Received 8 July 2010; revised 30 September 2010; accepted 6 October 2010

Objectives
To propose standardized consensus definitions for important clinical endpoints in transcatheter aortic valve implantation (TAVI), investigations in an effort to improve the quality of clinical research and to enable meaningful comparisons between clinical trials. To make these consensus definitions accessible to all stakeholders in TAVI clinical research through a peer reviewed publication, on behalf of the public health.

Background
Transcatheter aortic valve implantation may provide a worthwhile less invasive treatment in many patients with severe aortic stenosis and since its introduction to the medical community in 2002, there has been an explosive growth in procedures. The integration of TAVI into daily clinical practice should be guided by academic activities, which requires a harmonized and structured process for data collection, interpretation, and reporting during well-conducted clinical trials.

Methods and results
The Valve Academic Research Consortium established an independent collaboration between Academic Research organizations and specialty societies (cardiology and cardiac surgery) in the USA and Europe. Two meetings, in San Francisco, California (September 2009) and in Amsterdam, the Netherlands (December 2009), including key physician experts, and representatives from the US Food and Drug Administration (FDA) and device manufacturers, were focused on creating consistent endpoint definitions and consensus recommendations for implementation in TAVI clinical research programs. Important considerations in developing endpoint definitions included (i) respect for the historical legacy of surgical valve guidelines; (ii) identification of pathophysiological mechanisms associated with clinical events; (iii) emphasis on clinical relevance. Consensus criteria were developed for the following endpoints: mortality, myocardial infarction, stroke, bleeding, acute kidney injury, vascular complications, and prosthetic valve performance. Composite endpoints for TAVI safety and effectiveness were also recommended.

Conclusion
Although consensus criteria will invariably include certain arbitrary features, an organized multidisciplinary process to develop specific definitions for TAVI clinical research should provide consistency across studies that can facilitate the

†The Valve Academic Research Consortium (VARC) consists of representatives from several independent Academic Research Organizations, several Surgery and Cardiology Societies, members of the U.S. Food and Drug Administration, and several independent experts (Appendices 1 and 2).

Introduction

Since the introduction of transcatheter aortic valve implantation (TAVI) in 2002, there has been increasing interest in the field of catheter-based treatment of high-surgical-risk patients with symptomatic aortic stenosis (AS). Introduction of this new technology should ideally follow the standard bench-to-bedside evidence-based medicine pattern, starting with pre-clinical testing and advancing to clinical investigations. Unfortunately, the explosive growth of TAVI (Figure 1) has created a ‘clinical data conundrum’: investigators were not prepared to optimally organize and interpret clinical data for this radically different treatment, rendering thoughtful assessment of clinical trial outcomes difficult and inter-study results comparisons problematic.

Surgical valve clinical research guidelines have been developed using a more traditional ‘multi-society approach’, have been revised approximately every 10 years, incorporate not merely clinical endpoints but also issues such as structural valve deterioration and non-structural valve dysfunction, and often divide clinical events into those that are valve and non-valve related. Interventional cardiology has a tradition of agreed upon clinical endpoint definitions and clinical trial methodologies, and recently has incorporated a consensus process to standardize key endpoint definitions by convening an Academic Research Consortium (ARC) among Academic Research Organizations (AROs) from the USA and Europe joined by representatives from the USFDA and device manufacturers. The ARC process demonstrated the power of a well-managed international goal-directed academic consortium collaborating effectively with the FDA and industry to establish consensus clinical endpoint definitions and to improve the conduct of clinical research.

In the spirit of the ARC-mission statement, the ‘Valve Academic Research Consortium’ (VARC) was organized as an amalgam of the ARO and multi-society guideline models with strong participation from independent experts, the FDA, and medical device manufacturers (Appendices 1 and 2). Two in-person meetings on 19 September 2009 in San Francisco, CA and on 5–6 December 2009 in Amsterdam, the Netherlands, involving VARC study group members and invited guests (including the FDA and industry representatives) provided much of the substantive discussion from which this consensus manuscript was derived.

The goals of VARC are to combine the expertise of surgeons, interventionalists, medical cardiologists, clinical trialists, and other specialists (representing relevant disciplines including echocardiography, vascular medicine, and neurology) to arrive at a consensus for (i) selecting appropriate clinical endpoints reflecting device, procedure and patient-related effectiveness and safety, and (ii) standardizing definitions for single and composite clinical endpoints.

Importantly, this first consensus manuscript was not intended as a ‘guidelines statement’ or a ‘guidance document’, but rather should be viewed as a roadmap to facilitate the standardization of future TAVI and other aortic valve clinical research.
Principles for selecting and defining clinical endpoints for transcatheter aortic valve implantation investigations: general considerations

Criteria for endpoint definitions
The definitions of major clinical endpoints must follow a multi-step thought process.

- Each major endpoint should address issues that establish either the safety and/or the effectiveness of the proposed new therapy.
  - Safety is characterized by the avoidance of device-related or procedural complications.
  - Effectiveness is a more complex descriptor, as it encompasses both the avoidance of negative disease-related outcomes and objective measures of clinical functional benefit.
- The endpoints should relate short- and long-term pathophysiological mechanisms to meaningful clinical events.
- Endpoint definitions must be consistent with the body of published literature, but still reflect unique or evolving aspects of the new therapy.
- The emphasis should be on definitions that accurately represent essential patient-oriented clinical outcomes.
- The endpoints must be well defined (preferably through blinded adjudication processes) such that they can be subjected to statistical analysis.

It is helpful to reference a standardized definition format regarding (i) the specific treatment, (ii) the place of occurrence, (iii) the time of occurrence, and (iv) the specific type of endpoint.

Device, procedure, and patient-oriented outcomes
Endpoint definitions for TAVI will in most cases be characterized in relation to the specific implant device, the implant procedure, and the resultant patient-oriented outcomes, which can occur at any time after the procedure. During the early phases of therapy development, particular attention must be directed to the safety and performance of the device. Therefore, VARC tries to strike a compromise by also elucidating device and procedure-related events, which are essential to the understanding of a new class of catheter-based therapies.

Since TAVI is fundamentally the placement of a prosthetic aortic valve and will be compared with surgical aortic valve replacement (AVR), tradition should be respected and crucial endpoints such as all-cause mortality and device durability must be assessed longitudinally for the life of the implant. However, primary clinical endpoints used in pivotal clinical trials for regulatory approval of TAVI devices should incorporate a shorter time domain of 1 to 2 years after the index procedure. These recommended shorter time horizons should not discourage the standard long-term follow-up procedures for prosthetic heart valves.

Proposed safety and efficacy endpoints

Mortality
All-cause mortality in surgical clinical trials has become the ‘gold standard’ in previously published consensus and guideline documents. The advantage of reporting all-cause mortality is that it is both objective (without bias) and pragmatic from the standpoint of ascertainment and adjudication. However, the use of all-cause mortality in high-risk TAVI patients may be misleading, resulting in disproportionate reporting of mortal events unrelated to either the treatment device or the procedure. Therefore, VARC proposes to use all-cause mortality as a primary clinical endpoint, but also recommends further subdivision of mortality, specifically denoting cardiovascular mortality as an important secondary endpoint (Table 1). Of note, ‘unknown’ deaths should be considered as cardiovascular in origin and to improve the ascertainment of death, the social security death index or national death registries should be utilized in cases of patients lost to follow-up.

Consistent with surgical guidelines and surgical clinical trial practices, mortality should be formally assessed and reported at 30 days after the index procedure (or longer if the patient was not discharged from the treatment hospital or a secondary convalescent facility). Since there may be either unknown or under-reporting of early device failure modes, a more appropriate duration for all-cause mortality as a primary endpoint in TAVI clinical trials is 1 year after the index procedure. After 1 year, mortality should be recorded at yearly intervals for a minimum of 5 years, or ideally, for the duration of the prosthetic valve implant, in the form of well-defined post-approval surveillance registries.

Myocardial infarction
In 2007, the joint ESC/ACC/AHA/WHF task force for the redefinition of Myocardial infarction (MI) established diagnostic criteria and updated guidelines for a universal MI definition to be used in clinical trials. This universal MI definition is highly sensitive, relying heavily on the measurement of cardiac biomarkers (preferably troponin). Conversely, surgical valve guidelines have adopted a

| Table 1 Mortality |
|-------------------|
| **Cardiovascular mortality** |
| Any one of the following criteria: |
| - Any death due to proximate cardiac cause (e.g. MI, cardiac tamponade, worsening heart failure) |
| - Unwitnessed death and death of unknown cause |
| All procedure-related deaths, including those related to a complication of the procedure or treatment for a complication of the procedure |
| Death caused by non-coronary vascular conditions such as cerebrovascular disease, pulmonary embolism, ruptured aortic aneurysm, dissecting aneurysm, or other vascular disease |
Many patients have coexistent aortic valve and coronary artery MIs, unless the MI was caused by a coronary embolus.12 A ‘minimalist’ approach to MI definitions, usually ignoring biomarker diagnoses and excluding both intra-operative and post-operative MIs, unless the MI was caused by a coronary embolus.12 Valve Academic Research Consortium proposes a more ‘centrist’ approach to MI definitions after TAVI, recognizing that many patients have coexistent aortic valve and coronary artery disease,15 which requires an MI definition that does not exclude peri-procedural or late MIs that may impact patient outcomes. Valve Academic Research Consortium proposes to define peri-procedural MI as an acute ischaemic event that is associated with documented and/or evidence of fresh thrombus by coronary angiography and/or at autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood. Spontaneous MI (>72 h after the index procedure) Any one of the following criteria: Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile URL, together with evidence of myocardial ischaemia with at least one of the following: ECG changes indicative of new ischaemia [new ST-T changes or new left bundle branch block (LBBB)]. New pathological Q waves in at least two contiguous leads Imaging evidence of new loss of viable myocardium or new wall motion abnormality Sudden, unexpected cardiac death, involving cardiac arrest, often with symptoms suggestive of myocardial ischaemia, and accompanied by presumably new ST elevation, or new LBBB, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood. Pathological findings of an acute myocardial infarction. **Table 2** Myocardial infarction Peri-procedural MI (≥72 h After the index procedure) New ischaemic symptoms (e.g. chest pain or shortness of breath), or new ischaemic signs (e.g. ventricular arrhythmias, new or worsening heart failure, new ST-segment changes, haemodynamic instability, or imaging evidence of new loss of viable myocardium or new wall motion abnormality). AND Elevated cardiac biomarkers (preferably CK-MB) within 72 h after the index procedure, consisting of two or more post-procedure samples that are >6–8 h apart with a 20% increase in the second sample and a peak value exceeding 10x the 99th percentile upper reference limit (URL), or a peak value exceeding 5x the 99th percentile URL with new pathological Q waves in at least two contiguous leads. Spontaneous MI (>72 h after the index procedure) Any one of the following criteria: Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile URL, together with evidence of myocardial ischaemia with at least one of the following: ECG changes indicative of new ischaemia [new ST-T changes or new left bundle branch block (LBBB)]. New pathological Q waves in at least two contiguous leads Imaging evidence of new loss of viable myocardium or new wall motion abnormality Sudden, unexpected cardiac death, involving cardiac arrest, often with symptoms suggestive of myocardial ischaemia, and accompanied by presumably new ST elevation, or new LBBB, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood. Pathological findings of an acute myocardial infarction.

Stroke

Recently, two reports have indicated a high frequency of new perfusion abnormalities (presumably embolic) detected by diffusion-weighted magnetic resonance imaging (MRI) studies soon after TAVI,16,17 although the clinical significance of these early perfusion defects remains unclear. Strokes during and after TAVI may occur due to embolic events from multiple sources, procedure-related aortic dissections, ischaemia from hypotension, or haemorrhagic complications associated with adjunctive pharmacotherapy. Insights on stroke definitions are in a state of evolution and VARC examined viewpoints derived from several sources, including recent multi-society consensus documents12,18,19 and multi-center randomized trials, in which stroke was an important endpoint.20–29 Valve Academic Research Consortium considered five important issues in arriving at clinically relevant stroke definitions, as follows: (i) a clinical diagnosis of stroke which ruled out metabolic or toxic encephalopathy, pharmacological influences, and non-central neurological symptoms, (ii) the role of neuroimaging studies for confirmation of the diagnosis, (iii) the distinction of stroke vs. transient ischaemic attack (TIA) (including timing), (iv) categorization of stroke into major and minor events based on the degree of disability as defined by conventional neurological assessment tools, and (v) sub-classification of strokes into haemorrhagic, ischaemic, and undetermined categories. Table 3 outlines the diagnostic criteria and specific definitions for TIA and stroke as proposed by VARC. There is growing acceptance that neuroimaging is an important biomarker for the diagnosis of neuronal injury and stroke,18,19 and diffusion-weighted MRI is generally considered the procedure of choice in the context of acute neurological syndromes.30 If a stroke is reported without evidence of confirmation of the diagnosis by the methods outlined in Table 3, the event may still be considered a stroke on the basis of the clinical presentation alone, but formal adjudication by qualified neurologists who are members of, or consultants to, a clinical events committee is mandatory. Patients with a global encephalopathy will not be reported as a stroke without unequivocal neuroimaging findings. Diagnosis of stroke in patients with a previously documented neurological deficit is more problematic and requires clinical assessment by a neurologist accompanied by appropriate new CT or MRI findings. In patients with a previous stroke and persistent neurological deficits, baseline pre-treatment neurological consultation and neuroimaging studies are recommended. The earliest time of new neurological symptoms is defined as the time of onset of the stroke or TIA. When a patient awakens or begins responding (if previously unconscious) after the index
procedure with obvious new signs of a neurological deficit, the stroke or TIA is considered to have occurred during the index procedure. The diagnosis of a transient ischemic attack (TIA) is considered to have occurred during the index procedure with obvious new signs of a neurological deficit, the final determination of major vs. minor stroke will be adjudicated by the neurology members of the clinical events committee. The Modified Rankin Score will be further stratified into ischaemic, haemorrhagic, or undetermined origin utilizing newly proposed definitions by an FDA consensus panel. Ischaemic stroke is defined as an acute symptomatic episode of focal or global cerebral, spinal, or retinal dysfunction caused by an infarction of central nervous system tissue. Haemorrhagic stroke is an acute symptomatic episode of focal or global cerebral or spinal dysfunction caused by a non-traumatic intraparenchymal, intraventricular, or subarachnoid haemorrhage. An undetermined stroke is a stroke with insufficient information to allow categorization as either of ischaemic or haemorrhagic origin. 

### Table 3 Stroke

| Stroke diagnostic criteria | Stroke definitions |
|---------------------------|-------------------|
| Rapid onset of a focal or global neurological deficit with at least one of the following: change in level of consciousness, hemiplegia, hemiparesis, numbness or sensory loss affecting one side of the body, dysphasia or aphasia, haemianopia, amnesia or amnestic fugax, or other neurological signs or symptoms consistent with stroke. | Transient ischaemic attack: New focal neurological deficit with rapid symptom resolution (usually 1–2 h), always within 24 h |
| Duration of a focal or global neurological deficit ≥ 24 h; OR < 24 h, if therapeutic intervention(s) were performed (e.g., thrombolytic therapy or intracranial angioplasty); OR available neuroimaging documents a new haemorrhage or infarct; OR the neurological deficit results in death. | Neuroimaging procedure (MR or CT scan or cerebral angiography) |
| No other readily identifiable non-stroke cause for the clinical presentation (e.g., brain tumour, trauma, infection, hypoglycaemia, peripheral lesion, pharmacological influences). | Lumbar puncture (i.e. spinal fluid analysis diagnostic of intracranial haemorrhage) |

**a** Patients with non-focal global encephalopathy will not be reported as a stroke without unequivocal evidence based upon neuroimaging studies. **b** Modified Rankin Score assessments should be made by qualified individuals according to a certification process. If there is discordance between the 30 and 90 day Modified Rankin Scores, a final determination of major vs. minor stroke will be adjudicated by the neurology members of the clinical events committee.

### Table 4 Bleeding

| Life-threatening or disabling bleeding |
|--------------------------------------|
| Fatal bleeding OR                    |
| Bleeding in a critical area or organ, such as intracranial, intraspinal, intracerebral, or periarterial necessitating pericardiocentesis, or intramuscular with compartment syndrome OR |
| Bleeding causing hypovolemic shock or severe hypotension requiring vasopressors or surgery OR |
| Overt source of bleeding with drop in haemoglobin of ≥ 5 g/dL or whole blood or packed red blood cells (RBCs) transfusion ≥ 4 units |

| Major bleeding |
|----------------|
| Overt bleeding either associated with a drop in the haemoglobin level of at least 3.0 g/dL or requiring transfusion of two or three units of whole blood/RBC AND |
| Does not meet criteria of life-threatening or disabling bleeding |

| Minor Bleeding |
|----------------|
| Any bleeding worthy of clinical mention (e.g., access site haematoma) that does not qualify as life-threatening, disabling or major |

**Minor strokes** should be adjudicated by the neurology members of the clinical events committee. For the purposes of clinical trial endpoints, VARC advocates that only major strokes should be considered as an important safety endpoint, however, all neurological events should be reported as adverse events.

Stroke will be further stratified into ischaemic, haemorrhagic, or undetermined origin utilizing newly proposed definitions by an FDA consensus panel. Ischaemic stroke is an acute symptomatic episode of focal cerebral, spinal, or retinal dysfunction caused by an infarction of central nervous system tissue. Haemorrhagic stroke is an acute symptomatic episode of focal or global cerebral or spinal dysfunction caused by a non-traumatic intraparenchymal, intraventricular, or subarachnoid haemorrhage. An undetermined stroke is a stroke with insufficient information to allow categorization as either of ischaemic or haemorrhagic origin.

### Bleeding complications

Bleeding is a critical safety endpoint in evaluating contemporary pharmacological agents and interventional devices. Valve Academic Research Consortium carefully reviewed several literature sources including (i) landmark clinical trials assessing the effects of anti-thrombotic medications in stable and acute coronary syndromes; (ii) a report by the Control of Anticoagulation Subcommittee of the International Society on Thrombosis and Haemostasis; and (iii) surgery guidelines after cardiac valve procedures.

The definition of clinically meaningful bleeding was guided by the following principles: (i) the definition must be based on objective criteria, including an obvious source of bleeding or number of transfusions; (ii) serious or meaningful bleeding must result in death, be life-threatening, be proven to be associated with...
Acute kidney injury

The natural history of acute kidney injury (AKI) in a variety of clinical settings is now well understood, including the recognition that even small decreases in kidney function can have a dramatic impact on the risk for subsequent mortality. In recent reports, AKI has been observed in 12–28% of patients undergoing TAVI and was associated with a four times higher post-procedural mortality.

In defining the stages of AKI, VARC proposes adopting serum creatinine criteria from the ‘modified’ RIFLE (Risk, Injury, Failure, Loss, and End-stage kidney disease) classification (Table 5). The RIFLE classification has been validated in the setting of intensive care units and cardiac surgery and provides practical definitions for early stages of renal dysfunction when kidney injury can still be prevented, as well as stages when the kidney has already been damaged and renal failure is established. Modifications of the original RIFLE classification include two important changes: (i) smaller changes in serum creatinine (0.3 mg/dL) are included in stage 1 (‘Risk’), (ii) the ‘Loss’ and ‘End-stage kidney disease’ categories have been removed due to a lack of uniform indications and timing of renal replacement therapy (RRT) and variability in RRT resources in different countries. An outer bound of 72 h from the index procedure for diagnosing AKI was selected based on evidence that adverse outcomes were observed when the elevation occurred within 24 to 48 h of the procedure and to ensure that the process was both acute and related to the procedure itself rather than as a consequence of post-procedural multi-organ system failure. Risk, Injury, Failure, Loss, and End-stage kidney disease classifications also stress the predictive value of urine output criteria in defining AKI, but VARC has not included this measure in the definition of AKI since urine outputs may not be measured accurately or routinely in all cases.

Valve Academic Research Consortium proposes to utilize the modified RIFLE classification to (i) capture even the earliest stages of AKI (stage 1) on case report forms, (ii) define AKI as either stage 2 or 3, and (iii) report any case of RRT (haemodialysis, peritoneal dialysis, or haemofiltration) occurring during the index hospitalization or within 30 days after the index procedure. Given the well-recognized damaging impact of contrast media on renal function, VARC also recommends to report the volume and type of contrast medium used during the index procedure.

Vascular complications

Recent TAVI literature indicates that major vascular complications using various non-standardized definitions (e.g. with or without including the need for blood transfusions) occur at a frequency of 4–34% and are associated with a two- or three-fold higher 30-day mortality. In defining vascular complications, VARC referenced the reporting standards of the Society of Vascular Surgery for defining and reporting vascular complications following endovascular aortic graft repair procedures.

Valve Academic Research Consortium proposes to report both major and minor vascular complications, but to only consider major vascular complications as an important clinical endpoint. Of note, the ‘access site’ is defined as any location (arterial or venous) traversed by a guide-wire, a catheter or a sheath [including the left ventricular (LV) apex and the aorta] and ‘access related’ is defined as any adverse clinical consequence possibly associated with any of the access sites used during the procedure. The VARC definitions for major and minor vascular complications are described in Table 6.

Many vascular situations require special notice. Femoral vascular access and closure in many centers is routinely achieved using surgical cut-down procedures, and therefore, pre-planned surgical access and/or closure should be considered as part of the procedure and not as a complication. Similarly, uncomplicated non-femoral (e.g. retroperitoneal, iliac, subclavian, or aortic) surgical access for sheath entry (planned or unplanned) is not considered a vascular complication, unless untoward clinical consequences are documented (e.g. bleeding complications). However, interventional or surgical repair for failed percutaneous closure of the arteriotomy site during the index procedure without other clinical sequelae (Table 6) is considered a minor vascular complication. Considering the recent proliferation of vascular access approaches and the recognition that specific access sites and techniques may be associated with either increased or decreased complications,
### Table 6  Vascular access site and access-related complications

| Major vascular complications |
|------------------------------|
| Any thoracic aortic dissection |
| Access site or access-related vascular injury (dissection, stenosis, perforation, rupture, arterio-venous fistula, pseudoaneurysm, haematoma, irreversible nerve injury, or compartment syndrome) leading to either death, need for significant blood transfusions (≥4 units), unplanned percutaneous or surgical intervention, or irreversible end-organ damage (e.g. hypogastric artery occlusion causing visceral ischaemia or spinal artery injury causing neurological impairment) |
| Distal embolization (non-cerebral) from a vascular source requiring surgery or resulting in amputation or irreversible end-organ damage |

| Minor vascular complications |
|------------------------------|
| Access site or access-related vascular injury (dissection, stenosis, perforation, rupture, arterio-venous fistula or pseudoaneuysms requiring compression or thrombin injection therapy, or haematomas requiring transfusion of ≥2 but <4 units) not requiring unplanned percutaneous or surgical intervention and not resulting in irreversible end-organ damage |
| Distal embolization treated with embolectomy and/or thrombectomy and not resulting in amputation or irreversible end-organ damage |
| Failure of percutaneous access site closure resulting in interventional (e.g. stent-graft) or surgical correction and not associated with death, need for significant blood transfusions (≥4 units), or irreversible end-organ damage |

VARC strongly recommends that detailed information is recorded on the access site and technique for each procedure.

A special circumstance relates to complications associated with the left-ventricular apex site during transapical TAVI procedures. Although such complications are less frequent than transarterial vascular complications, a recent report indicates that the clinical consequences (including death) can be more serious.89 Major complications associated with transapical TAVI procedures include bleeding, pseudoaneurysm formation (with or without rupture), and haemodynamic instability requiring urgent transarterial cardio-pulmonary bypass support. Valve Academic Research Consortium proposes that all such complications associated with transapical TAVI be reported in case report forms and that clinical consequences resulting from such complications be registered under the appropriate clinical endpoints (e.g. bleeding, stroke, mortality).

### Table 7  Potential failure modes of prosthetic valve dysfunction

| Aortic stenosis |
|----------------|
| Stent creep |
| Pannus |
| Calcification |
| Support structure deformation (out-of-round configuration), under-expansion, fracture, or trauma (cardio-pulmonary resuscitation, blunt chest trauma) |
| Mal-sizing (prosthesis-patient mismatch) |
| Endocarditis |
| Prosthetic valve thrombosis |
| Native leaflet prolapse impeding prosthetic leaflet motion |

| Aortic regurgitation |
|---------------------|
| Pannus |
| Calcification |
| Support structure deformation (out-of-round configuration), recoil, under-expansion, fracture, insufficient radial strength, or trauma (cardio-pulmonary resuscitation, blunt chest trauma) |
| Endocarditis |
| Prosthetic valve thrombosis |
| Malposition (too high, too low) |
| Acute mal-coaptation |
| Leaflet wear, tear/perforation, prolapse, or retraction |
| Suture breakage or disruption |
| Native leaflet prolapse impeding prosthetic leaflet motion |

The clinical presentation of patients with prosthetic valve dysfunction is usually consistent with symptoms and signs of either valvular regurgitation or stenosis. Valve Academic Research Consortium proposes only two criteria to evaluate impaired prosthetic valve performance: (i) prosthetic valve haemodynamics assessed by echocardiography and (ii) associated clinical findings indicating impaired cardiovascular or valvular function (e.g. new or worsening congestive heart failure). Transthoracic echocardiography (TTE) is usually adequate to evaluate prosthetic aortic valve function, although transoesophageal echocardiography (TEE) may be very useful in the setting of technically challenging or complex cases. Serial echocardiography evaluations after surgical AVR and TAVI should be performed at baseline, soon after the index procedure (ideally within 24–48 h, but always before discharge), at 1 month (especially for TAVI), 12 months, and yearly thereafter.91,92 This follow-up schedule is more intensive than recommended in the AHA/ACC and ESC guidelines for follow-up after surgical AVR,91,92 but more frequent documentation of valve function and position is considered desirable for TAVI clinical trials.

Although the VARC definitions for impaired prosthetic valve performance discount mechanistic characterizations, valve failure mode(s) should be recorded whenever possible in case report forms (Table 7). In addition to echocardiography, multi-slice computed tomography may also provide useful insights into the responsible patho-biological mechanisms of device malfunction.93,94

### Prosthetic valve performance

The clinical presentation of patients with prosthetic valve dysfunction is usually consistent with symptoms and signs of either valvular regurgitation or stenosis. Valve Academic Research Consortium proposes only two criteria to evaluate impaired prosthetic valve performance: (i) prosthetic valve haemodynamics assessed by echocardiography and (ii) associated clinical findings indicating impaired cardiovascular or valvular function (e.g. new or worsening congestive heart failure). Transthoracic echocardiography (TTE) is usually adequate to evaluate prosthetic aortic valve function, although transoesophageal echocardiography (TEE) may be very useful in the setting of technically challenging or complex cases. Serial echocardiography evaluations after surgical AVR and TAVI should be performed at baseline, soon after the index procedure (ideally within 24–48 h, but always before discharge), at 1 month (especially for TAVI), 12 months, and yearly thereafter.91,92 This follow-up schedule is more intensive than recommended in the AHA/ACC and ESC guidelines for follow-up after surgical AVR,91,92 but more frequent documentation of valve function and position is considered desirable for TAVI clinical trials. Although the VARC definitions for impaired prosthetic valve performance discount mechanistic characterizations, valve failure mode(s) should be recorded whenever possible in case report forms (Table 7). In addition to echocardiography, multi-slice computed tomography may also provide useful insights into the responsible patho-biological mechanisms of device malfunction.93,94
clinical signs, symptoms, and/or events (e.g. re-hospitalization for worsening symptoms, re-operation or death).

Transcatheter aortic valve implantation devices are associated with a higher frequency of mild and moderate paravalvular aortic regurgitation (AR) than surgical AVR. There is a need to develop improved definitions and to better understand the long-term clinical implications of paravalvular prosthetic AR. Unfortunately, the precise grading of paravalvular AR remains controversial and many echocardiography experts believe that grading schemes for prosthetic central and paravalvular AR should be different. 

Recently, in the setting of TAVI, criteria for assessing paravalvular AR severity have emphasized a 'jet anatomy' classification, stressing the location, circumferential extent, and width of the AR jet. Haemodynamic factors can also be useful to assess the AR severity immediately after valve implantation (e.g. loss of aortic dicrotic notch, equalization of end-diastolic aortic and left ventricular pressures). Since there is lack of clarity concerning the long-term clinical implications of mild and moderate paravalvular AR after TAVI, echocardiography core laboratories are useful to ensure consistent evaluation methods. Echocardiograms should be performed annually in those patients known to have post-procedural paravalvular AR.

Prosthetic aortic valve thrombosis and endocarditis

Although prosthetic valve thrombosis and prosthetic valve endocarditis have been included as potential failure modes for prosthetic valve dysfunction (Table 7), they require reporting as individual endpoints. Valve thrombosis is any thrombus attached to or near an implanted valve that occludes part of the blood flow path, interferes with valve function, or is sufficiently large to warrant treatment. Furthermore, valve thrombus found at autopsy in a patient whose cause of death was not valve related or found at operation for an unrelated indication should also be reported as

---

**Table 8** Prosthetic aortic valve stenosis criteria<sup>a</sup>

| Parameter                                      | Normal      | Possible stenosis | Significant stenosis |
|-----------------------------------------------|-------------|-------------------|----------------------|
| Peak velocity (m/s)<sup>b</sup>               | <3          | 3–4              | >4                   |
| Mean gradient (mmHg)<sup>b</sup>              | <20         | 20–35            | >35                  |
| Doppler velocity index                        | ≥0.30       | 0.29–0.25        | <0.25                |
| Effective orifice area (cm<sup>2</sup>)       | >1.2        | 1.2–0.8          | <0.8                 |
| Contour of the jet velocity through the prosthetic valve | Triangular, early peaking | Triangular to intermediate | Rounded, symmetrical contour |

AR, aortic regurgitation; CW, continuous wave; LVO, left ventricular outflow; PW, pulsed wave.
Prosthetic valve ‘associated’ complications

Depending on the design characteristics and final implant position, prosthetic aortic valves may come in close contact with the anterior mitral valve leaflet, the interventricular fibrosa, the aortic annulus, the ventricular septum, the aortic sinuses and root, the coronary arteries, and the cardiac conduction system. Collectively, these anatomic structures, which are contiguous with the prosthetic aortic valve, are referred to as the aortic valvar complex (Figure 2). As such, prosthetic aortic valve procedures, and in particular TAVI, may have untoward effects on any of these structures which may result in important clinical consequences. Therefore, VARC proposes to group these complications as a separate endpoint category. However, it must be noted, that some of these adverse events may not be directly related to The Valve prosthesis itself, but may occur before or after valve implantation (e.g. conduction disturbances after pre-implant balloon aortic valvuloplasty).

Conduction disturbances and cardiac arrhythmias

The close anatomical relationship between the aortic valvar complex and the branching atrioventricular bundle explains the possible development of conduction abnormalities following prosthetic aortic valve procedures.117,118 Following surgical AVR, new-onset bundle branch block has been reported in 16–32% of patients and the need for permanent pacemakers in 3–8% of patients.119–123 In early experiences with TAVI, new-onset bundle branch block has occurred in up to 45% of patients and the need for permanent pacemakers has varied from as low as 4% to as high as 33%. 95–98,124–128 Differences among devices and heterogeneity in physician and country-based healthcare thresholds may explain the significant inter-hospital variability in new permanent pacemaker requirements after TAVI.

Although the implications of persistent left bundle branch block (LBBB) after TAVI are currently unknown, the presence of new bundle branch block after surgical AVR has been associated with increased risk of subsequent arrhythmic events during follow-up (specifically, syncope, AV dissociation, and sudden death).119,120 Owing to this association between conduction system abnormalities and adverse patient outcomes following surgical AVR and several anecdotal reports after TAVI of either early post-discharge severe bradyarrhythmia or sudden cardiac death,15 VARC recommends to carefully document the occurrence of new conduction system abnormalities (left bundle branch block and third degree atrioventricular block), as well as the requirements and indications for new permanent pacemakers within 30 days after the procedure. The timing (days) and location (intra-procedural, in-hospital, or post-discharge) of the event should also be recorded. To accurately capture such events, daily ECGs and continuous telemetry ECG monitoring should be considered while the patients are in-hospital, and should be required in patients with any evidence of new conduction abnormalities or arrhythmias.

Although conduction abnormalities associated with TAVI have been a recent concern, it bears noting that new onset atrial fibrillation and ventricular arrhythmias have also been observed after both TAVI and surgical AVR procedures.128 In particular, new onset atrial fibrillation occurs in as many as 20–30% of patients after conventional surgical AVR129,130 and any valid comparison of transcatheter vs. surgical aortic valve treatment strategies should include a careful analysis of post-therapy supra-ventricular and ventricular arrhythmias.

Coronary obstruction

Mechanical coronary artery obstruction following TAVI or surgical AVR is rare and occurs in <1% of patients.96,97 The obstruction typically occurs during the index procedure. Importantly, clinical signs and symptoms may be subtle and not appreciated until

![Figure 2](https://academic.oup.com/eurheartj/article-abstract/32/2/205/515534/0010) The aortic valvar complex, including the aortic valve, annulus, sinuses, aorta, coronary arteries, membranous septum, and the mitral valve.
after the procedure. Possible mechanisms for mechanical coronary obstruction include (i) impingement of the coronary ostia by the Valve support structure in the setting of suboptimal valve positioning and/or ‘small aortic root’ anatomy; (ii) embolization from calcium, thrombus, air, or endocarditis; (iii) displacement of native aortic valve leaflets towards the coronary ostia during TAVI, and (iv) suture-related kinking or obstruction or cannulation-related obstruction of the coronary ostia associated with surgical AVR.

The diagnosis of TAVI-associated coronary obstruction can be determined by imaging studies (coronary angiography, intravascular ultrasound, multi-slice CT angiography, or echocardiography), surgical exploration, or autopsy findings. Cardiac biomarker elevations and ECG changes indicating new ischaemia provide corroborative evidence.

Other prosthesis-related adverse events

The short- and long-term consequences of contact, trauma, or impingement on the anterior mitral valve leaflet by the ventricular end of a transcatheter aortic valve are currently unknown. Nevertheless, any new mitral valve dysfunction (e.g. worsening mitral regurgitation or stenosis) or disruption (e.g. chordal rupture, leaflet perforation, anterior mitral valve leaflet aneurysm) related to contact with the transcatheter valve implant or mitral valve endocarditis should be carefully documented. Other infrequent complications following TAVI include new ventricular septal defects and aortic root rupture/perforation/dissection, occurring either during the pre-implant balloon aortic valvuloplasty, or during the transcatheter valve implant.

Clinical benefit endpoints

In addition to the avoidance of mortality, specific endpoints to establish the clinical benefit after TAVI are important. Objective benefit parameters derived from the heart failure literature can be adapted in valve-related clinical trials. Several choices are available, including exercise performance, assessment of New York Heart Association (NYHA) functional status, and various quality of life and frailty questionnaires. Each of these symptom evaluation tools has strengths and weaknesses in the TAVI patient population, which is disproportionately represented by elderly, frail, individuals with multiple co-morbidities. For instance, exercise test performance is an appealing endpoint, represented by elderly, frail, individuals with multiple co-morbidities. However, quality-of-life questionnaires are also prone to bias and must be uniformly administered. The time points for assessment of the aforementioned clinical benefit endpoints should be at 30 days, at 6 months, and at 1 year after initiating therapy. Valve Academic Research Consortium recommends that if any measure of clinical benefit is utilized in clinical trials, there must be careful oversight and adjudication by experienced clinical events committees.

The assessment of ‘frailty’ in patients with advanced valvular heart disease has become increasingly important and is usually not included in surgical-risk algorithms. Frailty is loosely defined as a biological syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiological systems, and causing vulnerability to adverse outcomes.

Various frailty indices have been developed and have been correlated with worsening clinical outcomes in geriatric patients in intensive care units and after surgery. In general, the evaluation of frailty demands a composite analysis of several categorical and continuous variables including mobility, strength, endurance, activities of daily living, cognitive impairment, and nutritional status (as discerned by body mass index and biomarkers such as serum albumin). Although there is no standard frailty index which has been applied and validated in high-risk AS patients, multiple preliminary efforts are ongoing and VARC proposes to include measures of frailty in future clinical trials as a component of clinical benefit endpoints.

Therapy-specific endpoints

Given the complex nature of TAVI procedures and the rapid evolution of devices and procedural techniques, VARC proposes to record in case report forms (but not as formal endpoints) an open category of therapy-specific endpoints which may be relevant to clinical outcomes or device performance. Examples of such events include the following: (i) the unplanned use of cardiopulmonary bypass to manage haemodynamic compromise or to reverse procedural complications; (ii) conversion from a ‘failed’ percutaneous transcatheter procedure to an ‘open’ surgical AVR or to a surgical-access TAVI; (iii) ventricular perforation (for any reason) with and without cardiac tamponade; (iv) prosthetic valve migration or dislocation from the native aortic valve landing zone; (v) frequency, reasons, and results after post-TAVI balloon dilation; (vi) frequency, reasons, and results after placement of a second valve over the original valve, so-called ‘TAVI-valve-in-valve’; (vii) integrity of the support structure, including strut fractures, compression or other evidence of geometry distortion (requires careful serial imaging modalities including cine-fluoroscopic analyses and echocardiography); (viii) instances of device recapture (with or without repositioning), or retrieval (removal from the body) which occur during the index procedure; (ix) re-intervention (either percutaneous or surgical) for any reason after the index procedure. As appropriate, the timing of these events (during the index procedure, in-hospital,
Table 10  Composite endpoints

| Device success |
|----------------|
| Successful vascular access, delivery and deployment of the device and successful retrieval of the delivery system |
| Correct position of the device in the proper anatomical location |
| Intended performance of the prosthetic heart valve (aortic valve area >1.2 cm² and mean aortic valve gradient <20 mmHg or peak velocity <3 m/s, without moderate or severe prosthetic valve AR) |
| Only one valve implanted in the proper anatomical location |

Combined safety endpoint (at 30 days)
- All-cause mortality
- Major stroke
- Life-threatening (or disabling) bleeding
- Acute kidney injury—Stage 3 (including renal replacement therapy)
- Peri-procedural MI
- Major vascular complication
- Repeat procedure for valve-related dysfunction (surgical or interventional therapy)

Combined efficacy endpoint (at 1 year or longer)
- All-cause mortality (after 30 days)
- Failure of current therapy for AS, requiring hospitalization for symptoms of valve-related or cardiac decompensation
- Prosthetic heart valve dysfunction (aortic valve area <1.2 cm² and mean aortic valve gradient ≥20 mmHg or peak velocity ≥3 m/s, OR moderate or severe prosthetic valve AR)

Clinically relevant composite endpoints

Although VARC discourages the overuse of composite endpoints, to achieve overall impressions of safety and effectiveness may require the incorporation of more than single endpoints. These strategic assessments of TAVI as an alternative therapy should ideally include device, procedure, and patient-oriented factors. Valve Academic Research Consortium proposes three composite endpoints (Table 10): device success (intra-procedure), a combined safety endpoint (at 30 days), and a combined efficacy endpoint (at 1 year or longer).

Device success is a ‘technical’ composite endpoint meant to characterize the acute device and procedural factors which underlie vascular access, delivery, and performance of the TAVI system. Echocardiography should be routinely utilized as the standard for measuring prosthetic valve stenosis and regurgitation immediately after TAVI, and should always be performed in a resting state, either within 24–48 h after the index procedure or before hospital discharge.

The 30-day combined safety endpoint is a hierarchical composite of the most relevant patient-oriented safety endpoints previously defined by VARC (Table 10). In addition, a repeat procedure in the first 30 days (either surgery or intervention) to treat valve-related dysfunction is also incorporated in this endpoint. Examples of urgent repeat procedures would include balloon aortic valvuloplasty or repeat TAVI (valve-in-valve) to treat either paravalvular or central severe AR after the TAVI. The focus on 30-day events after the index procedure is meant to isolate safety concerns largely pertaining to early device performance and the procedure. Nonetheless, overall patient safety also requires a careful examination of pertinent individual safety endpoints over the life history of the device.

The time-sensitive assessment of TAVI effectiveness requires a more delayed combined efficacy endpoint incorporating major clinical and valve performance factors. Valve Academic Research Consortium proposes a 1-year (or longer) time interval for the combined efficacy endpoint integrating three important endpoints: (i) all-cause mortality after 30 days, meant to reflect therapy effectiveness by measuring prevention of AS-related mortality over time; (ii) failure of the current therapy for AS, requiring hospitalization for symptoms of valve-related or cardiac decompensation (adjudicated episodes of heart failure, angina, or syncope requiring an aortic valve procedure or intensification of medical management); (iii) evidence of prosthetic valve dysfunction, defined using strict echocardiography criteria, possibly in conjunction with other signs of functional deterioration.

Discussion

The VARC was convened in response to an urgent call for standardized clinical research processes involving the emerging field of transcatheter valve therapies, and more specifically, TAVI in high-surgical-risk patients with AS. The inter-disciplinary nature of TAVI, combining aspects of both surgical and interventional therapies, presented special challenges and required an enlightened and collaborative approach to the development of clinical research recommendations and endpoint definitions.\(^{160,161}\) The VARC initiative is an attempt to achieve a necessary consensus among the various subspecialties and stakeholders, such that this innovative treatment strategy may be evaluated objectively and according to a set of practical endpoint definitions.

This consensus manuscript is not intended to be interpreted as a ‘guidelines’ or ‘guidance’ document and although thoroughly reviewed by individuals from seven cardiology and cardiac surgery societies, the content has not been subjected to a formal society guidelines review process. These standardized endpoints are measurable, apply to both predicate surgical and new transcatheter therapies, can be adjudicated by clinical events committees, and can be used to compare findings from different clinical trials. By intent, this consensus manuscript was not device-specific and the definitions can be applied to next generation and iterative TAVI devices already under early stages of clinical investigation.\(^{162–165}\)

Given the rapid growth in transcatheter valve therapies, and the potential exposure of this technology to lower risk patient populations, it is certain that this preliminary attempt to arrive at consensus endpoint definitions for TAVI will need refinement in the future. In principle, the consensus process calls for the highest standards of clinical research, including (i) inter-disciplinary experts gathering to arrive at standardized endpoint definitions,
(ii) harmonized and well-structured data collection, interpretation, and reporting for specific TAVI-related clinical events, and (iii) the consistent use of central core laboratories and independent, blinded endpoint adjudication.

Many of the endpoints discussed in this manuscript are sufficiently general that they can be applied to other AS populations and to other valvular heart disease clinical research scenarios, both surgical and interventional. This is particularly germane to TAVI clinical research, as new studies involving lower risk AS patients are already being considered. Importantly, recent reports and randomized trials using new catheter-based mitral valve therapies to treat mitral regurgitation also suffer from non-standardized endpoint definitions and might well benefit from a comparable VARC consensus effort.

This consensus manuscript, which represents the 'first step' in a much longer road to help improve clinical research in valvular heart disease, has several limitations. The endpoint definitions were intended to be reasonably broad, but nonetheless in some instances are also intentionally narrow to address the specific considerations of TAVI in high-surgical-risk patients with severe AS. Therefore, application of all of these endpoint definitions to other patient populations may be problematic. The important area of pre-clinical device testing, both assessments of valve and support structure properties and in vivo animal studies, is beyond the scope of this manuscript. Other aspects of clinical trial design and clinical trial methodologies are also essential to optimize clinical research, but similarly, a comprehensive treatment of these subjects could not be included in this manuscript. Finally, many global endpoints, such as stroke and bleeding and some specific endpoints, such as paravalvular regurgitation, are themselves in a state of evolution, subject to modifications by other consensus committees in the near future.

The VARC process embodied in this manuscript was an ambitious multi-disciplinary attempt to bring order through consensus, thereby providing standardization of clinical research in the burgeoning area of transcatheter aortic valve therapy. Hopefully, this template can also serve as a model to improve clinical research methodologies in the evaluation of new therapies for other cardiovascular diseases.

Funding

Grants were provided to the ARC Board including representatives of The Cardiovascular Research Foundation, Cardialysis, Duke Clinical Research Institute and Harvard Clinical Research Institute to cover the costs of travel, meeting rooms, and lodging for academic attendees at the San Francisco and Amsterdam meetings by Edwards Lifesciences and Medtronic Corporation. All funds not utilized for the aforementioned travel-related purposes have been returned to the sponsors. Funding to pay the Open Access publication charges for this article was provided by Cardialysis BV on behalf of the Valve Academic Research Consortium.

Conflict of interest: VARC Participants will provide Conflict of Interest Disclosures individually prior to publication. The VARC meetings involved members of the Interventional Cardiology Devices Branch, of the Office of Device Evaluation, Center for Devices and Radiological Health, USFDA. The opinions or assertions herein are the private views of the authors and are not to be construed as reflecting the views of the FDA.

**Appendix 3**

**Minimum data collection and endpoint requirements after TAVI**

- Mortality (all cause and cardiovascular)
- Myocardial Infarction (peri-procedural and spontaneous)
- Stroke (major and minor)
- Bleeding (life threatening or disabling and major)
- Acute kidney injury (modified RIFLE stage 2 and 3, including RRT)
- Vascular complications (major)
- Prosthetic valve performance (requires serial echocardiography assessments)
  - Prosthetic valve stenosis (possible and significant) and regurgitation (moderate or severe with special reference to paravalvular regurgitation)
  - Prosthetic valve thrombosis
  - Prosthetic valve endocarditis
  - Prosthetic valve-associated complications
    - Conduction disturbances and cardiac arrhythmias (including new LBBB, new permanent pacemaker implantation, and new supra-ventricular or ventricular arrhythmias) and
    - Coronary obstruction
- Clinical benefit endpoints
  - Symptom status (global assessments using NYHA classification and some measure of quality of life)
  - Repeat hospitalization (>30 days after the index procedure) for valve-related or cardiac decompensation
- Therapy specific endpoints (ventricular perforation at any time resulting in cardiac tamponade, prosthetic valve embolization, and acute or delayed valve-in-valve treatment)
- Composite endpoints
  - Device success
  - Combined safety endpoint (at 30 days)
  - Combined efficacy endpoint (at 1 year or longer)
