Department of Physics, University of Tsukuba, Tsukuba, Ibaraki 305-8571, Japan

We propose topological semimetals generated by the square-root operation for tight-binding models in two and three dimensions, which we call square-root topological semimetals. The square-root topological semimetals host topological band touching at finite energies, whose topological protection is inherited from the squared Hamiltonian. Such a topological character is also reflected to emergence of boundary modes with finite energies. Specifically, focusing on topological properties of squared Hamiltonian in class AIII, we reveal that a decorated honeycomb (decorated diamond) model hosts finite-energy Dirac cones (nodal lines). We also propose a realization of a square-root topological semimetal in a spring-mass model, where robustness of finite-energy Dirac points against the change of tension is elucidated.

I. INTRODUCTION

In a past decade, novel classes of topological phases have been extensively explored [1]. Focusing on non-interacting fermions, there are two kinds of topological phases according to the bulk spectrum. One is a gapped topological phase where bulk has an energy gap and nontrivial topological numbers are defined for Bloch or Bogoliubov bands. Examples include topological insulators (TIs) [2–7] and topological superconductors (TSCs) [8–13]. In TIs and TSCs, the nontrivial topology is known to result in robust boundary modes; this relation is called bulk-boundary correspondence [14, 15]. The other kind of topological phase is a gapless topological phase, also termed a topological semimetal (TSM), [16–20] where bulk bands themselves have gapless points or nodes, protected by nontrivial topology. Topologically-protected boundary modes appear in TSMs as well. For instance, flat edge modes protected by the winding number appear in graphene nano-ribbon with the zigzag edge [21–23] and the \( d_{x^2-y^2} \) superconductor [24, 25].

Recently, an interesting proposal to obtain a class of TIs was made by Arkinstall, et al., that is, to take square-root of topological tight-binding Hamiltonians [26]. TIs thus obtained are called square-root TIs. The square-root operation for tight-binding models is carried out by adding the “mediating sites” between sites of original lattice having non-zero particle transfer, and letting the nearest-neighbor (NN) transfer between the original sites and mediating sites; this implies that the model is naturally chiral symmetric as the bipartition of the entire lattice to the original sites and the mediating sites is possible. The square of the model is equal to the direct sum of the original model and another model defined on mediating sites (up to the constant shift). When topological models are set as an original Hamiltonian, its square-root inherits the topological nature of it. So far, tight-binding models of TIs [26, 27], higher-order TIs [28], and non-Hermitian TIs [29] created by the square-root operation were proposed. Their experimental realization was also actively pursued in various artificial materials, such as photonic crystals [26, 27], electric circuits [30], and phononic crystals [31]. Interestingly, in square-root TIs preserving the chiral symmetry, topologically-protected boundary modes appear at positive and negative energies in a pairwise manner, which reflects the square-root nature of the model. Along with the above significant progress in insulators and superconductors, to our best knowledge, square-root topology of semimetals has not been explored yet.

Therefore, in this paper, we propose that TSMs can also be generated by the square-root operation. We term such TSMs square-root TSMs (SR-TSMs). SR-TSMs have topological band touching at finite energies and the topologically-protected nature of them can be elucidated by considering a squared Hamiltonian.

As concrete examples, we study a series of \( d \)-dimensional decorated diamond model, i.e., a decorated honeycomb model in two dimensions and a decorated diamond model in three dimensions. Their mediating sites correspond to the line graphs [32, 33], i.e., the \( d \)-dimensional pyrochlore lattice [34]. The models are a suitable platform for the SR-TSMs since the squared Hamiltonian is composed of \( d \)-dimensional diamond and pyrochlore lattices, both of which are well-known examples of the TSM in class AIII. Specifically, the Dirac points arise in two dimensions (i.e., the honeycomb and kagome lattices), and the nodal line SM is realized in three dimensions (i.e., the diamond and pyrochlore lattices). We show that the \( d \)-dimensional decorated diamond model indeed hosts the nodal points or lines at finite energies, inherited from the \( d \)-dimensional diamond and pyrochlore models. Furthermore, the decorated models also succeed to the characteristic boundary modes in the \( d \)-dimensional diamond model, i.e., the flat edge modes in the two-dimensional case and the flat surface state in the three-dimensional case. They appear at finite energies, and are topologically protected by the winding number defined for the \( d \)-dimensional diamond-lattice sector squared Hamiltonian.

We further propose that the SR-TSM is feasible in a spring-mass model [35–47], a periodic array of mass points connected by springs. Focusing on the two-dimensional case, i.e., the decorated honeycomb spring-mass model, we reveal that the finite-energy band touching points are robust against the change of tension parameter, i.e., the introduction of the inter-mode coupling between longitudinal and transverse modes, which manifests their topologically-protected nature by the winding number.

The rest of this paper is structured as follows. We first argue...
a generic recipe for constructing SR-TSMs of class AIII in Sec. II. Then, in the following two sections, we reveal how this construction works through the concrete examples. In Sec. III, we study the decorated honeycomb model as an example of SR Dirac semimetals in two dimensions. In Sec. IV, we study the decorated diamond model, as an example of SR nodal line semimetals in three dimensions. Section V is devoted to the spring-mass-model realization of the SR-TSM. In Sec. VI, we summarize this paper.

II. GENERIC CONSTRUCTION OF SQUARE-ROOT TOPOLOGICAL SEMIMETALS

In this section, we describe a generic recipe of constructing SR-TSMs, focusing on those in class AIII. Consider a bipartite lattice with even number of sublattices and its line graph whose sites are placed on edges of the NN bonds of the original lattice. Then, let us consider the Hamiltonian with the NN hoppings on a composite lattice of the original lattice and its line graph. Then, let us consider the Hamiltonian with the NN hoppings on the decorated honeycomb model, as an example of SR nodal line semimetals, focusing on those in class AIII. Consider a bipartite lattice with even number of sublattices and its line graph, respectively, and the sublattices of the original lattice and the line graph, and the decorated diamond model in three dimensions. Section V is devoted to the spring-mass-model realization of the SR-TSM. In Sec. VI, we summarize this paper.

II. GENERIC CONSTRUCTION OF SQUARE-ROOT TOPOLOGICAL SEMIMETALS

In this section, we describe a generic recipe of constructing SR-TSMs, focusing on those in class AIII. Consider a bipartite lattice with even number of sublattices and its line graph whose sites are placed on edges of the NN bonds of the original lattice. Then, let us consider the Hamiltonian with the NN hoppings on a composite lattice of the original lattice and its line graph:

\[ H = \sum c_k^\dagger \mathcal{H}_k c_k, \]

where \( c_k = (c_{k,1}, \cdots c_{k,N}, c_{k,N+1}, \cdots, c_{k,N+M})^\top \). Here, \( N \) and \( M \) are the numbers of the sublattices for the original lattice and the line graph, respectively, and the sublattices of the composite lattice are labeled such that the sublattices 1-\( N \) belong to the original lattice whereas the sublattice \((N + 1)\)-(\( N + M \)) to the line graph. As the NN hoppings on the composite lattice occur only between the original lattice and the line graph, the Hamiltonian matrix \( \mathcal{H}_k \) can be written in a form:

\[ \mathcal{H}_k = \begin{pmatrix} O_{N,N} & t \Psi_k^\dagger \\ t \Psi_k & O_{M,M} \end{pmatrix}. \]

Here, \( t \) is the transfer integral, \( \Psi_k \) is the \( M \times N \) matrix which reflects the connectivity between the original lattice and the line graph, and \( O_{n,m} \) stands for the \( n \times m \) zero matrix.

From (2), we see that the model preserves the chiral symmetry, namely, \( \mathcal{H}_k \) anti-commutes a matrix \( \Gamma \):

\[ \Gamma = \begin{pmatrix} I_N & O_{N,M} \\ O_{M,N} & -I_M \end{pmatrix}, \]

where \( I_n \) is the \( n \times n \) identity matrix. Due to this chiral symmetry, the square of \( \mathcal{H}_k \) is block-diagonalized, since \( (\mathcal{H}_k)^2 \) commutes \( \Gamma \). Specifically, we have

\[ (\mathcal{H}_k)^2 = \begin{pmatrix} t^2 \Psi_k^\dagger \Psi_k & O_{N,N} \\ O_{M,N} & t^2 \Psi_k \Psi_k^\dagger \end{pmatrix}. \]

Notably, \( t^2 \Psi_k^\dagger \Psi_k \) corresponds to the Hamiltonian on the original lattice with the on-site potential \( Mt^2 \) and the NN hopping \( t^2 \), whereas \( t^2 \Psi_k \Psi_k^\dagger \) to that on the line graph with the on-site potential \( Nt^2 \) and the NN hopping \( t^2 \) [34]. The eigenenergies of these two matrices are identical except for the zero-energy flat band in that for the line graph. In addition, we can define the topological winding number for the squared Hamiltonian in the original lattice subspace. To be specific, as \( N \) is even, we can find a \( N \times N \) matrix \( \Sigma \) which anti-commutes \( \tilde{h}_k := t^2 \Psi_k^\dagger \Psi_k - Mt^2 I_N \). Then, the following winding number can be defined [22, 23]:

\[ \nu(k_1, \cdots, k_{j-1}, k_{j+1}, \cdots) = \int_0^1 \frac{dk_j}{4\pi i} \text{Tr} \left[ \Sigma \partial_{k_j} \left( \log \tilde{h}_k \right) \right], \]

where \( k_j \in [0,1] \) is defined such that \( \mathbf{k} = \sum_{j=1}^d k_j \mathbf{b}_j \) with \( d \) being the spatial dimension and \( \mathbf{b}_j \) being the \( j \)-th reciprocal lattice vector.

The dispersion relation of the Hamiltonian of the composite lattice is given by the square of that for \( (\mathcal{H}_k)^2 \), with the signs + and −. This means that, if the NN hopping model on the original lattice has band touching at zero energy, the Hamiltonian \( \mathcal{H}_k \) has the band touchings as well, and their energies are \( \pm \sqrt{M} |t| \), i.e., the TSM is realized in the composite-lattice model. However, we cannot define the topological winding number protecting the band touchings from the composite-lattice model itself, as they are at finite energies. Instead, they are protected by the winding number for the squared Hamiltonian defined in Eq. (5). We thus call this TSM the SR-TSM. In addition, the topologically protected band touching also leads to the finite-energy boundary modes, which is another characteristic of the SR-TSM.

In the following two sections, we show the concrete models, namely, the decorated honeycomb model in two dimensions and the decorated diamond model in three dimensions. Additionally, we remark that the SR-TSM obtained in the above procedures is stable against the on-site potential that is proportional to \( \Gamma \); see Appendix A for details.

III. EXAMPLE 1: SQUARE-ROOT DIRAC SEMIMETAL IN DECORATED HONEYCOMB MODEL

A. Model and bulk properties

We first study the decorate honeycomb model, which is a composite lattice of honeycomb and kagome lattices [Fig. 1(a)]. This model was studied in the literature [48–50], and the aim of this paper is to present a renewed viewpoint of the SR-TSM.

The lattice has five sublattices degrees of freedoms; two of them come from the honeycomb lattice and the rest from the kagome lattice. Then, $\Psi_k$ of Eq. (2) is a $3 \times 2$ block matrix given as

$$
\Psi_k = \begin{pmatrix} 
1 & e^{ik \cdot a_1} \\
e^{ik \cdot a_2} & 1
\end{pmatrix}.
$$

Note that the two lattice vectors in Eq. (6) are $a_1 = \left( \frac{1}{2}, \frac{\sqrt{3}}{2} \right)$ and $a_2 = \left( -\frac{1}{2}, \frac{\sqrt{3}}{2} \right)$; the corresponding reciprocal lattice vectors are $b_1 = (\frac{2\pi}{a}, \frac{2\pi}{b})$ and $b_2 = (-\frac{2\pi}{a}, \frac{2\pi}{b})$.

As explained in Sec. II, the square of $\mathcal{H}_k$ is

$$
\mathcal{H}^2_k = \begin{pmatrix} 
\mathcal{H}^{(H)}_k & \mathcal{O}_{3,2} \\
\mathcal{O}_{3,2} & \mathcal{H}^{(K)}_k
\end{pmatrix},
$$

where $\mathcal{H}^{(H)}_k$ and $\mathcal{H}^{(K)}_k$ correspond to the honeycomb lattice model with the NN hopping $t^2$ and the on-site potential $3t^2$ and the kagome lattice model with the NN hopping $t^2$ and the on-site potential $2t^2$, respectively. For later use, we define

$$
\xi^{(H)}_k = 1 + e^{ik \cdot a_1} + e^{ik \cdot a_2},
$$

which is the $(2, 1)$ component of $\mathcal{H}^{(H)}_k$.

The band structure for this model is shown in Fig 1(b). We find Dirac cones at $K$ and $K'$ points (the latter is not shown in the figure), whose energies are $\varepsilon = \pm \sqrt{3} |t|$. These Dirac cones are inherited from those of the honeycomb and kagome models.

B. Edge modes and topological protection

Figure 2(a) shows the dispersion relation for the cylinder, obtained by assigning the open boundary condition in the direction of $a_1$. The edge shape is chosen to be the zigzag edge. In the momentum space, $k_2$ defined in Sec. II remains to be a good quantum number. We see flat edge modes at $\varepsilon = \pm \sqrt{3} |t|$, connecting the Dirac points in the bulk; this is reminiscent of the edge modes of the conventional honeycomb model under the zigzag edge, besides the fact that their energies are finite rather than zero.

The finite-energy flat edge modes are topologically protected by the winding number for the honeycomb sector of the squared Hamiltonian, as we discussed in Sec. II. Specifically, we can define the following winding number as a function of $k_2$:

$$
\nu(k_2) = \frac{1}{2\pi i} \int_0^1 dk_1 \frac{\partial_{k_1} q_k^{(H)}}{q_k^{(H)}}.
$$

Note that the definition of Eq. (9) coincides with that of Eq. (5) when setting $\Sigma = \text{diag}(1, -1)$. This winding number is exactly identical to that for the honeycomb model, but we perform the integration in (9) for completeness. Changing the variable as $z = e^{2\pi i k_1}$, we have

$$
\nu(k_2) = \frac{1}{2\pi i} \int_C dz \frac{1}{z + 1 + e^{2\pi i k_2}},
$$

where $C$ is a unit circle in the complex plane. Using Cauchy’s residue theorem, we find that $\nu(k_2)$ is $0$ if $|1 + e^{2\pi i k_2}| > 1$ or $1 + e^{2\pi i k_2} < 1$. At the critical point, where $|1 + e^{2\pi i k_2}| = 1$, (i.e., $k_2 = \frac{1}{2}, \frac{2}{3}$) the band gap closes at certain $k_1$, which is nothing but $K$ and $K'$ points [51]. In fact, this also manifests the topological stability of the Dirac points in a bulk, because the winding number defined by the contour integral around the Dirac point takes non-trivial value [22, 23, 52]. The bulk-edge correspondence tells us that the number of zero-energy boundary mode for $\mathcal{H}^{(H)}_k - 3t^2$ (per edge) is equal to $\nu(k_2)$ at each $k_2$. Then, by taking into account the constant shift of $3t^2$, we find that the edge modes with energies $\pm \sqrt{3} |t|$ arise in the decorated honeycomb model. In Fig. 2(b), we plot $\nu(k_2)$, which clearly coincides with the above argument, in that $\nu(k_2)$ is one where the edge modes exist, while it is zero otherwise.
IV. EXAMPLE 2: SQUARE-ROOT NODAL-LINE SEMIMETAL IN DECORATED DIAMOND MODEL

A. Model and bulk properties

Next, we consider the decorated diamond model [Fig. 3(a)], which is a composite lattice of the diamond and the pyrochlore lattices, as an example of the SR nodal-line semimetal. In this model, the number of sublattices is six; two of them come from the diamond lattice and the rest four from the pyrochlore lattice. Hence, $\Psi_k$, introduced in Sec. II, becomes $4 \times 2$ matrix given as

$$
\Psi_k = \begin{pmatrix}
1 \\
e^{i k \cdot a_1} 1 \\
e^{i k \cdot a_2} 1 \\
e^{i k \cdot a_3} 1
\end{pmatrix},
$$

(11)

where $a_1 = (0, \frac{1}{2}, \frac{1}{2})$, $a_2 = (\frac{3}{2}, 0, \frac{1}{2})$, $a_3 = (\frac{1}{2}, \frac{1}{2}, 0)$ are lattice vectors; the corresponding reciprocal lattice vectors are $b_1 = 2\pi (-1, 1, 1)$, $b_2 = 2\pi (1, -1, 1)$, $b_3 = 2\pi (1, 1, -1)$.

The square of $H_k$ is a direct sum of the diamond model and the pyrochlore model:

$$
H_k^2 = \begin{pmatrix}
H_k^{(D)} & 0 \\
0 & H_k^{(P)}
\end{pmatrix},
$$

(12)

The matrix $H_k^{(D)}$ corresponds to the diamond lattice model with the NN hopping $t^2$ and the on-site potential $4t^2$; similarly, $H_k^{(P)}$ corresponds to the diamond lattice model with the NN hopping $t^2$ and the on-site potential $2t^2$. We again define the quantity corresponding to $(2, 1)$ component of $H_k^{(D)}$:

$$
q_k^{(D)} = 1 + \sum_{j=1}^{3} e^{i k \cdot a_j},
$$

(13)

which we will use in the next subsection.

In Fig. 3(b), we plot the bulk band structure. We see nodal lines between X and W points, which are inherited from the diamond and pyrochlore models.

B. Surface states and topological protection

Let us investigate the boundary modes of this model. Consider a slab geometry whose surface is parallel to the plane spanned by $a_1$ and $a_2$. In this case, $k_1$ and $k_2$ remain to be good quantum number, while $k_3$ is not. In Fig. 4(a), we plot the band structure for the slab on the high-symmetry lines of the surface Brillouin zone [green lines in Fig. 4(b)]. We see that the flat surface states appear, whose energies are $\pm 2|t|$.

As discussed in Sec. II, the topological protection of the surface state can be dictated by calculating the following winding number as a function of $k_1$ and $k_2$:

$$
\nu(k_1, k_2) = \frac{1}{2\pi i} \int_0^1 dk_3 \frac{\partial k_3 q_k^{(D)}}{q_k^{(D)}}.
$$

(14)
Performing the integration in the same manner as in Eqs. (9) and (10), we find that \( \nu(k_1, k_2) \) takes 0 (1) if \( |1 + e^{i2\pi k_1} + e^{i2\pi k_2}| > 1 \) \( (|1 + e^{i2\pi k_1} + e^{i2\pi k_2}| < 1) \). For the critical case where \( |1 + e^{i2\pi k_1} + e^{i2\pi k_2}| = 1 \), \( k_1 = \frac{1}{2}, k_2 = \frac{1}{2}, \) and \( k_1 - k_2 = \pm \frac{1}{2} \), the band gap closes at some \( k_3 \), which correspond to the nodal lines. Similarly to the decorated honeycomb lattice, this result indicates the topological protection of the bulk nodal lines and the surface states. Namely, the finite winding number indicates the existence of zero-energy surface state for \( \mathcal{H}_k^{(D)} - 4t^2 \), hence the the surface states whose energies are \( \pm 2|t| \) appear for the decorated diamond model. Figure 4(b) shows the map of the winding number as a function of the surface wavevectors. Clearly, the above correspondence between the surface states and the winding number can be confirmed.

V. REALIZATION IN A SPRING-MASS MODEL

In this section, we argue the realization of the SR-TSM we have discussed so far in a spring-mass model. We consider a system of mass points and springs aligned on the decorated honeycomb lattice [Fig. 5(a)]. Here the mass points on sublattices 3, 4, and 5 are placed on dents of the floor which cause the gravitational potential \([39, 45, 47]\). The Lagrangian of the system is given as

\[
\mathcal{L} = -U_s - U_{sp},
\]

with

\[
T = \frac{m}{2} \sum_R (\dot{x}_{R,\mu})^2,
\]

\[
U_s = \sum_R g_{R,\mu\nu} x_{R,\mu} x_{R,\nu},
\]

and

\[
U_{sp} = \frac{\kappa}{2} \sum_{(R, R')} \left( x_{R,\mu} - x_{R',\mu} \right) \gamma_{R - R',\mu\nu} \left( x_{R',\nu} - x_{R,\nu} \right).
\]

Here, we have assumed the summation over repeated indices \( \mu \) and \( \nu(\mu, \nu = x, y) \), and the dot in Eq. (16) stands for the time derivative. In Eq. (15), \( T \) is the kinetic energy, \( U_s \) is the potential energy from the dents on the floor, and \( U_{sp} \) is the potential energy describing the restoring force of the springs. The vector \( R \) specifies the sites which forms a decorated honeycomb lattice. The natural length of a spring is denoted by \( l_0 \). The ratio of between distance of neighboring sites (specified by \( R \) and \( R' \)) and \( l_0 \) is denoted by \( \eta = l_0/|R - R'| \), which determines the tension of the spring. The distance between neighboring sites is chosen as the unit of length. The vector \( x_R = (x_{R,x}, x_{R,y}) \) describes the displacement of the mass point at the site \( R \).

As for the matrix \( g_R \) in Eq. (17), we set

\[
g_R = \begin{cases} 
0 & \text{if } R \in 1, 2 \\
\kappa \left( 1 - \frac{1}{2} \eta \right) \tau_0 + \kappa \eta \tau_2 & \text{if } R \in 3 \\
\kappa \left( 1 - \frac{1}{2} \eta \right) \tau_0 - \frac{\kappa}{2} \sqrt{3} \tau_x + \tau_z & \text{if } R \in 4 \\
\kappa \left( 1 - \frac{1}{2} \eta \right) \tau_0 - \frac{\kappa}{2} \sqrt{-3} \tau_x + \tau_z & \text{if } R \in 5 
\end{cases}
\]

with \( \tau_0 \) being the \( 2 \times 2 \) identity matrix and \( \tau = (\tau_x, \tau_y, \tau_z) \) being Pauli matrices. Note that the potential is introduced so that the eigenvalue problem is equivalent to that for the tight-binding model in the strong tension limit, as we will show later \([39, 45, 47]\). We also note that \( \eta \) has to be smaller than \( \frac{2}{3} \) so that the dents have an ellipsoidal surface (i.e., the all the eigenvalues of \( g_R \) are positive).

The matrix \( \gamma \) in (18) is a \( 2 \times 2 \) matrix whose elements is defined as

\[
\gamma_{R,\mu\nu} = (1 - \eta) \delta_{\mu\nu} + \eta \delta_{\mu R} \delta_{\nu R'},
\]

with \( \hat{\delta}_R = \delta R/|\delta R| \) and \( \delta R \) being the vector connecting the neighboring sites, respectively.

The normal modes of the frequency \( \omega \) is obtained as follows. Writing \( R = \vec{r} + r_\alpha \) with \( \vec{r} \) and \( r_\alpha \) are the position of the unit cell and the position of the sublattice \( \alpha \) of which \( R \) belongs to, respectively, we apply the Fourier transformation:

\[
x_{R,\mu} = \frac{1}{N} \sum_k u_{k,\mu} e^{i k \cdot \vec{r}}.
\]

FIG. 5. (a) A schematic figure of the spring-mass decorated honeycomb model. We have introduced potential force arising from the dents of the floor so that the diagonal elements of \( \Gamma(k) \) become \( \Gamma_{ii}(k) = 3\varepsilon(1 - \eta/2) \) for \( i = 1, \ldots, 10 \). Dispersion relations of the spring-mass decorated honeycomb model for \( \kappa = m = 1 \) with (b) \( \eta = 0 \) and (c) \( \eta = 0.25 \). Green circles denote the finite-energy Dirac points.
Then, from the Euler-Lagrange equation
\[
\frac{d}{dt} \left( \frac{\delta L}{\delta u^\alpha_{\mathbf{k},\mu}} \right) - \frac{\delta L}{\delta u^\alpha_{-\mathbf{k},\mu}} = 0,
\]
we obtain the equation of motion in the momentum space:
\[
\dot{u}_k = -\Gamma(k) u_k,
\]
with
\[
u_k = \begin{pmatrix} u_{k,x}^1 & u_{k,y}^1 & \cdots & u_{k,x}^5 & u_{k,y}^5 \end{pmatrix}^T
\]
and
\[
\Gamma(k) = \frac{\kappa}{m} \begin{pmatrix} 1 - \eta(k) \end{pmatrix} I_{10}
- \frac{\kappa}{m} \begin{pmatrix} \gamma_k(1,3) & \gamma_k(1,4) & \gamma_k(1,5) \\
\gamma_k(2,3) & \gamma_k(2,4) & \gamma_k(2,5) \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \end{pmatrix}.
\]

Here, \( \gamma_k(\alpha,\beta) \) are \( 2 \times 2 \) matrices obtained by performing the Fourier transformation of \( \gamma \) in Eq. (20). Their explicit forms are given in Appendix B. The matrix \( \Gamma(k) \) is referred to as the dynamical matrix in the literature. By further assuming the relation
\[
u_k(t) = e^{i\omega t} \phi_k,
\]
we have
\[
\omega^2 \phi_k = \Gamma(k) \phi_k.
\]

Solving the above eigenvalue equation, we have the dispersion relation for the spring-mass system.

Figure 5(b) shows the dispersion relation for \( \eta = 0 \). In this figure, we can see that the band structure of the tight-binding model is reproduced up to the constant shift \( 3\kappa/m \) which does not matter for the topological properties. We note that for \( \eta = 0 \) the transverse and longitudinal modes are decoupled and each band is doubly degenerate. Namely, each of Dirac cones for \( \omega^2 \sim 4.7 \) and \( \omega^2 \sim 1.2 \) at K point is doubly degenerate, which is consistent with the fact that the winding number of \( \Gamma(k) \sim 3 \frac{2\pi}{3} I_2 \) is two.

For a finite value of \( \eta \), the transverse and longitudinal modes are coupled. Then, the doubly degenerate Dirac cone with the winding number two is not gapped out but splits into two Dirac cones each of which has the winding number one, as shown in Fig. 5(c). More precisely, one of the Dirac cones remains at K point, while the other is placed on the K-M line. This behavior, which is reminiscent of the bilayer graphene with AA stacking [55, 56], is also seen in the spring-mass model on a conventional honeycomb lattice [37]. The result manifests that the SR-TSM in the spring-mass decorated honeycomb model is robust against inclusion of the inter-mode coupling.

**VI. SUMMARY**

We have proposed the SR-TSM, where topologically-protected point or line nodes are inherited from the squared Hamiltonian. As concrete examples, we study the decorated honeycomb model and the decorated diamond model, where the SR Dirac semimetal and SR nodal-line semimetal are realized, respectively. There, the Dirac cones and nodal lines appear at finite energy, and they are protected by the winding number defined for the squared Hamiltonian. We can also see the bulk-boundary correspondence between this winding number and the finite-energy flat edge or surface modes.

We have further proposed that the SR-TSM can be realized in a spring-mass model with the decorated honeycomb arrangement. We have found that the finite-energy band touching points are robust against the change of the tension parameter \( \eta \), which indicates their topological protection by the winding number of the parental honeycomb model.

**ACKNOWLEDGMENTS**

We wish to thank Y. Kuno for bringing our attention to the square-root topological insulators, and for the collaboration in the earlier work (Ref. [28]). This work is supported by the JSPS KAKENHI, Grant Nos. JP17H06138, JP20K14371 (T. M.), JP20H04627 (T. Y.), MEXT, Japan.

**Appendix A: Stability against on-site potential**

We show that the SR-TSM is stable against the on-site potential proportional to the chiral operator \( \Gamma \) of Eq. (3). Consider the Hamiltonian
\[
\mathcal{H}_k^O = \begin{pmatrix} V \Psi_k & \Psi_k^\dagger \\
\Psi_k^\dagger & -V \Psi_k \end{pmatrix},
\]
where \( V \) is the strength of the on-site potential. Importantly, the square of \( \mathcal{H}_k^O \) is still block-diagonalized as
\[
(\mathcal{H}_k^O)^2 = \begin{pmatrix} V^2 I_N + \Psi_k^\dagger \Psi_k & \mathcal{O}_{N,M} \\
\mathcal{O}_{M,N} & V^2 I_M + \Psi_k^\dagger \Psi_k \end{pmatrix}.
\]

This indicates that the on-site potential proportional to the chiral operator causes a mere constant shift to the squared Hamiltonian. Consequently, the topological nature of the Hamiltonian without on-site potential is unchanged.

![Figure 6](image.png)
To confirm this, we calculate the band structures of bulk and cylinder in the decorated honeycomb model with on-site potential. The results are shown in Fig. 6, where we clearly see that the finite-energy Dirac cones in bulk and the flat edge modes in cylinder, indicating that the stability of the SR-TSM against the on-site potential.

Appendix B: Details of the dynamical matrix

Here we list the forms of $\gamma_k^{(\alpha,\alpha')} \in \mathbb{R}^{3 \times 3}$ in Eq. (24):

$$\gamma_k^{(1,3)} = \begin{pmatrix} 1 - \eta & 0 \\ 0 & 1 \end{pmatrix}, \quad (B1a)$$

$$\gamma_k^{(1,4)} = e^{-ik \cdot a_1} \begin{pmatrix} 1 - \eta & 0 \\ 0 & 1 + \frac{3\eta}{4} \end{pmatrix}, \quad (B1b)$$

$$\gamma_k^{(1,5)} = e^{-ik \cdot a_2} \begin{pmatrix} 1 - \eta & -\frac{\sqrt{3\eta}}{4} \\ -\frac{\sqrt{3\eta}}{4} & 1 - \frac{3\eta}{4} \end{pmatrix}, \quad (B1c)$$

$$\gamma_k^{(2,3)} = \begin{pmatrix} 1 - \eta & 0 \\ 0 & 1 \end{pmatrix}, \quad (B1d)$$

$$\gamma_k^{(2,4)} = \begin{pmatrix} 1 - \frac{\eta}{2} + \frac{\sqrt{3\eta}}{4} & \frac{\sqrt{3\eta}}{4} \\ \frac{\sqrt{3\eta}}{4} & 1 - \frac{3\eta}{4} \end{pmatrix}, \quad (B1e)$$

$$\gamma_k^{(2,5)} = \begin{pmatrix} 1 - \frac{\eta}{2} + \frac{\sqrt{3\eta}}{4} & \frac{\sqrt{3\eta}}{4} \\ -\frac{\sqrt{3\eta}}{4} & 1 - \frac{3\eta}{4} \end{pmatrix}, \quad (B1f)$$
