sigma$. Now the superzweibein becomes dynamical and transforms under this symmetry by

$$\delta E^A_M = \partial_M \alpha^N E^A_N + \alpha^N \partial_N E^A_M. \quad (5.7)$$

The scalar field $X(\sigma)$ transforms by

$$\delta X = \alpha^M \partial_M X. \quad (5.8)$$

Now the covariant derivative is defined by $D_A \equiv E^A_M \partial_M$. With this definition, $D_A X$ transforms as a scalar under (5.6).
But now that we have introduced a dynamical superzweibein, we have an additional
gauge symmetry, namely local transformations of the tangent space. In particular, we have the symmetries
\[ \delta E^0_M = 0, \quad \delta E^1_M = E^0_M \psi, \]
(5.9)
where \( \psi \) is an infinitesimal Grassmann-odd function of \( \sigma \). We would like to reduce the
number of gauge symmetries to simplify matters. We choose a gauge-fixing condition
that may appear somewhat strange, but is useful in the sense that the residual gauge
symmetries are the standard gauged SUSY transformations. In particular, we postulate
that the superzweibein take the form
\[
E^A_M = \begin{pmatrix} E + i \theta \chi & \chi \\ -i \theta & 1 \end{pmatrix}^A_M, \quad E(\tau, \theta) \equiv e(\tau) + i \theta \chi(\tau),
\]
(5.10)
and thus the inverse superzweibein is
\[
E^M_A = \frac{1}{E} \left( \begin{array}{cc} 1 & -\chi \\ i\theta & e \end{array} \right)^M_A,
\]
(5.11)
where \( e(\tau) \) is a real-valued field and \( \chi(\tau) \) is a Grassmann-odd field. We also require that
the residual super-reparameterization symmetry have a restricted \( \alpha^M \), namely
\[
\alpha^M(\sigma) = \left( \xi(\tau) + \frac{i}{e} \theta \varepsilon(\tau), \varepsilon(\tau) - \frac{i}{e} \theta \varepsilon(\tau) \chi \right)^M,
\]
(5.12)
where \( \xi \) is a real-valued infinitesimal function of \( \tau \) and \( \varepsilon \) is a Grassmann-odd infinitesimal
function of \( \tau \). This restricted form of \( \alpha^M \) allows the inverse superzweibein to remain in
the desired form (5.11) if we endow \( e(\tau) \) and \( \chi(\tau) \) with the transformation properties
\[
\delta e = \partial_\tau (\xi e) + 2i \varepsilon \chi, \quad \delta \chi = \partial_\tau (\xi \chi) + \varepsilon.
\]
(5.13)
We can therefore identify \( e \) as the worldline einbein and \( \chi \) as its superpartner, i.e. the
gravitino. In this gauge, the covariant derivatives are
\[
D_0 = \frac{1}{E} (\partial_\tau - \chi \partial_\theta), \quad D_1 = \frac{1}{E} (i \theta \partial_\tau + e \partial_\theta),
\]
(5.14)
and the invariant integration measure is
\[
\int d^2 \sigma \ sdet(E^A_M) = \int d\tau d\theta \ E,
\]
(5.15)
where sdet is the superdeterminant defined as follows. Let \( A, D \) be Grassman-even and
\( B, C \) be Grassmann-odd matrices. Then define
\[
sdet \begin{pmatrix} A & B \\ C & D \end{pmatrix} = \det(A) \det(D - C \cdot A^{-1} \cdot B)^{-1}.
\]
(5.16)
It is straightforward to check that \( sdet(E^A_M) = E \).
6 Spin-1/2 point-particles

It was demonstrated in [13, 22–27] that the effective action describing a spin-1/2 particle could be derived by imposing $\mathcal{N} = 1$ worldline supersymmetry. In this section we will impose this gauge symmetry at the level of the coset construction. It turns out that including a mass term requires a little extra machinery, so we begin by considering the massless case.

6.1 Massless

A massless, spinning particle must always travel at the speed of light with the direction of the spin parallel (or antiparallel) to the velocity. Without loss of generality, let us choose the direction of motion to be parallel to $\hat{z}$. Then, the unbroken Poincaré symmetry generators are

$$P_u \equiv P_0 - P_3, \quad J_i \equiv J_i + \epsilon^{3ij} K_j,$$

(6.1)

and the broken generators are

$$P_v = P_0 + P_3, \quad P_m, \quad K_i \equiv K_i + \epsilon^{3ij} J_j,$$

(6.2)

where the indices $m, n = 1, 2$. Notice that $J_i$ are the generators of the (full) little group of massless particles; it is easy to check that their commutation relations are just like those of the generators for the two-dimensional Euclidean group. Additionally, in this basis of translation generators, the non-zero components of the metric are $\eta_{uv} = \eta_{va} = 1/2$ and $\eta_{mn} = \delta_{mn}$. Lastly, we assume that there are no internal symmetries, so Poincaré is the full symmetry group.

It is well-known that spin-1/2 particles enjoy worldline SUSY, so we define our coset on the superspace coordinates $\sigma^M = (\tau, \theta^M)$. The most general group element is

$$g(\sigma) = e^{iX^\alpha(\sigma) P_\alpha + iX^m(\sigma) P_m + i\epsilon^n J_i K_i + i\epsilon^3 J_i J_i},$$

(6.3)

where $\alpha, \beta$ run over $u, v$. We now impose the following gauge symmetries. First, since $P_u$ is unbroken, we have the freedom to impose super-reparameterization symmetry given by (5.12) and (5.13). And since $J_i$ are unbroken, we may impose the rotational gauge symmetry

$$g \to g \cdot e^{iX^i(\sigma) J_i},$$

(6.4)

where $X^i$ is a generic function of $\sigma$. We may therefore gauge-fix $\theta^i = 0$.

With this gauge-fixing condition, the Maurer-Cartan form is

$$g^{-1} \partial_M g = iE^A_M (\nabla_A X^\alpha P_\alpha + \nabla_A X^m P_m + \nabla_A \epsilon^1 K_i + \Omega^i_A J_i),$$

(6.5)

where the covariant derivatives of $X^\mu$ are

$$\nabla_A X^\alpha = E^M_A \partial_M X^\mu A_\mu^\alpha,$$

$$\nabla_A X^m = E^M_A \partial_M X^\mu A_\mu^m,$$

(6.6)
such that $\mathcal{A}_\mu = (e^{i\nu^i(\sigma)\Omega_i})^\mu$. The precise forms of $\nabla_{\mathcal{A}} \eta^i$ and $\Omega^i_{\mathcal{A}}$ will not be important for the construction of the leading-order action.

We may now impose IH constraints. In particular, it is consistent with symmetries to fix

$$0 = \nabla^0 X^\nu, \quad 0 = \nabla^0 X^m. \quad (6.7)$$

These IH constraints can be used to solve for $\eta^i$ in terms of $X^\mu$, thereby leaving $X^\mu$ as the only remaining Goldstone. However, these constraints also force $\nabla^0 X^\mu$ to be null, which we do not wish to impose by hand. Instead, the fact that the particle moves along a null-trajectory should be a result of the equation of motion. The reason these IH constraints are over-constraining is that if we were to include $\eta^i$ in our effective action, they would serve as Lagrange multipliers. In particular, the constraints they would place on the dynamics of $X^\mu$ would be redundant with the constraints imposed by $\epsilon$ and $\chi$. Thus, we could just as well not include $\eta^i$ in our EFT at all as they would be entirely redundant. We will investigate this further in the following subsection.

We now can construct the leading-order effective action

$$S = \frac{1}{2i} \int d\tau d\theta E \nabla_0 X^\mu \nabla_1 X_\mu, \quad (6.8)$$

which can be immediately simplified to

$$S = \frac{1}{2i} \int d\tau d\theta E D_0 X^\mu D_1 X_\mu. \quad (6.9)$$

We can explicitly perform the $d\theta$ integral, which yields an action defined only on the particle worldline $\tau$. Letting $X^\mu(\tau, \theta) = X^\mu(\tau) + i\theta \psi^\mu(\tau)$, we have

$$S = \int d\tau \left( \frac{1}{2e} \dot{X}^\mu \dot{X}_\mu + \frac{i}{2} \dot{\psi}^\mu \psi_\mu - \frac{i}{e} \chi \psi^\mu \dot{X}_\mu \right). \quad (6.10)$$

Upon quantization, we will see that this action describes a spin-1/2 point-particle.

### 6.2 On-shell inverse Higgs

We now investigate the nature of the on-shell IH constraint for the case of the massless spin-1/2 particle. To do so, we construct the leading-order action without removing the Lorentz Goldstones $\eta^i$. Using the covariant derivatives of (6.6), we may construct our leading-order action. We have

$$S = \frac{1}{2i} \int d\tau d\theta E \left( \nabla_0 X^\mu \nabla_1 X_\mu + C \nabla_1 X^\mu \right), \quad (6.11)$$

for some constant $C$. Expanding the covariant derivatives, we have $\nabla_1 X^\mu = D_1 X^\mu \Delta_\mu$. At this point, it is convenient to define the superfield $L^\mu \equiv C \Delta_\mu$, which can then be expanded as

$$L^\mu = L_\mu + i \theta \lambda_\mu. \quad (6.12)$$

---

7We choose to normalize the fields so that the overall coefficient in front of the action is $1/2i$. 

---
Notice that \( L_\mu \) is constrained to be a null-vector, meaning that \( L^2 = 0 \) and \( L_\mu \lambda^\mu = 0 \). Performing the \( d\theta \) integral, our action becomes

\[
S = \int d\tau \left( \frac{1}{2e} (\dot{X}^\mu - i\chi \psi^\mu)^2 + \frac{i}{2} \dot{\psi}^\mu \psi_\mu + \frac{1}{2} \dot{X}^\mu L_\mu + \frac{ie}{2} \psi^\mu \lambda_\mu \right). \tag{6.13}
\]

Now let us compute the equations of motion. By varying \( e \) and \( \chi \) we find the respective equations

\[
e^{-2}(\dot{X}^\mu - i\chi \psi^\mu)^2 = \psi^\mu \lambda_\mu, \quad \psi^\mu \dot{X}_\mu = 0. \tag{6.14}
\]

And by varying \( L_\mu \) and \( \lambda_\mu \) subject to the constraints \( L^2 = 0 \) and \( L_\mu \lambda^\mu = 0 \), we have

\[
\dot{X}^\mu \propto L_\mu, \quad \psi^\mu \propto L^\mu. \tag{6.15}
\]

Notice that the second equation of (6.15) implies that \( \psi^\mu \lambda_\mu = 0 \). Plugging this expression into the first equation of (6.14) gives \((\dot{X} - i\chi \psi)^2 = 0\), which is exactly the constraint obtained by varying \( e \) in the action (6.10). Additionally, the second equation of (6.14) is the same constraint found by varying \( \chi \) in (6.10). We thus have reproduced the constraint equations arising from the standard action (6.10) that does not contain any Lorentz Goldstones. Then, we can interpret (6.15) as equations that specify the Lorentz Goldstones \( L_\mu \).

We therefore conclude that the inclusion of the Lorentz Goldstones does not give us anything new, so they are entirely extraneous degrees of freedom and can simply be omitted from the EFT.

### 6.3 Massive

Notice that in the scalar action (4.17), the term involving the mass is essentially a cosmological constant-term. In the spin-1/2 action (6.10), however, there is no such mass term. The reason is that in a theory with SUSY, an ordinary cosmological constant-term of the form \( \int d\tau e \) does not respect the full gauge symmetry group. In this section, we will see how a symmetry-invariant cosmological constant-term can be included in the action.

The intuition is as follows. Suppose that the point-particle existed in a five-dimensional spacetime such that the momentum along the fifth dimension is fixed by \( p^5 = m \), for some constant \( m > 0 \). Since the particle is massless, the on-shell condition is \( p_\mu p^\mu + (p^5)^2 = 0 \), or equivalently, \( p_\mu p^\mu + m^2 = 0 \). Thus, if we are only concerned with the motion of the particle along the four spacetime coordinates \( x^\mu \) for \( \mu = 0, 1, 2, 3 \), then the particle behaves as if it has mass \( m \).

Going through a procedure almost identical to that of the previous subsection, we find the effective action for a massless spin-1/2 particle in 5D is

\[
S = \int d\tau \left( \frac{1}{2e} \dot{X}^\mu \dot{X}_\mu + \frac{i}{2} \dot{\psi}^\mu \psi_\mu - \frac{i}{e} \chi \psi^\mu \dot{X}_\mu + \frac{1}{2e} \dot{X}^5 X_5 + \frac{i}{2} \dot{\psi}^5 \psi_5 - \frac{i}{e} \chi \psi^5 \dot{X}_5 \right), \tag{6.16}
\]

where we have defined \( X^5(\tau, \theta) = X^5(\tau) + i\theta \psi^5(\tau) \). At this point, it is helpful to work in the “Hamiltonian picture” in which we include the conjugate momentum \( p^5 \) of \( X^5 \). We thus have

\[
S = \int d\tau \left( \frac{1}{2e} \dot{X}^\mu \dot{X}_\mu + \frac{i}{2} \dot{\psi}^\mu \psi_\mu - \frac{i}{e} \chi \psi^\mu \dot{X}_\mu + \dot{X}^5 p_5 - \frac{e}{2} (p^5)^2 + \frac{i}{2} \dot{\psi}^5 \psi_5 - i\chi \psi^5 p_5 \right). \tag{6.17}
\]
Fixing $p^5 = m$ for constant $m > 0$ we have\footnote{Notice that we are not integrating out $p^5$; instead, we are constraining the system to have $p^5 = m$.} \[ S = \int d\tau \left( \frac{1}{2e} \dot{X}^\mu \dot{X}_\mu + \frac{i}{2} \bar{\psi}^\mu \gamma^\mu \psi - \frac{i}{e} \bar{\chi} \gamma^5 \psi - \frac{m^2 e}{2} + \frac{i}{2} \bar{\psi}^5 \psi^5 - \frac{im}{2} \bar{\chi} \gamma^5 \psi \right), \] (6.18)

which agrees with the massive spin-1/2 action from [13]. In particular, notice that the equation of motion for $e$ is (gauge fixing $\chi = 0$) \[ \frac{1}{e^2} \dot{X}^\mu \dot{X}_\mu + m^2 = 0, \] (6.19)

which is exactly the on-shell condition for a massive particle.

### 6.4 Coupling to gauge fields

Oftentimes relativistic particles carry electric charge and their intrinsic quantum spin gives rise to a magnetic moment. In this subsection we will see how to couple the spin-1/2 point particles to the electromagnetic $U(1)$ gauge field. Coupling to more complicated gauge fields requires a fairly straightforward generalization.

Suppose that $\mathcal{A}_\mu(x)$ is the electromagnetic gauge field in the bulk with gauge symmetry $\mathcal{A}_\mu(x) \to \mathcal{A}_\mu(x) + \partial_\mu \alpha(x)$. (6.20)

If we wish to couple it to the point particle, we must perform a pull-back to the particle’s super-worldvolume by

\[ \mathcal{A}_M(\sigma) = \frac{\partial X^\mu(\sigma)}{\partial \sigma^M} \mathcal{A}_\mu(X(\sigma)), \] (6.21)

where $\mathcal{A}_\mu(X(\sigma)) = \mathcal{A}_\mu(X(\tau)) + i \bar{\psi}^\nu(\tau) \partial_\nu \mathcal{A}_\mu(X(\tau))$. Let $Q$ be the generator of the gauged $U(1)$ symmetry and let $g(\sigma)$ be the group element parameterized by the Goldstone fields. For present purposes, we will keep $g(\sigma)$ quite general. The only assumption we will make is that the worldvolume coordinates are $\sigma^M = (\tau, \theta)^M$, endowed with $\mathcal{N} = 1$ local SUSY. Note that since $Q$ is a symmetry of the theory, it can appear in the group element with its own Goldstone

\[ g(\sigma) = \ldots e^{i\bar{\psi}(\sigma)Q} \ldots. \] (6.22)

If $Q$ is unbroken, then $g$ may enjoy a right-acting gauge symmetry

\[ g(\sigma) \to g(\sigma) \cdot e^{\delta(\sigma)Q}, \] (6.23)

not to be confused with the gauge symmetry (6.20).

The correct way to include the gauge field in Maurer-Cartan form is [6]

\[ g^{-1}(\partial_M + i \mathcal{A}_M(\sigma)Q)g = iE_M^A(\cdots + B_A(\sigma)Q + \cdots), \] (6.24)

where $B_A(\sigma) = E_A^M \mathcal{A}_M(\sigma) + D_A(\sigma)$. Then the leading-order coupling with the point-particle is

\[ \frac{q}{i} \int d\tau d\theta E B_1(\sigma) = q \int d\tau \left( \dot{X}^\mu \mathcal{A}_\mu + \frac{ie}{2} \bar{\psi}^\mu \gamma^\mu \dot{\mathcal{F}}^\mu \right), \] (6.25)
where \( q \) is the electric charge of the particle and \( \mathcal{F}_{\mu \nu} = \partial_\mu \mathcal{A}_\nu - \partial_\nu \mathcal{A}_\mu \) is the electromagnetic field strength tensor. This coupling term agrees with the results of [13]. Notice that the Goldstone \( \pi \) is totally absent from this coupling. Further, notice that the first term on the r.h.s. of (6.25) is the standard electric coupling via the pull-back of the gauge field \( \mathcal{A}_\mu \), while the second term describes the magnetic-spin coupling.

7 Extended worldline SUSY

To construct an effective action for a particle of arbitrary spin \( s \in \mathbb{Z}/2 \), we will need to endow the particle’s worldline with a local extended \( \mathcal{N} = 2s \) SUSY. In this section, we will extend the superspace formalism of section 5 to allow for multiple supercharges. To our knowledge no such superspace formalism exists in the current literature; however many common elements can be found in [24]. It will turn out that for \( \mathcal{N} > 2 \), the superspace formalism will have to be supplemented by a multiplet calculus, which is a straight-forward extension of the one presented in [13].

7.1 Superspace revisited

As before, let us begin by considering global SUSY. We define the coordinates of superspace by

\[
\sigma^M = (\tau, \theta^1, \ldots, \theta^N)^M,
\]

where \( \sigma^0 \equiv \tau \in \mathbb{R} \) and \( \sigma^a \equiv \theta^a \) for \( a = 1, \ldots, N \) are Grassmann odd. Suppose we have a field defined on these coordinates, \( X(\tau, \vec{\theta}) \). Because \( \theta^a \theta^b = -\theta^b \theta^a \), the Taylor expansion in \( \theta^a \) will terminate after \( N + 1 \)-terms. It turns out, however, that only the first two terms are dynamical. We have

\[
X(\tau, \vec{\theta}) = X + i\vec{\theta} \cdot \vec{\psi} + \cdots,
\]

where \( X(\tau) \) is a real-valued field and \( \vec{\psi}(\tau) \) is a vector of Grassmann odd fields; thus \( X \) is Grassmann-even. The terms subsumed by \( \cdots \) in the above equation end up being non-dynamical fields whose only purpose is to allow SUSY to close off-shell.

We define integration and differentiation with respect to the Grassmann coordinates as equivalent operations, given by

\[
\int d\theta^a X = \partial_a X = i\psi^a,
\]

where \( \partial_a \equiv \partial/\partial \theta^a \).

Now we promote the global SUSY transformation to a local, gauge symmetry. Instead of introducing full superspace reparameterization invariance as we did in section 5, we will cut to the chase. We postulate that the supervielbein takes the block-matrix form

\[
E^A_M = \begin{pmatrix}
E + i\vec{\theta} \cdot \Gamma^b \\
-i\theta^a \\
egamma^b \delta_{ab}
\end{pmatrix}^A_M,
\]

where \( \Gamma^b \) are the gamma matrices.
where $E = e + i \bar{\theta} \cdot \bar{\chi}$ and $\Gamma^a = \chi^a + A^{ab} \theta^b$. Here, $e$, $\chi^a$ and $A^{ab}$ are fields defined on the coordinate $\tau$. Then the inverse supervielbein is

$$E^M_A = \frac{1}{E} \left( 1 - \frac{\Gamma^b}{E} \right) M^A. \quad (7.5)$$

In order for the supervielbein to retain the desired form, we take our reparameterization symmetries to be a restricted subset of coordinate transformations given by $\sigma^M \rightarrow \sigma^M - \alpha^M(\sigma)$, such that

$$\alpha^0(\sigma) = \xi(\tau) + i \bar{\theta} \cdot \bar{\epsilon}(\tau), \quad \alpha^a(\sigma) = \epsilon^a(\tau) - i \bar{\theta} \cdot \bar{\epsilon}(\tau) \Gamma^a + \theta^b \beta^{ab}(\tau), \quad (7.6)$$

where $\xi(\tau)$ and $\beta^{ab}(\tau) = -\beta^{ba}(\tau)$ are infinitesimal and real-valued, while $\epsilon^a(\tau)$ are infinitesimal and Grassmann-odd. Under this coordinate transformation, the component fields of the supervielbein transform as

$$\delta e = \partial_\tau (\xi e) + 2i \bar{\epsilon} \cdot \bar{\chi}, \quad \delta \chi^a = \partial_\tau (\xi \chi^a) + \epsilon^a A^{ab} \bar{\epsilon}^b - \beta^{ab} \chi^b, \quad \delta A^{ab} = \partial_\tau (\xi A^{ab}) + \dot{\beta}^{ab} + \beta^{ac} A^{cb} - \beta^{bc} A^{ca}. \quad (7.7)$$

We can therefore interpret $e$ as the worldline einbein, $\chi^a$ as the gravitinos and $A^{ab}$ as an $O(N)$ gauge field. Notice that in the case $N = 1$, $A^{ab}$ vanishes, which is why we did not encounter it in the spin-1/2 case.

The covariant derivatives are given by $D_A = E^M_A \partial_M$. Explicitly, we have

$$D_0 = \frac{1}{E} (\partial_\tau - \bar{\Gamma} \cdot \partial \bar{\theta}), \quad D_a = i \theta^a D_0 + \partial_a. \quad (7.8)$$

When acting on the scalar field $X$, we have

$$D_0 X = \frac{1}{E} (z + i \bar{\theta} \cdot \bar{\zeta}) \cdots, \quad D_a X = i \theta^a \left( z + i \bar{\theta} \cdot \bar{\zeta} \right) + i \bar{\psi}^a + \cdots, \quad (7.9)$$

where $z \equiv \bar{X} - i \bar{\chi} \cdot \bar{\psi}$ and $\zeta^a \equiv \bar{\psi}^a + A^{ab} \psi^b$ and $\cdots$ denote terms with non-dynamical fields. Finally, the invariant integration measure is $\int d\tau d^N \theta E$.

### 7.2 Method of multiplets

The construction of a SUSY-invariant action using the superspace formalism by integrating a Lagrangian over the whole of superspace for $\mathcal{N} > 2$ is still an unsolved problem. In fact, there is good reason to believe it impossible, which we will address in a later section. Further, even if we were to accomplish such a feat, the resulting action would contain a potentially very large number of auxiliary fields that are entirely non-dynamical and would only serve to ensure that the SUSY transformations close off-shell. We could then integrate
out such non-dynamical fields to obtain a simpler action that would enjoy SUSY only on-shell. It is the aim of this subsection to explain how to directly construct the on-shell SUSY action without worrying about the non-dynamical fields. We term this approach the method of multiplets.

Our multiplet approach will enable us to construct off-shell SUSY-invariant actions for global SUSY. Only at the end will we gauge this symmetry to obtain the desired local on-shell SUSY-invariant action. We begin by defining bosonic and fermionic multiplets. A bosonic multiplet is an ordered pair

$$\Sigma = (X, \vec{\psi})$$

(7.10)

where $X$ is Grassmann even and $\vec{\psi}$ is a Grassmann-odd $\mathcal{N}$-component vector. Under an infinitesimal global SUSY transformation, we have

$$\delta X = \xi \dot{X} + i \dot{\vec{\psi}}, \quad \delta \psi^a = \xi \dot{\psi}^a + \varepsilon^a X - \beta^{ab} \psi^b,$$

(7.11)

where $\xi$ and $\beta^{ab} = -\beta^{ba}$ are infinitesimal real constants and $\varepsilon^a$ are infinitesimal Grassmann-odd constants. Next, we define a fermionic multiplet as an ordered pair

$$\Phi = (\vec{f}, b)$$

(7.12)

where $\vec{f}$ is a Grassmann-odd $\mathcal{N}$-component vector and $b$ is Grassmann even. The components transform by

$$\delta f^a = \xi \dot{f}^a + i \varepsilon a^b - \beta^{ab} f^b, \quad \delta b = \xi b + \varepsilon \cdot \vec{f}.$$

(7.13)

We can add and multiply these multiplets together. The rule for addition is simply component-wise addition,

$$(X_1, \vec{\psi}_1) + (X_2, \vec{\psi}_2) = (X_1 + X_2, \vec{\psi}_1 + \vec{\psi}_2),$$

$$(f_1, b_1) + (f_2, b_2) = (f_1 + f_2, b_1 + b_2).$$

(7.14)

We are not permitted to add a bosonic multiplet to a fermionic multiplet. Next, we have the multiplication rules

$$(X_1, \vec{\psi}_1) \times (X_2, \vec{\psi}_2) = (X_1 X_2, X_1 \vec{\psi}_2 + X_2 \vec{\psi}_1),$$

$$(f_1, b_1) \times (f_2, b_2) = (\vec{f}_1 \cdot \vec{f}_2, b_1 f_2 - b_2 f_1),$$

$$(X, \vec{\psi}) \times (\vec{f}, b) = (X \vec{f}, X b + \vec{\psi} \cdot \vec{f}).$$

(7.15)

Notice that the first two products yield bosonic multiplets and the last product yields a fermionic multiplet.

Additionally, we can take derivatives of these multiplets. Acting on a bosonic multiplet we have

$$D_0(X, \vec{\psi}) = \left(\dot{X}, \dot{\vec{\psi}}\right), \quad D_a(X, \vec{\psi}) = \left(i \psi^a, \dot{X}\right).$$

(7.16)

It can be checked that $D_0(X, \vec{\psi})$ and $D_a(X, \vec{\psi})$ are, respectively, bosonic and fermionic multiplets. Acting on a fermionic multiplet, we have

$$D_0(\vec{f}, b) = \left(\dot{\vec{f}}, \dot{b}\right), \quad D_a(\vec{f}, b) = \left(\dot{ib}, \dot{\vec{f}}\right).$$

(7.17)
It can be checked that $D_0(\vec{f}, b)$ and $D_a(\vec{f}, b)$ are, respectively, fermionic and bosonic multiplets. Oftentimes, we will use the compact notation $D_A$ for $A = 0, \ldots, \mathcal{N}$. Lastly, given the fermionic multiplet $\Phi = (\vec{f}, b)$, the global SUSY-invariant integral is

$$\int_{\text{SUSY}} \Phi \equiv \int d\tau \ b. \quad (7.18)$$

We therefore see that the aim of the coset construction will be to construct a symmetry-invariant fermionic multiplet that will then be integrated according to the above rule. After the action is constructed in this manner, we can include the worldline gauge fields to promote the global SUSY to a local, gauge symmetry.

8 Higher-spin point-particles

The symmetry-breaking pattern of the Poincaré group for massless particles is the same for all values of spin $s$, namely the unbroken generators are (6.1) and the broken generators are (6.2). Thus, the only possible distinguishing features among the effective actions for particles of differing spins are the choices of worldvolume and gauge symmetries. It has been demonstrated in [24] that the EFT for a particle of spin $s$ enjoys $\mathcal{N} = 2s$ SUSY. At this stage, we will split the problem into two pieces. The first deals with spin 1 particles, corresponding to $\mathcal{N} = 2$. The effective action will be defined in terms of an integral over superspace and will thus lead to an off-shell SUSY-invariant action. The second will be valid for all $\mathcal{N} \geq 1$, but will instead rely on the multiplet formalism and as a result will yield local on-shell SUSY-invariant actions.

8.1 Spin-1 point particles

We define our coset on the superspace coordinates $\sigma^M = (\tau, \vec{\theta}^M)$ for $\vec{\theta} = (\theta^1, \theta^2)$. We take the unbroken translation generator $P_\alpha$ as an opportunity to impose the superreparameterization invariance (7.6) and (7.7), where the supervielbein is given by (7.4). Then, as in the spin-1/2 case, we take the unbroken little group generators $J_i$ as an opportunity to impose a gauge invariance that can be used to fix $\theta^i = 0$.

With this gauge-fixing condition the most general group element is

$$g(\sigma) = e^{X^\alpha(\sigma) P_\alpha + iX^m(\sigma) P_m + i\psi^i(\sigma) K_i}, \quad (8.1)$$

where $\alpha = u, v$ and $m = 1, 2$. The Maurer-Cartan form is

$$g^{-1} \partial_M g = iE^A_M (\nabla_A X^\alpha P_\alpha + \nabla_A X^m P_m + \nabla_A \psi^i K_i + \Omega^i_A J_i), \quad (8.2)$$

where the covariant derivatives of $X^\mu$ are

$$\nabla_A X^\alpha = E^M_A \partial_M X^\mu \Lambda^\alpha_\mu, \quad \nabla_A X^m = E^M_A \partial_M X^\mu \Lambda^m_\mu, \quad (8.3)$$

such that $\Lambda^\mu_\nu = (e^{i\psi^i(\sigma) K_i})^{\mu}_\nu$. The precise forms of $\nabla_A \psi^i$ and $\Omega^i_A$ will not be important for the construction of the leading-order action.
We impose on-shell IH constraints

\[ 0 = \nabla_0 X^\nu, \quad 0 = \nabla_0 X^m, \quad (8.4) \]

which allow us to remove \( \tau^i \) from the effective action. The leading-order effective action for \( \mathcal{N} = 2 \) is therefore

\[ S = \frac{1}{4} \int d\tau d^2\theta \, \epsilon^{ab} \nabla_a X^\mu \nabla_b X_\mu, \quad (8.5) \]

which can be immediately simplified to

\[ S = \frac{1}{4} \int d\tau d^2\theta \, \epsilon^{ab} D_a X^\mu D_b X_\mu, \quad (8.6) \]

where \( \epsilon^{ab} \) is the totally antisymmetric tensor such that \( \epsilon^{12} = -\epsilon^{21} = 1 \) and \( \epsilon^{11} = \epsilon^{22} = 0 \).

We can now expand the superfield \( X^\mu \) in powers of \( \vec{\theta} \), yielding

\[ X^\mu = X^\mu + i \theta^a \psi^{a\mu} + \frac{i}{2} \epsilon^{ab} \theta^a \theta^b F^\mu. \quad (8.7) \]

The integral over \( d^2\theta \) can now be explicitly evaluated, yielding an action defined on the worldline coordinate \( \tau \) by

\[ S = \int d\tau \left( \frac{1}{2e} (\dot{X} - i \vec{X} \cdot \vec{\psi})^2 + \frac{i}{2} \dot{\psi}^\mu \cdot \vec{\psi} + \frac{e}{2} F^2 - \frac{i}{2} A^{ab} \psi^{a\mu} \psi^{b\mu} \right). \quad (8.8) \]

Notice that the field \( F^\mu \) appears with no derivatives and that its equation of motion is simply \( F^\mu = 0 \). We can thus integrate it out at no cost, except the resulting action will only be invariant under SUSY on-shell.

### 8.2 Arbitrary-spin point particles

As mentioned earlier, for particles of spin \( s > 1 \) — which correspond to \( \mathcal{N} > 2 \) — we must admit defeat, at least in part, if we wish to construct a SUSY-invariant action using the superspace formalism. The reason is that no superspace integral can give rise to the desired invariant action. To see why, we propose the following power-counting argument. We let \( \mu \) count powers of energy; e.g. \( [\partial_\tau] = [d\tau]^{-1} = \mu^1 \). Begin by noticing that the actions we have calculated so far, (4.17), (6.10), (8.8) all contain a term of the form

\[ S \supset \int d\tau \frac{1}{2e} \dot{X}^2 + \cdots. \quad (8.9) \]

By assuming \( S \) scales as \( \mu^0 \), we therefore have the scaling of \( X \), and hence \( \vec{X} \), namely \( [X] = \mu^{-1} \). Further, notice that the commutator of two super-translations give rise to one temporal translation, so \( [D_0] = [D_0]^{1/2} = \mu^{1/2} \). Moreover, integration and differentiation with respect to Grassmann numbers are equivalent operations, so \( [d\theta] = \mu^{1/2} \). Lastly, our action should involve two factors of \( X \) and two covariant derivatives \( D \) and \( D' \), which can be either \( D_0 \) or \( D_\theta \). Then the action scales like

\[ [S] = [d\tau][d\mathcal{N}\theta][D][X][D'][X] = [D][D']\mu^{s-3}, \quad (8.10) \]
where we have used the fact that \( N = 2s \). But also, the action ought to scale like \( \mu^0 \), so we have \([D][D'] = \mu^{3-s}\). But since \( D \) and \( D' \) must scale as either \( \mu^1 \) or \( \mu^{1/2} \), this equation can only be satisfied if \( s \leq 1 \). In particular, for \( s = 0 \), we have \( D = D' = D_0 \); for \( s = 1/2 \), we have \( D = D_0 \) and \( D' = D_\theta \); and for \( s = 1 \), we have \( D = D' = D_\theta \).

We now use the multiplet formalism to construct actions invariant under global SUSY for arbitrary \( N \) and hence arbitrary spin. Let \( \Sigma^\mu = (X^\mu, \psi^a) \) and \( \eta^i = (\eta^i, \phi^i) \) be bosonic multiplets. We take the unbroken generators \( J_i \) as an invitation to impose gauge symmetries that allow us to remove the Goldstones associated with \( J_i \). Then, we can express the most general group element as the SUSY multiplet \(^9 g = e^{i \Sigma^\mu P_\mu} e^{i \Sigma^m P_m} e^{i \eta^i K_i} \). (8.11)

Using the SUSY covariant derivative (not to be confused with the covariant derivative generated by the coset) defined by (7.16), we can compute the Maurer-Cartan form by

\[
g^{-1} D_A g = i \left( \nabla_A \Sigma^\alpha P_\alpha + \nabla_A \Sigma^m P_m + \nabla_A \eta^i K_i + \Omega^i J_i \right),
\]

(8.12)

where the covariant derivatives of \( \Sigma^\mu \) generated by the coset are

\[
\nabla_A \Sigma^\alpha = D_A \Sigma^\alpha \Lambda^\alpha \mu,
\]

\[
\nabla_A \Sigma^m = D_A \Sigma^m \Lambda^m \mu,
\]

(8.13)

where \( \Lambda^\mu_\nu = (e^{i \eta^i K_i})^{\mu}_\nu \). The precise form of the other terms in the Maurer-Cartan form will not be important for the construction of the leading-order action. To remove the extraneous Goldstones \( \eta^i \), we impose the on-shell IH constraints \(^{10} 0 = \nabla_0 \Sigma^\nu, \quad 0 = \nabla_0 \Sigma^m \). (8.14)

To construct the effective action, we must build a symmetry-invariant fermionic multiplet, which can then be integrated according to the prescription (7.18). We see that at leading order, the only such option is \( \Phi = \nabla_0 \Sigma^\mu \nabla_a \Sigma_\mu \), which can be immediately simplified to \( \Phi = D_0 \Sigma^\mu D_\mu \Sigma_\mu \). We then have the leading-order action

\[
S = \int_{\text{SUSY}} \Phi = \int d\tau \left( \frac{1}{2} \dot{X}^2 + i \frac{1}{2} \dot{\psi}^a \cdot \bar{\psi}_a \right).
\]

(8.15)

We must now gauge the \( N = 2s \) extended worldline SUSY. In particular, we want an action that in invariant, up to terms proportional to the equations of motion, under the infinitesimal local transformations (7.7) and the on-shell SUSY transformations

\[
\delta X^\mu = \xi \dot{X}^\mu + i \bar{\varepsilon} \cdot \bar{\psi}_a^\mu,
\]

\[
\delta \psi^a = \xi \dot{\psi}^a + e^a \frac{1}{e} \left( \dot{X}^\mu - i \dot{\bar{X}}^\mu \right) - \beta^a_b \psi^b,
\]

(8.16)

\(^9\)Notice that the addition and multiplication rules (7.14) and (7.15) enable us to define arbitrary functions of the multiplets by employing a Taylor expansion.

\(^{10}\)It should be noted that these are only legitimate on-shell IH constraints because we are going to ultimately gauge the worldline SUSY. If we were to keep the SUSY global, then there would be no constraints imposed by gauge fields and the equations of motion arising from boost Goldstones would in fact be extremely important.
where $\xi$, $\varepsilon$, and $\beta^{ab}$ are now generic infinitesimal functions of $\tau$. In particular, we have

$$S = \int d\tau \left( \frac{1}{2e} z^2 + i \frac{1}{2} \tilde{\zeta}^a \cdot \tilde{\psi}_\mu \right),$$

(8.17)

where $z \equiv \dot{X} - i \tilde{X} \cdot \tilde{\psi}$ and $\zeta^a \equiv \dot{\psi}^a + A^{ab} \psi^b$. Equivalently, the expanded form of the action is

$$S = \int d\tau \left( \frac{1}{2e} (\dot{X} - i \tilde{X} \cdot \tilde{\psi})^2 + i \frac{1}{2} \dot{\psi}_\mu \cdot \psi^a - i \frac{1}{2} A^{ab} \psi^{a}_\mu \psi^b \right).$$

(8.18)

Comparing with [25], we find that we have successfully reproduced the action for on-shell extended local SUSY.

If we wish to include a mass-term in this action, we can follow the steps of sections 6.3 and arrive at the following additional terms in the action

$$S_{\text{mass}} = \int d\tau \left( - \frac{m^2 e}{2} + i \frac{1}{2} \tilde{\psi}_5 \cdot \tilde{\psi}_5 - im \tilde{X} \cdot \tilde{\psi}_5 - i \frac{1}{2} A^{ab} \psi_5^a \psi^b \right).$$

(8.19)

Thus, the full action for the massive higher-spin point particle is the sum of (8.18) and (8.19).

We close this section by coupling higher-spin point-particles to gauge fields using the multiplet formalism. Let $\mathcal{A}_\mu(x)$ be the electromagnetic $U(1)$ gauge field. In order for this field to appear in the Maurer-Cartan form, we must first convert it into a SUSY multiplet. Inspired by (6.21), we define the multiplet pullback by

$$\mathcal{A}_\mu = DA \Sigma^\mu \mathcal{A}_\mu(\Sigma),$$

(8.20)

where $\mathcal{A}_\mu(\Sigma) = (\mathcal{A}_\mu(X(\tau)), \tilde{\psi}_\nu(\tau) \partial_\nu \mathcal{A}_\mu(X(\tau)))$. We can now insert this multiplet pullback gauge field into the Maurer-Cartan form by

$$g^{-1}(D_A + i \mathcal{A}_A Q)g,$$

(8.21)

where $Q$ generates the $U(1)$ symmetry that is gauged by $\mathcal{A}_\mu$. Letting $\pi$ be the Goldstone multiplet field corresponding to $Q$, we have

$$g^{-1}(D_A + i \mathcal{A}_A Q)g = \cdots + B_A Q + \cdots,$$

(8.22)

where $B_A = A_A + i D_A \pi$.

To construct the leading-order coupling term, we must integrate a fermionic multiplet. The only option at leading-order is $B_a$, so we have the global SUSY-invariant term

$$q \int_{\text{SUSY}} B_a = q \int d\tau \left( \dot{X}^\mu \mathcal{A}_\mu + i \frac{1}{2} \tilde{\psi}_\mu \cdot \tilde{\psi}_\nu \mathcal{F}_{\mu \nu} \right),$$

(8.23)

where $q$ is the electric charge of the point-particle and $\mathcal{F}_{\mu \nu} = \partial_\mu \mathcal{A}_\nu - \partial_\nu \mathcal{A}_\mu$ is the electromagnetic field strength. Finally, gauging the worldline SUSY gives us

$$q \int d\tau \left( \dot{X}^\mu \mathcal{A}_\mu + i e \frac{1}{2} \tilde{\psi}_\mu \cdot \tilde{\psi}_\nu \mathcal{F}_{\mu \nu} \right).$$

(8.24)

Notice that for $\mathcal{N} = 1$, we recover the spin-1/2 coupling term (6.25) that we derived using the superspace formalism.
9 Quantization

After employing our novel coset construction to formulate actions with worldline SUSY, we now wish to demonstrate that they in fact describe point particles with intrinsic quantum spin. By quantizing the action with $N = 2s \in \mathbb{Z}$ worldline SUSY, we will find that the resulting wave function describes a point-particle of spin $s$. We will follow closely the procedure shown in [25].

Starting with equation (8.18), we find it convenient to express the action in the “Hamiltonian form,”

$$
S = \int d\tau \left( p^\mu \dot{X}_\mu - \frac{1}{2} g_p^\mu p_\mu - i \gamma^\mu \gamma^\nu p_\mu + \frac{i}{2} \gamma^\mu \cdot \gamma^\nu p_\mu - \frac{i}{2} A_{ab} \gamma^a \gamma^b \right). 
$$

(9.1)

It is then clear from the equations of motion for $e$, $\chi^a$ and $A_{ab}$ that

$$
\begin{align*}
  p^\mu p_\mu &= 0, \\
  p^\mu \gamma^a &= 0, \\
  (\gamma^\mu)_{[a} (\gamma^\nu b]} &= 0.
\end{align*}
$$

(9.2)

We then impose the (anti-)commutation relations

$$
[X^\mu, p_\nu] = i \delta^\mu_\nu, \quad \{\gamma^\mu, \gamma^\nu\} = 2 \eta^\mu\nu \delta_{ab}.
$$

(9.3)

To facilitate the quantization procedure, it is convenient to work with the usual identification $p_\mu = -i \partial / \partial X^\mu$. To realize the second anti-commutation relation, we work in the representation

$$
\psi^a = \frac{1}{\sqrt{2}} \gamma_5 \cdots \gamma_5 \gamma^\mu \gamma^\nu \gamma^\rho \cdots \gamma^\rho, 
$$

(9.4)

where we have used the Dirac $\gamma$ matrices, which satisfy $\{\gamma^\mu, \gamma^\nu\} = 2 \eta^\mu\nu$. Now, assuming $a < b$, it is straightforward to determine that

$$
(\psi^\mu)_{[a} (\psi^\nu b]} = -\frac{1}{2} \gamma_5 \cdots \gamma_5 \gamma^\mu \cdots \gamma^\mu \gamma^\nu \cdots \gamma^\nu \\
\hspace{2cm} \gamma^\rho \cdots \gamma^\rho \gamma_a \cdots \gamma_a. 
$$

(9.5)

The constraint equations coming from equations (9.2) for a spinor $\Psi_{\alpha_1 \cdots \alpha_N}$ are, respectively,

$$
\begin{align*}
  \Box \Psi_{\alpha_1 \cdots \alpha_N} &= 0, \\
  \partial_{\alpha_{a}} \beta_{a} \Psi_{\alpha_1 \cdots \alpha_{a} \cdots \alpha_N} &= 0, \\
  (\gamma^\mu)_{\alpha_a \beta_b} \gamma_b \Psi_{\alpha_1 \cdots \alpha_{a} \cdots \alpha_N} &= 0.
\end{align*}
$$

(9.6)

Following the procedures in [25], these constraints will finally give, in the SL(2, $\mathbb{C}$) notation,

$$
\partial_{\alpha_a} \beta_{a} \Psi_{\alpha_1 \cdots \alpha_{a} \cdots \alpha_N} = 0, \quad \Box \Psi_{\alpha_1 \cdots \alpha_N} = 0.
$$

(9.7)

But these are just the conditions that $\Psi_{\alpha_1 \cdots \alpha_N}$ be the wave function for a relativistic particle of spin $s = N/2$. We therefore conclude that our action (8.18) indeed describes a spin-$N/2$ point particle.
10 Massless spin-0 point-particles

When we constructed the EFTs for the massive boson, the resulting IH constraints could be solved directly for the Lorentz Goldstones, $\eta^i$ in terms of the translation Goldstones, $X^\mu$. However, when dealing with massless particles, the IH constraints over-constrained the translation Goldstones and we were forced to interpret them as on-shell IH constraints. In this section we will explore in more detail the relationship between Lorentz Goldstones and massless particles.

10.1 Without external einbein

Our aim is to construct an EFT for massless scalars without the introduction of an external einbein. The SSB pattern is identical to that of the spin-1/2 (and higher) massless particles. Explicitly, the unbroken generators are (6.1) and the broken generators are (6.2). The most generic group element is

$$g(\tau) = e^{iX^\mu(\tau)P_\mu + iX^m(\tau)P_m} e^{i\eta^i(\tau)K_i} e^{i\vartheta^i(\tau)J_i}, \quad (10.1)$$

where $\alpha = u, v$ and $m = 1, 2$. We impose full reparameterization symmetry $\delta \tau = -\xi(\tau)$ as well as a full $J_i$ gauge symmetry

$$g \rightarrow g \cdot e^{i\lambda^i(\tau)J_i}, \quad (10.2)$$

which allows us to gauge-fix $\vartheta^i = 0$. With this gauge-fixing condition, the Maurer-Cartan form is

$$g^{-1} \partial_\tau g = iE(P_u + \nabla X^v P_v + \nabla X^m P_m + \nabla \eta^i) + \Omega^i, \quad (10.3)$$

where the einbein is given by $E = \dot{X}^\mu \Lambda^\mu u$ and $\Lambda^\mu \nu = (e^{i\eta^j(\tau)K_j})^\mu \nu$. The covariant derivatives and spin connection will not appear at leading order in our EFT.

One might be tempted to impose the IH constraints $\nabla X^v = 0$ and $\nabla X^m = 0$, but this would imply that $\dot{X}^\mu$ is null. Further, since there are no external gauge fields that might constrain $\dot{X}^\mu$ to be null, these constraints do not admit an interpretation as on-shell IH constraints. Thus, we are forced to include the Lorentz Goldstones $\eta^i$ in our EFT.

The leading-order action is then

$$S = \int d\tau E = \int d\tau \dot{X}^\mu L_\mu, \quad (10.4)$$

where $L_\mu \equiv \Lambda^\mu u$. Importantly, $L_\mu$ is constrained to be a null vector, that is $L^2 = 0$.

The equations of motion found by varying $L_\mu$ and $X^\mu$ are respectively

$$\dot{X}^\mu \propto L^\mu, \quad \dot{L}_\mu = 0. \quad (10.5)$$

Since $L^2 = 0$ the first equation tells us $\dot{X}^2 = 0$, meaning that the particle travels along a null-trajectory. Then, the second equation tells us that $\ddot{X}^\mu = 0$, so the particle does not accelerate. This is exactly what we should expect of a massless particle. Thus, we have an effective action for a massless boson that does not include any external einbein at all; the price we pay is the inclusion of Lorentz Goldstones.
10.2 With external einbein

We now consider what happens if we include an external einbein $e$ such that worldline diffeomorphism symmetry acts by

$$\delta \tau = -\xi(\tau), \quad \delta e = \partial_\tau (e\xi). \quad (10.6)$$

As in the previous subsection we gauge-fix $\vartheta^i = 0$. The Maurer-Cartan form is

$$g^{-1}\partial_\tau g = ie(\nabla X^\alpha P_\alpha + \nabla X^m P_m + \nabla \eta^i) + \Omega^i, \quad (10.7)$$

where $\alpha = u, v$ and $m = 1, 2$. Since we have an external einbein, we should expect that on-shell IH constraints are permitted, and this is indeed the case. To be explicit about how these on-shell IH constraints can be used, we will wait to impose any IH constraints and keep $\eta^i$ in the action.

The leading-order action is

$$S = -\int d\tau e \left( \nabla X^\mu \nabla X_\mu + C \nabla X^u + m^2 \right), \quad (10.8)$$

for some constants $C$ and $m^2$. Define the field $L_\mu \equiv C \Lambda_\mu^u$, which is subject to the constraint $L^2 = 0$. Then our action becomes

$$S = -\int d\tau \left( \frac{1}{e} \dot{X}_\mu \dot{X}_\mu + \dot{X}_\mu L_\mu - m^2 e \right). \quad (10.9)$$

The constraint equation coming from $e$ is

$$\frac{1}{e^2} \dot{X}^2 = -m^2 \quad (10.10)$$

and the constraint equations coming from $L_\mu$ are

$$\dot{X}^\mu \propto L_\mu. \quad (10.11)$$

Upon squaring (10.11), we find that $\dot{X}^2 = 0$, which then forces $m^2 = 0$ on self-consistency grounds.

Thus, the effect of the on-shell IH constraint is to fix $m^2 = 0$. After imposing this constraint on $m^2$, we can simply drop the Lorentz Goldstones from our action. Thus the leading-order action is

$$S = -\int d\tau \frac{1}{e} \dot{X}_\mu \dot{X}_\mu, \quad (10.12)$$

which is the standard action for a massless spin-0 point-particle.

Finally, it is worth noting that ordinary IH constraints allow one to solve for the extraneous Goldstone in terms of other Goldstones; however, dynamical IH constraints [11, 12] instead serve to impose operator constraints on the terms of the action. Notice that the equations of motion for $L_\mu$ in the action (10.4) impose the operator constraint $\dot{X}^2 = 0$. We therefore may conceive of the equations of motion for $L_\mu$ as imposing dynamical IH constraints. Similarly when we impose on-shell IH constraints in the action (10.8) (which is equivalent to computing the equations of motion for $L_\mu$) we find a constraint equation that forces $m^2 = 0$. Thus on-shell IH constraints bear a striking resemblance to dynamical IH constraints.
11 Spinning particles

So far, we have been dealing with point-particles, that is particles with no spatial extent. Now we turn our attention to particles that have spatial extent. As a result, there may exist angular momentum in the form of quantum spin or classical rotation.

11.1 Spinning spin-less particles

Consider a spin-0 particle with spatial extent. Since we are keen on implementing our new coset construction, we will focus on constructing the Polyakov-type action with an intrinsic worldline einbein. The Nambu-Goto-type action for a spinning spin-0 particle can be constructed with the ordinary coset construction; interested readers may consult [6] for such a derivation.

As before, the symmetry group is Poincaré alone, so the most general group element is given by (4.9). We impose worldline-reparameterization symmetry on the coordinate $\tau$ given by (4.10), where once again $e(\tau)$ is the einbein. Because the particle has finite spatial extent, rotations are spontaneously broken, so we cannot impose a local rotational gauge symmetry of the form (4.11). Thus, the rotation Goldstones cannot be gauge-fixed to zero.

We have supposed that our particle has some sort of finite extent, but we have so far been vague about its shape. At the level of the coset construction, what distinguishes a lumpy object from a sphere or a cylinder? The answer is symmetry: a sphere has an internal SO(3) symmetry, a cylinder has an internal $\text{SO}(2) \times \mathbb{Z}_2$ symmetry, and a lumpy object has no internal symmetry. To treat all of these possibilities (and more) simultaneously, we suppose that the symmetry group of the object is $S \subset \text{SO}(3)$. Then we impose the rigid symmetry

$$g \rightarrow g \cdot S,$$

where $S \in S$ is constant.\footnote{This right-acting rigid rotation symmetry is an example of (3.6).}

We may now compute the Maurer-Cartan form

$$g^{-1} \partial_\tau g = i e(\nabla X^\mu P_\mu + \nabla \eta^i K_i + \nabla \vartheta^i J_i),$$

(11.2)

where the covariant derivatives are

$$\nabla X^0 = e^{-1} \dot{X}^\nu \Lambda_{\nu}^0,$$

$$\nabla X^i = e^{-1} \dot{X}^\nu \Lambda_{\nu}^j R^{ij},$$

$$\nabla \eta^i = e^{-1} (\Lambda^{-1} \partial_\tau \Lambda)^{0j} R^{ij},$$

$$\nabla \vartheta^i = e^{-1} 2 \epsilon^{ijk} (\Lambda R)^{-1} \partial_\tau (\Lambda R)^{jk},$$

(11.3)

where $\Lambda_{\mu}^\nu \equiv (e^{\eta(\tau) K_i})^\mu_\nu$ and $R^{ij} \equiv (e^{\vartheta(\tau) J_i})^{ij}$. We impose the IH constrains $\nabla X^i = 0$, which can be solved to give (4.15), but now since we have to contend with the rotation Goldstones, it is profitable to dig deeper into these IH constraints. In particular, defining the orthonormal basis of vectors

$$n^{(i)}_{\mu} = \Lambda_{\mu}^j R^{ij}, \quad u^{\mu} = \Lambda^\mu_{0},$$

(11.4)
the IH constraints merely state that \( e^{-1} \dot{X}^\mu \) is orthogonal to \( n^i_\mu \), meaning that \( e^{-1} \dot{X}^\mu \) is parallel to \( u^\mu \). We can thus identify \( u^\mu \) as the four-velocity of the particle. Therefore, the matrix \( R^{ij} \) encodes information about the rotation of the particle in its own inertial rest frame.

With the boost Goldstones successfully eliminated, \( \nabla \vartheta^i \) is now expressible entirely in terms of \( X^\mu \) and \( \vartheta^i \) alone. Recalling (4.16), the leading-order action is given by

\[
S = - \int d \tau \left( \frac{1}{e} \dot{X}^\mu \dot{X}_\mu - e m^2 - \frac{e}{2} I_{ij} \nabla \vartheta^i \nabla \vartheta^j \right),
\]

(11.5)

where \( I_{ij} \) is the moment of inertia tensor. Notice that the internal symmetry group \( \mathcal{S} \) determines the symmetries of \( I_{ij} \).

### 11.2 Spinning spinning particles

We now consider the case of a particle with spin \( s = 1/2 \) and finite spatial extent. Such a particle, in addition to spin-angular momentum, may now have ‘orbital’ angular momentum, or classically, it may rotate in space. We are primarily interested in massive particles as the concept of rotation is most evident when a particle has an inertial rest frame. We thus take the global symmetry group to be Poincaré with the addition of a \( U(1) \) symmetry generated by \( P_5 \). We can think of \( P_5 \) as generating translations along a compactified dimension. As we have done previously for massive particles with spin, we will ultimately constrain the momentum along the 5-direction by \( p^5 = m \). Then we can interpret \( m \) as the mass.

The additional symmetries we impose are the usual \( \mathcal{N} = 2s \) local SUSY and the internal rotation symmetry (11.1). The most general group element is

\[
g(\sigma) = e^{i X^\mu(\sigma) P_\mu} e^{i X^5(\sigma) P_5} e^{i \vartheta^i(\sigma) K_i} e^{i \varphi(\sigma) J_i},
\]

(11.6)

where \( P_\mu \equiv P_\mu - \delta^0_\mu P_5 \). The resulting Maurer-Cartan form is

\[
g^{-1} \partial_M g = i (E^{-1})^A_M (\nabla_A X^\mu P_\mu + \nabla_A X^5 + \nabla_A \vartheta^i K_i + \nabla_A \varphi^i J_i),
\]

(11.7)

where the covariant derivatives are

\[
\nabla_A X^0 = E^M_A \partial_M X^\nu \Lambda^0_\nu,
\]

\[
\nabla_A X^i = E^M_A \partial_M X^\nu \Lambda^i_\nu R^{ji},
\]

\[
\nabla_A X^5 = E^M_A \partial_M X^5 + \nabla_A X^0,
\]

\[
\nabla_A \vartheta^i = E^M_A ((\Lambda R)^{-1} \partial_M (\Lambda R))^0_i,
\]

\[
\nabla_A \varphi^i = \frac{1}{2} E^M_A e^{ijk} ((\Lambda R)^{-1} \partial_M (\Lambda R))^{jk},
\]

such that \( \Lambda^\mu_\nu = (e^{i \vartheta^i(\sigma) K_i})^\mu_\nu \) and \( R^{ij} = (e^{i \varphi(\sigma) J_i})^{ij} \).

We may now impose IH constraints \( \nabla_0 X^i = 0 \), which can be solved to give

\[
\frac{\vartheta^i}{\vartheta} \tanh \vartheta = \frac{D_0 X^i}{D_0 X^0},
\]

(11.9)
thereby removing the boost Goldstones entirely. Notice that $\nabla_1 X^i$ have not been removed and may still appear in the action. We thus have the additional terms

$$S_{\text{rot}} = \frac{1}{2i} \int d\tau d\theta \mathcal{E} \left( I_{ij} \nabla_0 \theta^i \nabla_1 \theta^j + \bar{w} \cdot \left( \nabla_0 \bar{\theta} \times \nabla_1 \bar{X} \right) \right), \quad (11.10)$$

where $I_{ij}$ is a symmetric tensor and $\bar{w}$ a constant three-vector. The full spin-1/2 spinning-particle action is therefore given by a sum of (8.19) and (11.10). Just like the spin-0 case, $I_{ij}$ is the moment of inertia. Now, however, we have an additional term that has no spin-less counter-part, namely the terms involving $\bar{w}$. We interpret this term as a kind of ‘spin-orbit’ coupling; it couples the intrinsic spin of the object to the rigid-body rotation. Further, the form of $I_{ij}$ and $\bar{w}$ must respect the symmetry group $S \subset \text{SO}(3)$. Notice that only certain symmetry groups $S$ permit a nonzero $\bar{w}$. In particular $\bar{w} \neq 0$ is only possible if $S \subset \text{U}(1)$. By contrast, $I_{ij} \neq 0$ is always permitted.

12 Summary

In this paper, we defined a generalized coset construction for systems with spontaneously broken Poincaré symmetry. The motivation was that when Poincaré symmetry is preserved, Goldstone’s theorem is extremely restrictive: all Goldstones must be spin-0 bosonic particles with vanishing mass; however, when Poincaré symmetry is spontaneously broken, many more possibilities exist. In particular, Goldstone’s theorem can be satisfied by excitations that possess any spin, may be bosonic or fermionic, and need not admit a particle or quasiparticle representation. Thus, systems with identical symmetry-breaking patterns may possess inequivalent Goldstone spectra. To illustrate this diversity, we chose to focus on the relativistic point particle. All relativistic point-particles have identical (or nearly identical) SSB patterns; yet they can have any mass $m \geq 0$ and have any spin $s \in \mathbb{Z}/2$. With our new-and-improved coset construction, we formulated effective actions for point-particles of arbitrary mass and spin. Along the way we identified a novel kind of inverse Higgs constraint that we termed the \textit{on-shell IH constraint}, which arises when constructing EFTs for massless particles. This IH constraint bears a striking resemblance to the so-called dynamical IH constraint used to construct EFTs for fermi liquids \[11, 12\]. Finally, we used this new coset construction to formulate EFTs for particles of arbitrary spin and finite spatial extent. In particular, we found a kind of spin-orbit coupling that describes interactions between physical rotation and quantum spin.

With our new coset philosophy, the SSB pattern is no longer the only object of concern. Inspired by \[9, 10\], we parameterized the full symmetry group with Goldstone fields defined on a worldvolume of our choosing and then imposed Gauge symmetries associated with the unbroken symmetry generators. Thus, the three ingredients that go into this novel coset construction are (1) identifying the SSB pattern, (2) choosing a worldvolume on which to construct the action and (3) picking a particular set of gauge symmetries. We were free to choose whatever gauge symmetries we liked; if we imposed the largest possible set of gauge symmetries, then the Goldstones associated with unbroken generators could be gauge-fixed to zero, thereby recovering the standard coset construction. To allow for a wide range of
spins — including both bosonic and fermionic particles — we found that it was necessary
to impose an $\mathcal{N} = 2s$ local SUSY on the worldline, where $s$ is the spin of the particle. This
gauged SUSY is imposed at the level of the coset, meaning that once the gauge symmetries
are specified, constructing an invariant action is just a matter of ‘turning the crank’ and
using the coset to read-off symmetry-invariant terms. Thus, this new coset construction
provides the same advantages as the usual coset construction.

We expect that this new coset construction will prove useful in a number of areas.
In particular, the ordinary coset construction has proved to be a valuable tool when con-
structing EFTs for condensed matter systems [15, 17, 19]. Since our new coset construction
allows for fermionic degrees of freedom, it is our hope and expectation that these new tech-
niques will facilitate useful extensions of the coset construction to account for phases of
matter with low-energy fermionic excitations. For example EFTs for fermi liquids, non-
fermi liquids, and bad metals might now be realizable using this novel method of cosets.
We also hope to extend this coset construction to allow for non-equilibrium EFTs defined
on the Schwinger-Keldysh contour [9] and to allow for explicitly broken symmetries [28]
that exhibit fermionic degrees of freedom. Finally, it would be of great interest to identify
the rules that determine which gauge symmetries ought to be imposed. Since we are free to
choose from an infinite set of gauge symmetries, it would be extremely useful to construct
a dictionary between physical attributes of the system and emergent gauge symmetries in
the coset construction.

Acknowledgments

We would like to thank Alberto Nicolis and Lam Hui for their wonderful mentorship and
Ioanna Kourkoulou for many insightful conversations. This work was partially supported
