ABSTRACT: Biochemical studies of purified and dissected fungal polyketide synthase and nonribosomal peptide synthetase (PKS-NRPS) hybrid enzymes involved in biosynthesis of pseurotin and aspyridone indicate that one α-methylation step during polyketide synthesis is a prerequisite and a key checkpoint for chain transfer between PKS and NRPS modules. In the absence of the resulting γ-methyl feature, the completed polyketide intermediate is ofﬂoaded as an α-pyrole instead of being aminocacylated by the NRPS domain. These examples illustrate that precisely timed tailoring domain activities play critical roles in the overall programming of the iterative PKS (and NRPS) functions.

Ungal polyketide synthase-nonribosomal peptide synthetase (PKS-NRPS) hybrid enzymes involved in biosynthesis of pseurotin and aspyridone indicate that one α-methylation step during polyketide synthesis is a prerequisite and a key checkpoint for chain transfer between PKS and NRPS modules. In the absence of the resulting γ-methyl feature, the completed polyketide intermediate is ofﬂoaded as an α-pyrole instead of being aminocacylated by the NRPS domain. These examples illustrate that precisely timed tailoring domain activities play critical roles in the overall programming of the iterative PKS (and NRPS) functions.
standard (Figure 2a). Removal of PsoG, which is responsible for hydroxylation of the spirocycle to yield 2, led to the production of two compounds 7 and 8 with the same molecular formula (C21H23NO4, m/z 354 [M + H]+, Figures S2 and S3, Supporting Information), both of which have similar UV absorption spectra as 2. Although the structures of these compounds were not determined due to low abundance, we putatively assigned one of the two compounds to be the spirocyclic compound as shown in Figure 1b. This intermediate can be derived from the 5-exo epoxide opening of 6. Formation of the epoxide intermediate 6 from the tetramic acid intermediate 5 is proposed to be catalyzed by the FMO domain of PsoF. Removal of PsoF or excision of the MT domain of PsoF led to complete loss of product accumulation at selected ion monitoring detection limits (Figure S2, iv and v, Supporting Information). The yeast reconstitution experiment is therefore consistent with the genetic analyses in A. fumigatus and demonstrates that recombinant PsoA retained the expected programming rules.

The yeast reconstitution results also confirmed a distinguishing biochemical feature of PsoA compared to other known PKS-NRPS, which is the incorporation of a propionyl starter unit that is reflected in 1 and 2. All characterized fungal HRPKSs are primed with acetyl unit which can either be derived from acetyl-CoA directly or through the decarboxylation of malonyl-CoA. The incorporation of a propionyl starter unit therefore points to unexpected level of programming rules by PsoA. In other PKS systems where different starter units are incorporated, additional enzymatic machineries, such as starter unit acyltransferase, are typically present.

Figure 1. Methylation-dependent acyltransfer by fungal PKS-NRPS. (a) Selected γ-methylation containing polyketide–nonribosomal peptide natural products produced from fungi. The final position of the γ-methyl group in the polyketide portion is boxed. (b) Proposed biosynthetic pathway of azaspirene 2 and preaspyridone 3 illustrating the key γ-methyl containing intermediates 4 and 9, respectively. The KS domain of PsoA and ApdA use propionyl-CoA and malonyl-CoA as the starter unit to initiate polyketide synthesis, respectively. Domains labeled with 0 are nonfunctional and are complemented with in trans partners. The white arrow represents one round of Claisen-like chain elongation catalyzed by the KS domain.

Figure 2. Analysis of PsoA functions in S. cerevisiae and in vitro. (a) ESI-MS analyses of reconstitution of azaspirene 2 biosynthesis in BJ5464-NpgA: (i) untransformed BJ5464-NpgA control; (ii) BJ5464-NpgA transformed with vectors that encode PsoA, PsoB, PsoF, and PsoG; (iii) authentic standard of 2. (b) LC-MS analyses of in vitro reconstitution of PsoA, PsoF, and PsoB with selected cofactors and building blocks. All assays are performed with PsoA, NADPH, and malonyl-CoA in the presence of (i) propionyl-CoA; (ii) no additional substrate; (iii) propionyl-CoA, L-Phe and ATP; (iv) propionyl-CoA, PsoF and SAM; (v) propionyl-CoA, PsoF, L-Phe and ATP; (vi) propionyl-CoA, PsoF, SAM, L-Phe, and ATP; and (vii) propionyl-CoA, PsoF, SAM, L-Phe, ATP and PsoB. (c) Pyrone products 10–12 released from PsoA.

to facilitate the priming step. To examine this unusual feature of PsoA, as well as the importance of γ-methyl in 4 on PsoA function, the intact PKS-NRPS (436 kDa) was purified to homogeneity at 3 mg/L (Figure S1, Supporting Information) and subjected to assays in the presence of different combinations of substrates, cofactors, and accessory enzymes.

We first examined the effect of various alkyl acyl-CoA on the priming and catalytic iterations of PsoA. In the absence of L-Phe that is required for acyl transfer to the NRPS module, we observed the emergence of a pair of products of the in vitro assay (Figure 2b, vii), suggesting that priming and catalytic iterations of PsoA. In the absence of L-Phe identical to that of 8 was also included, we observed the emergence of a pair of reactions in the presence of di m/z propionyl-CoA, 1 mM malonyl-CoA, and 2 mM NADPH, we observed efficient production of an unsaturated α-pyrene 10 (m/z 193 [M + H]+, Figure 2b, i). The λmax (344 nm) of 10 is identical to that of 11, which was previously characterized and structurally verified.4a,10a The incorporation of four malonyl-extend units in 10 was verified through the incorporation of [2,13C]malonyl-CoA and the corresponding increase in mass of 10 by 4 amu (Figure S4, Supporting Information). This suggested that PsoA alone is able to incorporate the propionyl starter unit. The formation of 10 also shows that unmethylated tetraketide can be chain-extended by the PKS module to form γ-desmethyl version of 4. Hence this methylation step has no direct effect on the functions of the PKS module. When propionyl-CoA was removed, the production of 10 was replaced with 11, albeit with significantly lower turnover (Figure 2b, ii). Incubation of PsoA with acetyl-, isobutryl-, hexanoyl-, and octanoyl-CoA similarly led to the production of differently primed pyrone products, albeit at much lower yields compared to that of 10 (Figures S4 and S5, Supporting Information). A competition assay of PsoA in the presence of equimolar amounts of different acyl-CoAs led to the near-exclusive formation of 10 (Figure S4, Supporting Information), confirming that PsoA indeed preferentially uses the C3 starter unit to initial polyketide synthesis.

Intriguingly, additional L-Phe to the reaction with propionyl-CoA still resulted in the formation of 10 (Figure 2b, iii), and no phenylalanine-containing product was formed by PsoA. This points to the failure of the NRPS module to recognize the polyketide product that is unmethylated at the γ-position. Base hydrolysis or inclusion of PsoB, a hydrolase that was implicated to aid the release of aldehyde product, similarly did not lead to detection of any aminocacylated products. This is consistent with our initial hypothesis that the γ-methyl group present in the PKS product 4 may be essential in facilitating chain transfer between the PKS and NRPS modules.

We then examined the effect of including PsoF in the reaction. In the absence of L-Phe, addition of PsoF and SAM (1 mM) to the assay led to the production of a new pyrone 12 (Figure 2b, iv), which has the same λmax as 10, but with an increase in molecular weight of 14 mu that is consistent with the incorporation of an additional methyl group. MS/MS fragmentation analysis supports 12 as the 4-methylpyrone product (Figure S6, Supporting Information), which can be spontaneously cyclized from the PKS product 4. When L-Phe was also included, we observed the emergence of a pair of compounds that has the same retention time and masses as 7 and 8 observed from the in vivo studies extracts (Figure 2b, vi, and Figure S2, Supporting Information). Further inclusion of PsoB led to the production of 7 and 8 as the dominant products of the in vitro assay (Figure 2b, vii), suggesting that the PsoA enzymatic machinery is fully functional under the in vitro conditions. Due to difficulties associated with reconstituting the integral membrane protein PsoG in vitro, we were not able to achieve the complete biosynthesis of 2 in vitro.

The PsoA assays therefore strongly indicate methylation by PsoF on the polyketide precursor is critical in chain transfer to the NRPS module. To prove this, a direct assay with the NRPS module using the S-NAC version of 4 would be unambiguous.13 However, the 1,3,5-triketo moiety in 4 makes the acyl-S-NAC derivative intrinsically unstable and can rapidly undergo pyrone formation to yield 12. In the absence of proper substrates to interrogate NRPS gatekeeping functions, we turned to using the ApdA PKS-NRPS from the aspyridone pathway4 to examine whether γ-methyl dependent chain transfer is present in other fungal PKS-NRPSs.

ApdA synthesizes the tetracyclic acid preaspyridone 3 en route to aspyridine in A. nidulans (Figure 1b).4 The function of PKS-NRPS was previously reconstituted in vitro in which we showed the PKS module synthesizes a 4,6-dimethyl-3-oxooctanoyl 9 precursor that is aminocacylated with L-tyrosine by the NRPS module. We showed that similar to PsoA, exclusion of SAM (hence eliminating the MT function) did not lead to unmethylated version of 3.4a Given that the acyl-S-NAC compounds mimicking 9 are synthetically accessible, the ApdA NRPS serves as an excellent model system for confirming the γ-methyl dependent acyl transfer hypothesized for the PsoA and ApdA systems.

We tested the acyl transfer with a panel of linear (13a–c)14 and β-oxoacyl-γ-methyl-S-NAC substrates (14a–c) ranging in size between C7 and C9 (Figure 3) as variants of 9, the natural substrate of ApdA NRPS. Compounds 14a–c were synthesized and subjected to assays in the presence of di

![Figure 3. LC–MS analyses of the reactions of ApdA NRPS module supplied with various S-NAC substrates. (i–iii) Tetracyclic acid products were detected when β-ketoacyl-γ-methyl S-NAC (14a–c) were supplied as substrates; (iv–vi) no product was formed when β-ketoacyl S-NAC (13a–c) were used as substrates.](image-url)
from α-methyl carboxylic acids, via the corresponding α-methylacyl-Meldrum’s acids (Supporting Information, Figure S7–9). Each substrate was supplied to the recombinant ApdA NRPS module together with L-tyrosine and ATP. Each of 14a–Mc supported the synthesis of a new tetramic acid product (15a–Mc) that has the same UV absorption as 3 (Figure 3, i–iii; Figure S10, Supporting Information). The different retention times of the products are also consistent with the chain length of the supplied precursors. In contrast, no tetramic acid was observed when the linear precursors 13a–Mc were used (Figure 3, iv–vi). These results therefore confirmed that the γ-methyl present in 9 is essential for substrate recognition by the ApdA NRPS module, a property that may be shared by the PsoA NRPS toward 4. The ApdA NRPS, however, is not sensitive to the ϵ-methyl substitution present in the natural substrate 9, thereby pinpointing the gatekeeping recognition to the γ position. Although the NRPS displays preferential recognition toward the substrate 14b that is the same chain length as 9, overall the NRPS displayed considerable chain length tolerances, converting both the shorter C7 substrate 14c and the longer C9 substrate 14a to the corresponding tetramic acid product. The conversion of shorter methylated triketide (C6) substrate was not observed. This is consistent with the intact ApdA assay, where no acyl transfer of the earlier intermediate toward the substrate was not observed. This is consistent with the intact product. The conversion of shorter methylated triketide (C6) ε-methylation steps are programmed to serve as biochemical checkpoints or if the resulting methyl groups play essential roles in natural product functions.
