Abstract—This article introduces a new low-level boundary detector, sensitive to either small data changes or large gradients. The method relies on constrained random walks around each pixel, describing how nearby image values typically evolve on each side of this pixel. Textures are represented as probability distributions of such random walks, so a texture difference operator is statistically defined as a distance between these distributions in a suitable reproducing kernel Hilbert space. The method is thus not limited to scalar pixel values; any data type for which a kernel is available may be considered, including but not limited to color triplets. By adjusting the size of the neighborhoods that are compared, the method is implicitly scale-dependent, and we demonstrate how it can be used to infer characteristic scales in measured data.

I. INTRODUCTION

Finding transition zones in data sets is a fundamental operation for remote sensing of natural objects, for edge detection of images, or for the identification of objects by their boundaries. The best algorithms account for texture information [1], exploit eigen-decompositions for segmentation of similar regions [2], or improve their results with edge completion [3]. These high-level operations are very efficient at finding transitions, but they are global methods that require the whole image or a database for training. At the other end of the spectrum, we find low-level, pixel-based algorithms that can be applied locally and which are thus easily parallelizable. These methods include classical gradient-based edge-detection algorithms [4], but also decompositions on adaptive basis of functions [5], which may themselves be constructed with a priori knowledge (e.g. dictionary based analysis [6] and textons [7]). Repeating these low-level methods on multiple resolutions of the same image (e.g. with Gaussian blurring) is easy and leads to a space-scale analysis at each pixel [8]. This way, edges are found at different levels of details [9], hopefully allowing the user to remove all extraneous changes and focus on important object boundaries [10]. Wavelet-based analysis at each pixel also relate multiple scales together in feature descriptors [11], but by definition these do not allow finding characteristic scales, just relations between scales.

In this paper, we present a local algorithm, a low-level and scale-dependent data analysis that is able to identify characteristic scales in data sets. The main idea is to statistically characterize how data values evolve when exploring each side of a given pixel, then compare the statistical properties of each side, and use this instead of a pixel value gradient as the basis for edge recognition. We exploit random walks on images but in a different setting than [12]. Our method resembles the graph walks in [13], except that we additionally introduce a statistical comparison operator, that our method is adapted to images, directional, accounts for neighborhood information and is intrinsically scaled-dependent. Indeed, exploring the neighborhood of each pixel implies setting two scales: the spatial extent of that exploration, and the sensitivity to pixel value differences along each explored path. Once these are set, we quantify the difference between each side, and repeat the operation in the horizontal, vertical and diagonal directions. This gives, for each pixel and each prescribed set of (spatial, data) scales, a measure of how that pixel is a transition between distinct statistical properties on each of its sides. Depending on how these scales are set, we thus get a new kind of low-level edge detector, sensitive to either small data changes or large gradients, and at different resolutions. The method can be used to infer characteristic scales in natural data, these at which the boundaries capture most of the information. The method is not restricted to images, it is readily extendable to voxels or other spatially extended data. It is not restricted either to scalar (e.g. gray) valued pixels, any data type for which a reproducing kernel is available can be used (e.g. vector, strings, graphs). We present in particular the case for color triplets in Section VI. In the following, bold mathematical symbols denote pixels, plain symbols are values associated to these pixels. Capital mathematical symbols (resp. bold, plain) represent sets (of resp. pixels, values). Mathematical spaces are calligraphied.

II. ENCODING TEXTURE INFORMATION

A. Overview

Consider a pixel \( o \). From the center of that pixel, we want to compare how the texture on the left is statistically different from the texture on the right (Fig. 4), then up and down, and along the diagonals. Let \( +x \) and \( -x \) be the directions to compare on each side of the pixel (whether in straight or diagonal mode), with \( y \) along an orthogonal axis. A length scale is needed for characterizing the extent of the texture comparison. Let \( \lambda \) be this spatial length scale. Consider an isotropic Gaussian distribution of standard deviation \( \lambda \) along both \( x \) and \( y \), centered on the pixel \( o \). Splitting the plane into two halves at \( o \), and noting \( N^\pm(o) \) neighborhoods of pixels within these two halfs, consider the probability densities \( p^\pm(x,y) = C \cdot \exp \left( -\frac{x^2+y^2}{2\lambda^2} \right) \) for \( \pm x \geq 0 \) and 0 otherwise, in each half-plane, where the origin is taken at the center of pixel \( o \) and \( C \) is a normalizing constant. The texture characterization we propose amounts to:

A: monitoring pixel values taken along \( n \) independent random paths in each of these neighborhoods \( N^\pm(o) \);
B: such that the probability to visit a pixel \( a \in N^\pm(o) \) is given by \( p^\pm(a) = \int_{x,y,a} p^\pm(x,y) \, dx \, dy \);
C: and the average spatial extent of a random path is \( \lambda \).
As a result of this process, two sets \( S^\pm(o) \) are obtained for each pixel \( o \) along each pair of opposite directions. These sets each contain \( n \) random sequences of pixel values \( v(a) \), the image information (gray scale, RGB, etc.) at pixel \( a \). A set of paths thus contains the statistical description of a texture on the corresponding side of a pixel \( o \), at a prescribed characteristic spatial scale of \( \lambda \).

Each of the above points is detailed separately in the following subsections.

**B. Generating random paths**

Each pixel is considered to be a distinct state of a Markov chain. Transitions are allowed to the 4 neighborhood pixels, \( N(o) \). Generating random paths following subsections.

The Markov chain is then run for \( m \) steps for generating the pixel sequence \( \{a_i\}_{i=1}^m \). The values of these pixels are then taken along this path, so that \( s = \{s_i = v(a_i)\}_{i=1}^m \in S^\pm(o) \) is a length \( m \) excerpt of the texture in \( N^\pm(o) \). The process is repeated \( n \) times to get the full set \( S^\pm(o) \), in each direction, which is assumed to encode the full texture information provided \( n \) is large enough (Fig. 1).

**C. Building the Markov chain**

For each pixel \( a \), hence each state of the Markov chain, we first compute \( p^\pm(a) \). This is the probability of reaching this state in the limit distribution of the Markov chain. We now need to define a set of transitions that leads to this limit distribution.

Let \( p^\pm(a \rightarrow b) \) be the transition probability from state/pixel \( a \) to state \( b \). There are at most 5 non-null such probability transitions, from \( a \) to its neighborhood pixels \( b_1...5 \) and to itself \( b_5 = a \). The Markov chain is consistent with the limit distribution when:

\[
p^\pm(a) = \sum_{i=1}^{5} p^\pm(b_i)p^\pm(b_i \rightarrow a) \tag{1}
\]

while respecting the constraint

\[
\sum_{i=1}^{5} p^\pm(a \rightarrow b_i) = 1 \tag{2}
\]

The unknowns in this problem are the transition probabilities for every pair \( a, b \). We start by assigning initial transition probabilities \( p^\pm_{\text{ini}}(a \rightarrow b_i) = p^\pm(b_i)/\sum_{i=1}^{5} p^\pm(b_i) \). This, of course, does not provide the correct transition probabilities, just a starting point. We then run an iterative Levenberg-Marquardt optimisation scheme in order to solve Eq.1 and Eq.2.

**D. Ensuring sequences are consistent with the spatial scale**

For each sequence length \( m \), we note the average extent \( e(x) \) in \( x \) for generated sequences of this size: \( e(x) = \langle \max_{i \leq m} (\bar{x}(a_i)) - \min_{i \leq m} (\bar{x}(a_i)) \rangle \), with \( \bar{x}(a) \) denoting the \( x \) coordinate of the center of pixel \( a \). Averaging \( e(x) \) is done numerically over a large number of samples. We then select the value of \( m \) that gives a sequence of spatial extent \( e(x) = \lambda \) on average. The typical error on \( \lambda \) is less than 0.01 pixel for the neighborhoods we use.

Building the Markov chain and defining \( m \) needs to be done only once for each neighborhood size \( \lambda \) and for each considered orientation of the neighborhoods \( N^\pm(o) \). Distinct orientations lead to distinct \( p^\pm(a) \). There are at most 5 non-null such probability density functions for each pixel \( a \) around \( o \). We limit ourselves in this paper to straight and diagonal orientations, so that densities \( p^\pm(a) \) present a convenient symmetry in each of these two cases, but any angle is possible. Once these are precomputed, the same (straight, diagonal) Markov chains can be applied to each pixel \( o \) in the image (boundary conditions are dealt with in Section III-D).
III. COMPARING TEXTURES

The procedure described in the previous section is applied to each pixel on an image, leading to 4 pairs of sets $S^\pm(o)$ for each pixel $o$, corresponding to both straight and diagonal directions. Each set comprises $n$ sequences $s = \{s_i = v(a_i)\}_{i=1...m}$ of length $m$, with $m$ chosen so that sequences extend spatially to a characteristic scale $\lambda$ in the corresponding direction on average. This section details how to quantify the difference $d(S^-, S^+)$ between two sets $S^\pm(o)$, hence between textures on opposite sides of a pixel.

A. Comparing two sequences of pixel values

Let $s = \{s_i = v(a_i)\}_{i=1...m}$ be a sequence as defined above. Let $V$ be the space taken by pixel values $v(a) \in \mathcal{V}$, so that $s \in \mathcal{V}^m$. Consider a kernel $k : \mathcal{V}^m \times \mathcal{V}^m \to \mathbb{R}$, such that:

- $k(s, \cdot)$ is a function, in the Hilbert space $\mathcal{H}$ of functions from $\mathcal{V}^m$ to $\mathbb{R}$.
- For any function $f \in \mathcal{H}$ and for all $s \in \mathcal{V}^m$, the reproducing property holds: $\langle f, k(s, \cdot) \rangle_{\mathcal{H}} = f(s)$ with $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ the inner product in $\mathcal{H}$.
- Span $\{k(s, \cdot)\}_{s \in \mathcal{V}^m}$ is dense in $\mathcal{H}$.

A special case, the kernel value $k(s^-, s^+) = \langle k(s^-, \cdot), k(s^+, \cdot) \rangle_{\mathcal{H}}$ gives the similarity between $s^-$ and $s^+$. As is customary, we normalize $k$ such that $k(s, s) = 1$ and $k(s, t \neq s) < 1$ for all $s, t \in \mathcal{V}^m$.

This classic reproducing kernel Hilbert space (RKHS) representation lets us consider any pixel value: scalar (e.g. gray scale, reflectance), vector (e.g. RGB, hyperspectral components), or in fact any kind of data for which a kernel is available (e.g. graph, strings). Indeed, once a kernel is available for an element $a_i \in \mathcal{V}$, it is always possible to use the product kernel for the sequence $s \in \mathcal{V}^m$, hence to compute the similarity between two sequences. The method we present is thus generic, and applicable to wide range of “images”, broadly defined as spatially extended data. In particular, one way to handle color textures is presented in Section VI.

B. Quantifying texture differences

The random sequences defined above can be seen as samples of an underlying probability distribution over $\mathcal{V}^m$, which we identify with the texture information. It is possible that visually distinct patterns lead to the same distribution over $\mathcal{V}^m$, as we offer no uniqueness proof, and especially with $n < \infty$. However, the same visual ambiguity exists for other and widely used texture representation methods, for example when retaining only a small number of components in a suitable decomposition basis (\cite{11, 5, 2}). We make no claim on the superiority of our method in this respect, but it certainly offers a very different characterization of textures, complementary to other approaches.

Let us thus identify a texture as a probability distribution $P(s)$ over $\mathcal{V}^m$. In this view, the sets $S^\pm(o)$ are collections of observed samples for the textures in the neighborhoods $N^\pm(o)$. Quantifying the texture difference $d(S^-, S^+)$ amounts to performing a two-sample test for similar distributions, with similarity defined by a metric on probability distributions. Using the above RKHS representation, we exploit recent literature \cite{13, 15} to propose a consistent estimator for $d(S^-, S^+)$ that works reliably even for small number of samples $n$, irrespectively of the dimension of $\mathcal{V}$ and thus $\mathcal{V}^m$:

- For a distribution $P$, the average map $\mu_P \in \mathcal{H}$ is given by $\mu_P = EP[k(s, \cdot)]$.
- An estimator $\hat{\mu}_S$ is easily obtained from the sample set $S$, in the form $\hat{\mu}_S = \frac{1}{n} \sum_{i=1}^{n} k(s^i, \cdot)$, where $s^i$ denotes the $i$-th member of the set $S$.

Let $P$ and $Q$ be two distributions over $\mathcal{V}^m$. If the kernel is characteristic, then $P = Q$ if and only if $\|\mu_P - \mu_Q\|_{\mathcal{H}} = 0$. If $P \neq Q$, the norm directly quantifies the discrepancy between these distributions.

Thus, the texture difference $d(S^-, S^+)$ can be estimated with:

\[
d^2(S^-, S^+) = \|\hat{\mu}_{S^+} - \hat{\mu}_{S^-}\|^2_{\mathcal{H}}
\]

\[
= \langle \hat{\mu}_{S^+} - \hat{\mu}_{S^-}, \hat{\mu}_{S^+} - \hat{\mu}_{S^-} \rangle_{\mathcal{H}} = \frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} \left( k(s^i_+, s^j_+) - k(s^i_-, s^j_-) - 2k(s^i_+, s^j_-) \right)
\]

Thanks to being a consistent estimator \cite{15} for a norm in a suitable space, the operation we propose behaves very much like a pixel-based gradient norm, but on textures differences instead of pixel values, realizing of form of “texture gradient” (See Section V.C).

We define an overall Stochastic Texture Difference STD(o) for each pixel $o$ by considering the norm in the product space $\otimes_{i} \mathcal{H}_i$ over all directions, normalized by the number of directions, such that

\[
\text{STD}(o)^2 = \frac{1}{4} \sum_{i=1}^{4} d^2_i(S^i_-, S^i_+)
\]

with $i$ indexing in this paper the horizontal, vertical and the two diagonal pairs of sets.

The whole procedure is easily generalizable to higher dimensions (e.g. voxels), to arbitrary angles $\theta$ instead of diagonals (by computing the Markov chain for the limit distribution of the rotated neighborhood), to anisotropic neighborhoods, etc.

C. Choosing an appropriate data scale

In the results presented in the next sections, we use the inverse quadratic kernel for scalar valued pixels:

\[
k(s, t) = 1/\left( 1 + \frac{1}{m} \sum_{i=1}^{m} (s_i/k - t_i/k)^2 \right)
\]

This kernel is characteristic \cite{14}, and we found that it performs as well as the Gaussian kernel, but it is much faster to compute. We have normalized the sum of squares by $m$, so that

\[3\text{Technically, this is only true up to an arbitrary set with null probability. But such sets cannot be observed in practice, hence they can be safely ignored.}\]
straight and diagonal computations have comparable kernel values. The parameter $\kappa$ sets the scale at which the interesting dynamics occur in the observed signal values, and should be set a priori by the user or a posteriori in order to optimize some objective criterion. In Section IV-B, we use the reconstruction Peak Signal to Noise Ratio (PSNR) as a measure of accuracy for each value of $\lambda$ and $\kappa$. Other applications might have different criteria, for example a classification rate in a machine learning scenario. The important point is that the optimal spatial and data scales should be set a posteriori with such criteria, as it is not guaranteed that maximal PSNR (i.e. minimal squared reconstruction error) is the best compromise for every application (e.g. classification). Moreover, in most images, some spatial variations for the optimal $\kappa$ are expected, since not every part of the same image reflect the same object. Hopefully, if so desired, our method can be applied on arbitrarily shaped sub-parts of such images simply by masking out other parts as missing data, as detailed in the next section.

D. Handling missing data and image boundaries

Some images, like the satellite monitoring of sea surface temperature in Fig. 3, present missing data for some pixels, in this case corresponding to land masses. In that case, entries in some sequences $\{s_i\}_{i \leq m}$ may be missing. We deal with the issue by modifying the kernel to maintain a normalized average over the remaining entries in these sequences:

$$k(s, t) = 1 / \left(1 + \frac{1}{|C|} \sum_{i \in C} (s_i / \kappa - t_i / \kappa)^2 \right) \tag{6}$$

where $C$ is the set of common indices where both sequences have valid entries. When $C = \emptyset$, the kernel value cannot be computed. In that case, we average over remaining kernel evaluations, separately in each term of Eq. 3. When $d(S^-, S^+)$ cannot be evaluated in some directions $S^\pm$, then we average over remaining directions in Eq. 4 to define the texture discrepancy at that pixel. When all directions are invalid, for example in zones of missing data larger than the neighborhood $N^\kappa(\alpha)$, we set the texture discrepancy to Not a Number, indicating missing information. When a large zone of missing data is present, then some directions have to be ignored and textures are compared in the remaining directions. This process adaptively handles contours of missing data, discarding automatically directions toward missing data and considering only directions tangent to the large invalid zone.

This effect is exploited to deal with pixels at the boundary of an image. Standard techniques for handling such boundaries involve extending border pixel values, mirroring, or setting outside pixel values to zero. However, these methods are only needed to work around the inability of an image processing algorithm to deal with missing data. Since we can, the natural choice for pixels outside the image is to consider them missing. Thanks to the above method, computations at an image border are performed in exactly the same way as for any pixel within the image. Textures to the very border of the image are taken into account and, importantly, without introducing spurious discrepancies (such as setting outside pixels to null would) or spurious similarities (such as mirroring or extending border pixel values would).

IV. A SCALE-DEPENDENT TEXTURE DISCREPANCY DETECTOR

A. Demonstration on a synthetic test picture

The synthetic image of Fig. 2 left was designed to demonstrate the behavior of the algorithm on elementary patterns such as one-pixel width lines and chess boards. Labels in Fig. 2 middle, right are added for clarity of the discussion. A: points within thin (isolated) 1-pixel lines have the same neighborhood on each side of the line. Points next to these lines have a maximal difference between neighborhoods at 1-pixel scale, resulting in detected edges on each side of the line. At scale 2, points two pixels away also have asymmetric neighborhood, although less than the nearby pixels, hence localization of the maxima is preserved between scales $\lambda = 1$ and $\lambda = 2$ (for small $\kappa$ values, see Section III-C). B: sharp black/white transitions result in two-pixel wide boundaries, one pixel on each side of the transition, with weaker contributions further away at scale $\lambda = 2$. C: lines separated by 1 pixel are fully recognized as being part of the same texture at 1-pixel scale, hence disappear in the stochastic texture difference (STD) maps at scales $\lambda = 1$ and $\lambda = 2$. These STD values are nevertheless not null, unlike that of the uniform background, hence these patterns are grayed out instead of blanked out. Boundaries around these texture regions are detected, as in the isolated line case. D: chessboard patterns are also recognized at both scales, together with surrounding edges. The difference between the chessboard pattern and the spaced-out squares below is weakly detected in both cases, while the black/white inversion within the chessboard pattern is only visible at $\lambda = 1$. E: this repetitive pattern is better recognized at spatial scale $\lambda = 2$ and pixel value scale $\kappa = 0.25$ (the average value over a repeating block), but its elements are too isolated at scale $\lambda = 1$. The boundaries of that texture are also found at scale $\lambda = 2$. Pixels in the region below are too far apart for $\lambda \leq 2$. F: thin lines separated by 2 pixels also become part of the same texture with a surrounding edge at $\lambda = 2$, while lines separated by 3 pixels are isolated in both cases. G: The spiral center is a non-repeating pattern of lines 1 pixel apart, which can be recognized at scale $\lambda = 2$ (see the black branches within the spiral), while the spiral branches 3 pixels away are still isolated. H: the thin diagonal lines behave similarly than vertical and horizontal lines. Lines too close at either scale are merged into a unified texture with a surrounding edge.

This example clearly demonstrates the effect on changing the spatial scale $\lambda$. The next section also shows the effect of changing the data scale $\kappa$, on a real image presenting both low and large gray scale contrasts.

B. Typical behavior of the algorithm on a real image

The effect of analyzing the image at different spatial and data scales is demonstrated is Fig. 3. The classic “cameraman”
Figure 2. Reference black and white picture (left), stochastic texture differences at spatial scales of $\lambda = 1$ (center) and $\lambda = 2$ pixels (right), both with value scale $\kappa = 0.25$, averaged over 10 independent computations with $n = 500$. White stands for a null difference, black for maximum discrepancy. Capital letters markers are commented in the main text.

picture is shown in Fig. 3a. This picture presents jpeg quantization artifacts in the sky region and around the coat (A), large contrasts for the coat, the tripod and the camera handle (B), and fine grass texture with intermediate contrasts (C). Buildings in the background form another medium contrast set (D). At a very low $\kappa = 1/256$ of one gray level quantization (Fig. 3b), the STD is sensitive to small changes at that level. Boundaries are detected on jpeg artifacts and within the coat (E). On the other hand, all medium and large gray level gradients $\gg \kappa$ are ignored, as can be seen on the coat edge, camera handle and tripod (F) that have completely disappeared in this picture. The grass texture at intermediate gray level contrasts is also ignored. Conversely, setting $\kappa = 1$ in Fig. 3c and Fig. 3d, results in edges that are sensitive to large gray level differences, with the reversed situation. Buildings with intermediate contrast result in intermediate edge values (G). At $\lambda = 1$ pixel in Fig. 3c, edges are thin (H) but some jpeg quantization blocs are still faintly visible around the coat (I). This spatial scale is too low for matching the grass texture (J). With a larger $\lambda = 3$ pixels in Fig. 3d the edges become smoother (K), but jpeg artifacts are completely gone. Details of the texture finer than $\lambda = 3$ are merged (L).

The ability of an STD analysis to focus on specific scales could be very useful, for example, as a filtering guide for artifact removals (low $\kappa$) or for implementing new edge detectors (large $\kappa$).

C. Use on physical measurements with characteristic scales

The “cameraman” example demonstrates the ability of the algorithm to analyze and highlight image features at prescribed spatial and data scales. This is especially useful when dealing with physical data, for which processes occur at known scales, independently of the sampling resolution by which that process is measured (i.e. $\lambda$ is better expressed in real units rather than in pixels). As a demonstration, Fig. 4left shows remotely sensed sea surface temperature (s.s.t.), acquired in the infrared band with the MODIS instrument aboard the Terra and Aqua satellites. The covered region ranges from 15°E to 70°E in longitude and 0°S to 60°S in latitude. We use an 8-day composite image in order to remove the cloud cover. Missing data thus correspond to land masses, and is dealt with as described in Section III-D. The floating-point values of the temperature are used as input, from -1.2°C to 31.5°C. The processes we are looking for are oceanic currents, which typically induce a temperature variation of at most a few degrees, so we take a characteristic data scale of $\kappa = 1$°C. Their width is variable, between 50-100km, with transitions zones to the surrounding water of a few km, so we take an a priori spatial scale of $\lambda = 75$km. Fig. 4right shows the result of the analysis of the sea surface temperature with these
parameters, which clearly highlights the dynamics of the ocean at the prescribed scales.

V. MULTI-SCALE ANALYSIS

A. Method

The previous section presents the case where scales are chosen a priori, according to the user’s knowledge or objectives. But such information is not always available: in many cases, the goal is precisely to find what are the relevant scales to describe a data set. We thus need a methodology to identify which are the “best” scales in an image, with objective measurement criteria.

One hypothesis is that the “best” scales should identify correctly the most relevant structures in a data set, which we identify with the structures carrying most of the information. Assuming this is the case, then we propose the following methodology:

- Analyze the data for a given pair of scales $\lambda$ and $\kappa$.
- Select the 20% most discriminative points, taken to be pixels $x$ with the largest $d(x)$ STD values.
- Reconstruct the image from only these points, according to the method detailed below.
- Compare the reconstructed image with the original.

If the features are correctly determined and they indeed carry most of the information on the image, then the reconstruction should be very close to the original. This procedure can also be seen as a lossy compression of an image: information in the discarded pixels is lost and these are reconstructed from the retained pixels. Perfect features holding all the information would mean perfect restoration of the image after decompression. It should be noted that our goal is not to obtain the largest PSNR from the minimum amount of retained point, which is related topic addressed by other works in the literature [16]. Rather, we wish to use the simplest method, so that the reconstruction accuracy measures the sole influence of $\lambda$ and $\kappa$, and not their combined effect with additional reconstruction steps designed to improve the PSNR. This excludes anisotropic diffusion [17], weighting [18], exploiting dictionaries [19], etc.

Reconstruction is thus performed by minimizing a least square reconstruction error, equivalent to solving a Poisson

| Image     | Best $\lambda$ | Best $\kappa$ | min PSNR | max PSNR |
|-----------|----------------|--------------|----------|----------|
| cameraman | 1              | 0.41         | 12.0     | 28.3     |
| house     | 5.5            | 0.64         | 13.5     | 26.2     |
| lena      | 3              | 0.094        | 13.6     | 21.0     |
| seastar   | 3.5            | 0.11         | 13.7     | 18.2     |
| s.s.t.    | 7              | 0.027        | 10.8     | 23.9     |
| barbara   | 3.5            | 0.64         | 13.0     | 17.7     |

Equation [20]. More precisely, considering all pairs of neighbor valid pixels $a$ and $b$ (i.e. both are within image boundaries and without missing data), we seek the reconstructed image $J$ with pixel values $v_J \in V$ such that:

$$J = \left\{ v_J : \min_{a,b} \sum_{\lambda, \kappa} (v_J(b) - v_J(a) - g(a,b))^2 \right\}$$ (7)

Here $g(a,b) = v_I(b) - v_I(a)$ is the gradient of the original image $I$ whenever pixel $a$ is retained amongst the 20% with largest STD value, and null otherwise. This reconstruction is unique, optimal in the least square sense, and does not introduce any extra processing step on the image. It can be computed simply with sparse optimizers, such as [21]. We then add the mean of the original image that was lost in the process before comparing $J$ and $I$, and clamp pixels within the normalized $[0,1]$ interval.

In order to assert the quality of the reconstruction, we use the Peak Signal to Noise Ratio (PSNR) criterion, as defined by:

$$\text{PSNR}(I,J) = 10 \log_{10} \left( \frac{|C|}{\sum_{a \in C} (v_I(a) - v_J(a))^2} \right)$$

where $C$ is the set of common valid pixels in $I$ and $J$.

B. Results

In addition to the cameraman and sea surface temperature images, we also analyze the “lena”, “barbara”, “sea star” and “house” images, shown in Fig. 5. Their multiscale analysis maps are shown in Fig. 6 and the PSNR maxima are given in Table 1. Scales leading to better global reconstructions are clearly visible, forming distinct patterns for every picture.

Our method provides a new multi-scale analysis of an image, in order to highlight the characteristic spatial $\lambda$ and data $\kappa$ scale of its components. For example, we can see that the house picture has a maxima zone of at $\lambda = 5$ to 6 and high $\kappa$: this corresponds to the spatial extent and the contrast difference of the white borders of the roof, window frames and water drain. Other maxima are located at $\lambda$ of 1 and 1.5 pixels, with medium $\kappa$ gray scale contrast: these are the brick textures. With this method, automatically identified parameters for the sea surface temperature data are $\lambda \approx 59$ km and $\kappa \approx 0.9$°C. These are consistent with our a priori estimate in Sec. IV-C further validating our approach.
Figure 5. Classic reference images. From left to right, lena, barbara, house and sea star. We use the versions of lena, barbara and house from [22]. The sea star picture is the training example 12003 from the Berkeley segmentation data set [23]. We chose it as it presents some background texture with higher intensity spots, some blurry and some sharp edges.

Figure 6. Influence of the two scale parameters $\lambda$ and $\kappa$ on the reconstruction accuracy, measured with the peak signal to noise ratio (PSNR) as defined in the main text, when retaining 20% of the points with higher STD. Averages of 5 independent computations with $n = 100$ were used for computing the PSNR. The minimum and maximum values for the PSNR are given in Table I for each image. Using these per-image bounds, blue is the lowest accuracy, red the highest. The spatial scale $\lambda$ is given in pixels, the data scale $\kappa$ is given for $[0..1]$-normalized data values. An additional scale $\kappa \times 256$ is shown on the top to ease the interpretation of gray-scaled image results. Conversion factors for the sea surface temperature data are $\kappa \approx 0.03$ for $1^\circ$C and $\lambda \approx 1$ pixel for 3.46 km at the center of Fig. 4.

Figure 7. Erasing texture elements smaller than $\lambda = 3.5$ pixels. Left: Annotated original Barbara image. Middle: Reconstruction from 20% selected points at $\lambda = 3.5$ and $\kappa = 0.64$, corresponding to the maximum of Table I. Right: Reconstruction with 100% points but using the RKHS “texture gradient” instead of the image gradient.
C. Selective texture erasing

Similarly, the stripped patterns of the Barbara image are correctly matched on both scales. Fig. 7 shows in region A a texture of slanted stripes with a characteristic size \( \lambda < 2.5 \) and a low gray level contrast \( \kappa \). These textures are correctly detected in the PSNR map of Fig. 6 as the leftmost maxima with lower \( \lambda \) values. But the image also comprises other patterns of increasing contrast and size, as can be seen in regions B. Most of them have a characteristic size \( \lambda = 3.5 \), at which the PSNR reaches a maxima for a range of large gray scales \( \kappa \).

Fig. 7 (middle) shows that textures disappear in the reconstructed image from the 20% largest STD pixels. Some patterns, like in region C, present textures with a larger spatial extent. As was the case for the artificial image in section II, these patterns are not recognized with a smaller \( \lambda = 3.5 \), and they appear intact in the reconstruction. Our method can thus also be used for texture erasing [23], [25], preserving edges between different regions and around textured elements (D) but selectively removing all textures below a prescribed spatial scale \( \lambda \).

An alternative method is to seek the image with gradients (Eq. 7) that are as close as possible to the texture difference values (Eq. 5). Since there cannot be a linear correspondence between pixel gradients in image space and “texture gradients” in RKHS, involving a non-linear reproducing kernel, it is expected that distortions are produced in the reconstructed image, and assuming a meaningful image can be produced in the first place. Technical details for how to combine Eq. 5 into Eq. 7 are given in supplementary materials, and involve orienting the “texture gradient” with the average intensity on each side of a target pixel. Despite being necessarily imperfect, Fig. 7 (right) shows that a reconstruction can still be obtained this way, with a PSNR of 22.95 and erased textures below \( \lambda \), but with some amount of blurring. The interesting point is that the method works as intended, proving that our “texture gradient” operation in RKHS, when properly oriented, really behaves like a gradient.

VI. COLOR TEXTURE DIFFERENCES

The path generation procedure described in Section II-A makes no assumption on the nature of pixel values \( v \in \mathcal{V} \), just that sequences \( t \in \mathcal{V}^m \) can be compared with a suitable reproducing kernel. The case for scalar pixels is presented above, but the method works equally well on vector data. In this case, \( \mathcal{V} \) could be a color space, a set of spectral bands in remote sensing applications, polarized synthetic aperture radar reflectance values, or any other vector data. We deal here with the most common case of a triplet of RGB values. We first consider a kernel \( k : \mathcal{V} \times \mathcal{V} \to \mathbb{R} \) that compares two RGB triplets and produce a similarity value, then take the product space kernel in \( \mathcal{V}^m \) for comparing sequences.

Specifically, assuming \( \mathcal{V} \) is the set of all \( v = (R,G,B) \) triplets, we first consider the non-linear conversion operator \( \ell : \mathcal{V} \to \mathcal{L} \) to the CIE Lab space \( \mathcal{L} \) using the standard D65 white point. \( \ell(v) \) is thus a vector with entries \((L,a,b)\). Then, we implement the following color difference operators:

\[-\delta_1(v,w) = ||\ell(v) - \ell(w)||_E/100, \text{ based on the original intent of the Lab space to be perceptually uniform, so the norm in } \mathcal{L} \text{ should match a perceived color difference. This first formula is fast to compute.}\]

\[-\delta_2(v,w) = \Delta E(\ell(v),\ell(w))/100, \text{ based on the revised CIE DE 2000 standard [26] for producing a better perceptually uniform difference } \Delta E \text{ between two Lab triplets. This second formula is slower to compute, but presumably more accurate.}\]

The kernel between two sequences \( s,t \in \mathcal{V}^m \) is then easily adapted from Eq. 6 with the same notations:

\[k_{1,2}(s,t) = 1/\left(1 + \frac{1}{|C|} \sum_{i \in C} (\delta_{1,2}(s_i,t_i)/\kappa)^2\right)\] (8)

The data scale \( \kappa \) is now applied to the chosen \( \delta_1 \) or \( \delta_2 \) operator, in order to highlight small or large color differences. Note that we normalize \( \delta_1 \) and \( \delta_2 \) to be within \([0 . . 1]\) instead of the \([0 . . 100]\) Lab space range, so that \( \kappa \) values for the color case are comparable to the scalar case presented in the previous section.

Fig. 8 shows how the vector analysis, using either the Lab space norm or \( \Delta E \) for color matching, enhances the detected features compared to the scalar analysis on gray scale. In region A, the color difference in the top-left of the trompe-l’œil painting is well recognized in the vector analysis, but the contrast is not large enough in gray scale. The real wall and windows on the same house (B) are also much better analyzed in color, especially with the orange/beige difference. Another prominent difference is the lamp post (C) in front of the tree, which is lost in foliage details in the gray scale version but clearly contoured in the color analysis. Unlike points A and B, this effect is not only due to color contrast, but it also involves the texture difference between the lamp post and the tree foliage. Texture differencing between the two trees is clearly visible in D, where the green tree is well contoured in the color analysis, while both trees have similar textures in gray scale. The small patchs of blue sky (E) better stand out against more uniform foliage textures in the color versions, compared to the gray case where they are buried in noise. Color panels are also better recognized in F. The rainbow is not detected (G) by any of the analyses. But its slowly varying colors over a large spatial extent do not match the scales \( \lambda = 1.5 \) pixels and \( \kappa = 0.15 \) that are used here.

The effect of using the CIEDE2000 correction is visible by close inspection of the bottom images in Fig. 8. Compared to the original Lab space, the non-linear \( \Delta E \) correction gives slightly more contrast to the lower color differences, which was one of its purposes in the first place [26]. These effects are

5Assuming the gray scale perfectly matches a perceptual color intensity, then \( \kappa \) would have the same meaning in the color and the gray scale analysis. However, this is not the case, and gray scale conversion is an active topic of research [27]. Here we use the Y component of XYZ space, which is also used by The Gimp free software default’s gray conversion tool. Using the same normalized \( \kappa \), the scalar and vector analysis in Fig. 8 are thus expected to have a similar, but not exactly identical, general contrast range. On the other hand, the CIEDE2000 \( \Delta E \) formula was designed to correct slight discrepancies in the original Lab space perceptual uniformity, hence the contrast levels of the two vector analysis should be very similar, with only minor changes due to the \( \Delta E \) correction. This is what we observed in Fig. 8.
Figure 8. Texture difference analysis of a color image. Top-left: original image (full credit given in Appendix), rescaled to 600x450 pixels. Top-right: Scalar analysis using a gray version of the image. Bottom-right: Vector analysis in Lab space with the standard D65 white point. Bottom-left: Vector analysis using the CIE DE2000 perceptual color difference improvement $\Delta E$. All these analyses use the spatial scale $\lambda = 1.5$ pixels and the data scale $\kappa = 0.15$.

visible throughout the image, but maybe more clearly seen on the water (H) and stone wall (I) texture details. However, these effects are so small that, for most applications, computing $\Delta E$ may not be worth the added cost compared to working in the original Lab space.

In any case, our method provides a new way to include color information in image and texture analysis, highlighted especially by points A, B and C above. More generally, the method is applicable whenever a reproducible kernel can be defined to compare pixel elements, whether these are scalar, vector, strings, graphs, etc.

VII. CONCLUSION

We introduce a new low-level boundary detection method, based on statistical properties within the neighborhood of each pixel. We have demonstrated its use on synthetic and real images. In particular, our algorithm is able to retrieve characteristic scales in remotely sensed data. The method we present is not limited to scalar values and it is readily applicable to any kind of data for which a reproducing kernel is available. This includes vector data, and in particular color triplets. Thanks to being specified at prescribed spatial and data scales, our method implements a new kind of filter, very different from wavelet-based analysis [11] or decomposition on dictionaries [6]. For example, it can detect small discrepancies like jpeg quantization artifacts while being insensitive to large luminosity gradients, which could be useful for guided filtering of these artifacts. In the spatial domain, our method can detect repetitive texture patterns, as shown in Figs. 2 and 7 and produces a unique contour around these elements. This low-level algorithm represents textures in a statistical framework that is quite different from classic approaches like textons [7], and it also represents multi-scale information in a new framework. Our new method thus complements these techniques, and together with them has the potential to provide really new feature descriptors for images, with properties that need to be explored in future works.
**APPENDIX A: PRODUCING TEXTURE DISCREPANCY FOR MISSING DATA**

For directions tangent to an invalid data zone, half the neighborhood is valid and half is invalid, in both $S^+$ and $S^-$. This is a worst case approximation, since $N^±(o)$ is centered on the center of the valid pixel $o$, not on the edge. For such a $S^±$ pair, and replacing the neighborhood by another worst-case approximation of a binary valid/invalid choice (i.e. neglecting $m$ and the spatial extent $\lambda$ with many valid pixels in the neighborhood), the probability of never selecting a valid pair of pixels decreases exponentially as $\lambda^{2n}$ according to Eq. $3$ tending to null probability in the large $n$ limit. For a typical computation with $n = 100$, this is a ridiculously small $p \ll 10^{-3000}$ probability of an invalid result. Thus, for all practical purposes, valid pixels near an invalid boundary “always” produce a valid computation result, even for typical and small values of $n$.

In practice, even missing pixels within large missing data zones benefit from nearby valid pixels. Although we explicitly ignore these STD values due to their low accuracy, this process still allows getting relevant values for missing isolated pixels. Consider a neighborhood centered on that pixel. In that case, paths around that point may occasionally fall onto the missing pixel, but patterns are still matched outside that pixel. Since the modified kernel is normalized only on valid pixels, the valid patterns surrounding the missing pixel are still matched correctly in every direction. The price to pay is a loss of reliability as distance from a valid pixel grows. We do not exploit this feature in the data presented below, where no STD value is produced for missing pixels.

**APPENDIX B: COMBINING SCALES**

In Section III-C $\kappa$ sets the scale at which scalar pixel values are compared and should reflect a priori information on the image. [13] proposes to either take a Bayesian approach for letting $\kappa$ vary with a priori knowledge, or to take $d(S^+,S^-) = \sup_{\kappa} d_\kappa(S^+,S^-)$ over a range of $\kappa$ for a more systematic approach. We found that the latter does not perform well in practice. For example, a picture captured by a digital camera sensor in low light conditions presents some digital noise on the pixel values. A similar effect occurs for quantization noise and jpeg artifacts (see Section IV-B). Comparing distributions in $\mathcal{V}^m$ at the scale of this noise is meaningless, as it would reflect differences due to the sensor (resp. quantization algorithm) itself, but not the differences in the image textures. Given the sensor fluctuations, the distance $d_\kappa(S^+,S^-)$ at low $\kappa$ values is larger that at the natural scale of the image signal, hence the $\sup_\kappa$ approach does not work in this case. Physically, and for remotely sensed data in particular, the $\sup_\kappa$ approach amounts to mixing together different processes which have nothing to do with each other, such as the camera sensor noise and objects reflectance for the above example.

**APPENDIX C: RECONSTRUCTION FROM “TEXTURE GRADIENTS”**

For a pair of valid neighbor pixels $(a, b)$, consider the neighborhood $N^±(a)$ that includes $b$ and $N^±(b)$ that includes $a$. We add constraints in Eq. $7$ using Eq. $3$ for the gradients: $\min \sum_{a,b} (v_J(b) - v_J(a) \pm d(S^-(a),S^-(a)))^2 + (v_J(b) - v_J(a) \pm d(S^-(b),S^+(b)))^2$. The signs are determined using the average value of the original image pixels in each neighborhood: $\text{sign}(S^-(a),S^+(a)) = \text{sign}\left(\sum_{x\in N^+(a)} p(x)v_J(x) - \sum_{x\in N^-(a)} p(x)v_J(x)\right)$. and similarly for $b$. With this method, the result for $\lambda = 3.5$ and $\kappa = 0.64$ is shown in Fig. $7$ right.

**APPENDIX D: DATA AND CODE AVAILABILITY**

The code used in this paper is free software, available for download at [https://gforge.inria.fr/scm/?group_id=5803](https://gforge.inria.fr/scm/?group_id=5803) Images for Lena, Barbara, house, were fetched from [http://decsai.ugr.es/~ javier/denoise/test_images/index.htm](http://decsai.ugr.es/~ javier/denoise/test_images/index.htm) and match these used in [22]. We used the cameraman picture from McGuire Graphics Data at [http://graphics.cs.williams.edu/data/images.xml](http://graphics.cs.williams.edu/data/images.xml) The sea star is the training sample 12003 from the Berkeley segmentation S300 data set [23] and was downloaded from [http://www.eecs.berkeley.edu/Research/Projects/CS/Vision/bsd/BSDS300/html/dataset/images/gray/12003.html](http://www.eecs.berkeley.edu/Research/Projects/CS/Vision/bsd/BSDS300/html/dataset/images/gray/12003.html) The color image in Fig. $8$ comes from Wikimedia Commons, at [http://commons.wikimedia.org/wiki/File:2013-10-19_10-53-16-savoureuse-belfort.jpg](http://commons.wikimedia.org/wiki/File:2013-10-19_10-53-16-savoureuse-belfort.jpg) This long exposure photograph was taken by Thomas Bresson with a polarizing filter, and released under Creative Commons - Attribution - 3.0. The original image was cropped and resized to $600 \times 450$ pixels.

**ACKNOWLEDGEMENTS**

We thank Hicham Badri for useful discussions and examples of image reconstruction with the Poisson equation.
