AN INTEGRAL CONTROL FORMULATION OF MEAN FIELD GAME BASED LARGE SCALE COORDINATION OF LOADS IN SMART GRIDS

Arman C. Kizilkale, Rabih Salhab, Roland P. Malhamé

Abstract

Pressure on ancillary reserves, i.e., frequency preserving, in power systems has significantly mounted due to the recent generalized increase of the fraction of (highly fluctuating) wind and solar energy sources in grid generation mixes. The energy storage associated with millions of individual customer electric thermal (heating-cooling) loads is considered as a tool for smoothing power demand/generation imbalances. The piecewise constant level tracking problem of their collective energy content is formulated as a linear quadratic mean field game problem with integral control in the cost coefficients. The introduction of integral control brings with it a robustness potential to mismodeling, but also the potential of cost coefficient unboundedness. A suitable Banach space is introduced to establish the existence of Nash equilibria for the corresponding infinite population game, and algorithms are proposed for reliably computing a class of desirable near Nash equilibria. Numerical simulations illustrate the flexibility and robustness of the approach.

Key words: Mean field games; Optimal control; Smart grids; Decentralized control.

1 Introduction

Since the seventies, load management via direct load control and its predominantly price induced variant, demand response, have been considered as tools for shaping the load demand in power systems so as to achieve peak load shaving and valley filling [30]. Such measures help defer generation and capacity expansion, and operate generators in the vicinity of their most efficient operating point. However, the seriousness with which demand response (or load dispatch) are being considered is a relatively recent phenomenon. It is mainly caused by the increasing share of intermittent renewable energy sources (such as wind and solar) in the energy mixes of power producers worldwide [1-3]. The ensuing variability and diminished predictability of generation has indeed put strong pressures on the ability of independent system operators to maintain grid stability and insure reliable power delivery and transmission to consumers in their power pool [5,16].

One of the striking characteristics of so-called smart grids is an ability to rely on both an increasingly pervasive communication network, and an improved electricity distribution network, to shift the responsibility of balancing electricity demand with power generation from being solely a generation side task, to one shared increasingly by both producers and customers. Furthermore, the role of consumers is gradually changing in that they can also contribute to power generation or delivery, mostly through rooftop solar panels, electric batteries in dwellings or electric vehicles (EV’s) [13]. In that context, pricing or control dictated coordination of certain deferrable classes of loads (ex. pool pump loads, or energy storage capable loads such as electric space heaters or air conditioners) to compensate for fluctuations in intermittent renewable energy has become increasingly attractive relative to expensive battery storage alterna-

has produced: (a) new modeling requirements as power system operators will increasingly need bottom up type models to anticipate the aggregate behavior of customer loads to real time demand response pricing signals, in particular synchronization effects and the ensuing load rebound (see [31]); or the effects of direct control signals in load dispatch approaches; (b) new large scale load control challenges. This is particularly true when residential type load controls, or EV charging coordination are considered for demand dispatch, as the sheer number of control points (possibly in the millions) needed to achieve significant system impact make it essentially impossible to monitor centrally every load, and compound computational challenges; in that case, effective forms of hierarchical coordination with decentralized/distributed controls are most advisable (see [10, 29]). They allow scalability as computations become parallelized, provide more resilience to communication failure, an increased level of privacy, and a guarantee that local constraints can be locally satisfied. Decentralized control is also consistent with the multi-agent framework advocated for smart grids and microgrids in [15, 28]. As a result, on the modeling front, the approaches inspired from statistical physics, which start from physically based stochastic microscopic descriptions of loads and build via ensemble analysis macroscopic aggregate descriptions, and started in the eighties ([23, 25]), are making a strong comeback (see [9, 11, 24, 36, 38]). On the control theoretic front, game theory has witnessed a surge. More importantly though, one has to note the relatively novel development of so-called mean field games (MFG's) ([8, 19, 20, 22]): they combine in effect the bottom-up modeling power of statistical physics with the decentralized control theoretic potential of game theory. They are at their most basic level a game theory of large groups of class wise interchangeable agents, whose individual influence on the group asymptotically vanishes with the size, thus leading in the limit, under Nash equilibrium conditions to (i) predictability of the group behavior via the law of large numbers, (ii) decentralized individual control policies with a dependence on local state and statistical information on the agents’ dynamic and cost parameters, as well as their initial states distribution.

MFG approaches have found applications in numerous areas including economics (see [14] and the references therein), and engineering systems in general including CDMA communication systems, virus propagation in computer systems, crowd dynamics, traffic analysis, etc. (see [12] for a survey).

In this paper, we intend to illustrate how MFG's constitute a natural tool in aggregator based load dispatch, with the particular class of thermostatic electric heating loads aimed at. An aggregator is considered as a technically equipped broker, acting on behalf of a pool of customers to coordinate their loads as a virtual battery on the energy markets. Her role is to rely on a regularly updated updated load model to assess the time dependent load absorption or relief potential of the load pool under its responsibility, and to compute and send piecewise constant mean pool energy content targets which are feasible under comfort and security constraints, and which will result in overall economic gains for the pool, and indirectly, the quality of the environment. A MFG based computation of individual load control strategies will lead to decentralized locally computable and implementable controls thus achieving computational scalability, with minimal communication requirements, local compliance with comfort and security constraints, and as we shall see, a size of device contribution in direct relation to the device current ability to contribute.

Besides the application context, on the technical level, the fundamental novelty here is the introduction of integral control in the cost coefficients of what is otherwise an instance of a linear quadratic Gaussian MFG [19]. The integral control in the cost coefficient introduces with it both the potential benefits of robustness of integral controllers to inadequate modeling and disturbances which has been so successfully leveraged in applications [32], and the unfortunate risk of a cost coefficient going unbounded. After setting up our microscopic controlled device model and defining a cost function which weighs the individual's reluctance to contribute against the objective of having to meet the global aggregate target, we establish the existence of an asymptotic Nash equilibrium on an appropriately defined Banach space. This equilibrium may be on target (desirable equilibrium), or may correspond to an undesirable equilibrium (a cost coefficient going unbounded). We then develop an algorithm to reliably compute a near Nash strategy corresponding to a desirable equilibrium. Numerical results illustrate the flexibility of the approach and the robustness to modeling errors conferred by the integral control structure.

The rest of the paper is organized as follows. In Section 2 we introduce the model that will be used throughout the paper and propose our collective target tracking mean field formulation. In Section 3 we present a fixed point analysis for the equation system characterizing the limiting mean field, and we develop our \( \epsilon \)-Nash Theorem indicating that an approximate Nash Equilibrium is attained. We provide in Section 4 an algorithm that gen-
erates approximate desirable fixed point mean trajectories. Lastly, in Section 5, we provide simulation results together with comparisons to a prevailing target tracking control formulation.

The following notation is defined: the set of nonnegative real numbers is denoted by \( \mathbb{R}_+ \). The set \( C(0, \infty) \) denotes the family of all continuous functions on \([0, \infty)\), \( C_0(0, \infty) = \{ x : x \in C(0, \infty), \forall k_0 > 0, 0 \leq x(t) \leq k_0, \forall t \geq 0 \} \), \( C_b(0, \infty) = \{ x : x \in C(0, \infty), \sup_{t \geq 0} |x_t| < \infty \} \), and for any \( x \in C_b \), \( \| x \|_\infty \) denotes the supremum norm: \( \| x \|_\infty \equiv \sup_{t \geq 0} |x_t| \).

### 2 ELECTRIC SPACE HEATER MODELS

In the following, we first introduce the model for space heating dynamics that will be employed throughout the paper. Subsequently, a collective target tracking mean field control model is defined together with the individual control actions and the corresponding mean field system of equations is developed.

![Fig. 1. Equivalent thermal parameter (ETP) model of a household](image)

- We employ a one dimensional equivalent thermal parameter (ETP) model (see Fig. 1) [34] to describe the thermal dynamics of a single household, which is written as

\[
dx^i = \frac{1}{C_a} [ -U_a(x^i - x^{out,i}) + Q_h(t) ] dt + \sigma dw^i, \quad (1)
\]

where \( t \geq 0 \), \( x^i \) is the air temperature inside the household, \( x^{out,i} \) is the outside ambient temperature, \( C_a \) is the thermal mass of air inside, \( U_a \) is conductance of the walls and \( Q_h \) is the heat flux from the heater. Note that \( w^i, t \geq 0 \), is a standard Wiener process defined on \( (\Omega, \mathcal{F}, P) \) to reflect the noise on the system caused by random processes of heat gain and loss due to customer activity within the dwellings, and \( \sigma \) is its volatility term.

For brevity of notation, the system for heater \( \mathcal{A}_i \), \( 1 \leq i \leq N \), is equivalently written as

\[
dx^i_t = [ -a^i(x^i_t - x^{out,i}) + b^i u^i_t ] dt + \sigma dw^i_t, \quad (2)
\]

where \( x^i \equiv x^{in,i} \) and \( u^i \equiv Q_h^i \) for \( 1 \leq i \leq N \); \( a^i = U_a^i/C_a^i \) and \( b^i = (C_a^i)^{-1} \). \( \{ w^i, 1 \leq i \leq N \} \) are \( N \) independent Wiener processes on a probability space \((\Omega, \mathcal{F}, P, \{ \mathcal{F}_t \}_{t \in [0, T]} \) \). \( \{ \mathcal{F}_t \}_{t \in [0, T]} \) is the augmented filtration of \( \{ x^i_0, w^i_s, 0 \leq s \leq t, 1 \leq i \leq N \} \) \([21, Section 2.7]\), where \( x^i_0 \), \( 1 \leq i \leq N \), are the initial temperatures assumed i.i.d. with distribution \( P_0 \) and finite second moments \( \mathbb{E}[x^i_0^2] < \infty \), and also independent of \( \{ w^i, 1 \leq i \leq N \} \). Note that this model is similar to the model given in [25], where the thermostat control is exchanged with a linear control.

We consider that users “naturally” would like their devices to stay at their initial temperatures (normally attained via thermostat action and before the intervention of the power utility control center). Thus, we have reformulated the control effort as the signal required to make them deviate from that initial temperature; more precisely, the control effort to stay at the initial temperature is considered free and will not be penalized by the cost function to be defined. The corresponding dynamical equation is written as

\[
dx^i_t = [-a^i(x^i_t - x^{out,i}) + b^i(u^i_t + u^{free,i})] dt + \sigma dw^i_t, \quad (3)
\]

where \( u^{free,i} \equiv (b^i)^{-1} a^i(x^i_0 - x^{out,i}) \).

**A1:** We assume that the mean temperature is bounded from above and below by comfort levels; i.e., \( \underline{x} \leq \mathbb{E}x_0^i \leq \overline{x} \).

Note that \( l \) and \( h \) respectively represent the lowest and highest temperatures considered tolerable in the controlled dwellings (see Fig.3 below). These numbers are to be initially agreed upon with the participants in the control program (In our simulations, we took them to be respectively 17 and 25 degrees Celsius).

We assume a population of \( m \) types of agents, that is, the vector of individual parameters \( \theta^i := (a^i, b^i, x^{out,i}) \) takes values in a finite set \( \{ \Theta_1, \ldots, \Theta_m \} \), which does not depend on the size of the population \( N \). The empirical probability measure of the sequence \( \{ \theta^i \}_{i=1}^{\infty} \) is denoted by \( P^N_{\theta} (\Theta_s) = 1/N \sum_{i=1}^{N} 1_{\{ \theta^i = \Theta_s \}} \) for \( s = 1, \ldots, m \). We assume that \( P^N_{\theta} (\Theta_1), \ldots, P^N_{\theta} (\Theta_m) \) converges to \( \Theta_{m} = (n_1, \ldots, n_m) \), as \( N \rightarrow \infty \), where \( n_s > 0 \) for all \( 1 \leq s \leq m \).

### 2.1 General Characteristics of a Desirable Load Coordination Scheme

In this subsection, we briefly discuss the important characteristics of a desirable load coordination scheme by the aggregator. Given the potentially very large number of residential loads that the aggregator needs to coordinate to form a virtual battery of sufficient size, it is impossible to assume it will be able to centrally observe all loads. However, the aggregator can be assumed to have the ability to broadcast common signals such as a
temperature target \( y \). Thus, a first essential characteristic of the control scheme must be (i) Decentralization. This is because in the absence of local state observation and given the uncertain/stochastic nature of individual loads, open loop control signals could send regularly individual temperatures at undesirable levels, thus potentially causing customer withdrawals from the aggregator’s power pool. A local controller can always use the local information to ensure that comfort/security constraints are not violated. Another important feature is that the resulting control actions should lead quickly to the desired result with least disturbance to the customer, again to avoid potential customer withdrawals. This can be summarized as (ii) Minimality of forced temperature excursions. A third feature which is desirable but not essential is the minimization of the signalling overhead to achieve the objective, and summarized as (iii) Parsimony of communications.

In the following, we discuss the advantages, yet shortcomings of a simple, intuitive, standard LQG tracking controller which would have every device track the desired mean temperature level \( y \), and later compare its would be performance to that of our proposed MFG Based integral controller.

2.2 Advantages and Shortcomings of a Standard LQG Tracking Controller

Assuming the aggregator has set the objective of attaining a given population mean temperature target \( y \), a simple and effective control scheme for doing so is to broadcast \( y \) to all devices, and have each solve an LQG based control scheme for tracking level \( y \). For example, the individual cost function of devices would be as follows:

\[
J^LQ_i(u^i) = \mathbb{E} \int_0^\infty e^{-\delta t} \left[ (x^i_t - y)^2 q^LQ + (u^i_t)^2 r \right] \, dt. \tag{4}
\]

Clearly, such a control scheme, besides being very simple to implement, meets the criteria (i) and (iii) above, i.e. it is both decentralized and communications parsimonious. However, the fundamental shortcoming of such a controller is that, while the aggregator is interested only in having the mean population state settle at target \( y \), this controller sends instead all devices to that target. This not only maximizes individual user temperature excursions, thus falling short on criterion (ii) above, but furthermore will result in general in a slow controller since some devices are "undoing" the contribution of other devices (some devices are heating further, while others are cooling in order to reach a mean state \( y \).)

In the coordination scheme we propose next, instead of each agent state trying to track a common target \( y \), the individual cost structures (see (5) below) are formulated such that ultimately, it is only the mean of the population trajectories that tracks the desired target. In the resulting MFG, the novelty is that the mean field effect is mediated by the quadratic cost function parameters under the form of an integral error. The resulting concept will be called collective mean target tracking.

2.3 The Collective Mean Target Tracking Model

We employ the dynamics for the heaters given in (2), with the input redefined based on (3). Following a prescriptive game theoretic view of the coordination problem, the infinite horizon discounted cost function for agent \( A_i, 1 \leq i \leq N \), is defined as:

\[
J^c_i(u^i, u^{-i}) = \mathbb{E} \int_0^\infty e^{-\delta t} \left[ \frac{q^y_i}{2} (x^i_t - z)^2 + \frac{g^x_i}{2} (x^i_t - x^0_t)^2 + \frac{r}{2} (u^i_t)^2 \right] \, dt. \tag{5}
\]

We now discuss the role of each term in the integrand in (5), proceeding from left to right. \( z \) is actually either one of the limiting temperatures \( l \) and \( h \) referred to in Assumption A1. \( z \) is set to \( l \) if the objective is overall dwellings power/energy decrease, or \( h \) if instead it is overall increase. The value of \( z \) will thus define the direction (up or down) according to which individual dwelling temperatures will drift. However, the pressure to move in that direction is dictated by the coefficient \( q^y_i \), defined below as the integral of an increasing function of the deviation between the average state of agents and a temperature target \( y \). Thus:

\[
q^y_i = \left| \int_0^t g(x^N_{\tau} - y) \, d\tau \right|, \quad t \geq 0, \tag{6}
\]

where \( g \) is a real increasing continuous function on \( \mathbb{R} \) with \( |g(x)| \leq C(1 + |x|) \) for some \( C > 0 \). \( \forall x \in \mathbb{R} \), \( y \) is the main control center dictated mean target constant level, and \( x^N_{\tau} \equiv (1/N) \sum_{i=1}^{N} x^i \). Note that the time varying coefficient \( q^y_i \) is the only channel through which the mean field (mean dwellings temperature in our case) influence is felt by individual agents.

The target \( y \) is decided upon by the aggregator. The latter uses a macroscopic aggregate model of the dwellings to evaluate their current energy storage, and their short term power/energy release or increase potential so as to make bids on the energy market. Alternatively, in a microgrid for example, the aggregator could also be building an optimal dwellings energy content schedule, based on forecasts of the intermittent renewable power that will be available in the microgrid. We further note that energy content targets are equivalent to mean temperature targets.

While the first term was introduced to mathematically capture the aggregator’s objective of producing upwards/downwards drift of average dwellings temperature, the next term will simulate resistance of individuals to changes in their initial temperature at the start of the control period. Indeed, the associated cost increases
whenever $x_i^s$ moves away from its initial value $x_i^0$. Note that this introduces a further element of heterogeneity amongst agents. Finally, the last term penalizes the control effort, again redefined (recall (3)) as the agent effort involved in moving away from $x_i^0$. In summary, while the first term favors the aggregator, the next two terms in the cost integrand favor the individual agents.

The justification for the above cost function is that by pointing individual agents towards what is considered as the minimum (or maximum) comfort temperature $z$, it dictates a global decrease (or increase) in their individual temperatures. This pressure persists as long as the differential between the mean temperature and the mean target $y$ is high. The role of the integral controller is to mechanically compute the right level of penalty coefficient $q^{nl}_i$, $t \in [0, \infty)$, which, in the steady-state, should maintain the mean population temperature at $y$. When this happens, individual agents reach themselves their steady states (in general different from $y$ and closer to their initial diversified states than standard LQG tracking would dictate). Furthermore, if the mean state of agents is observed, this integral control adds robustness to model imperfections or inaccurate ambient temperature estimation. Note that other approaches to robustness in a MFG context are possible [17, 37]. However, they could not produce exact tracking of targets as integration control based algorithms can.

For each heater $i$, the set of admissible control laws is the set $U_i$ of $F_i$—progressively measurable $u_i^s$ such that $\mathbb{E} \int_0^\infty e^{-\delta t}|u_i^s|^2 dt < \infty$. It should be noted that whenever $(w_i,u_i^{-i}) \in \prod_{i=1}^N U_i$, then $J_i(u_i^s,u_i^{-i}) < \infty$. The $2\delta/3$ in the definition of $U_i$ is to force the term with $q_i^{nl}(x_i^s - z)^2$ in the cost to be finite.

In order to derive the limiting infinite population MF equation system, we start this time assuming a given (albeit initially unknown) cost penalty trajectory $q^p \in C_l(0,\infty)$ and constant $q^{ro}$. We show later in Lemma 9 that the candidates $q^p$ actually belong to $C_l[0,\infty)$. Given $q^p$ and $q^{ro}$, individual agents $A_i$, $1 \leq i \leq N$, solve a standard target tracking LQG problem [6] with time varying cost coefficient. Using techniques similar to those used in [18, Lemma A.2], one can show that the original control law of this LQG problem is,

$$(u_i^s)^o = -b_i r^{-1}(\pi_i^s x_i^s + \alpha_i^s - \pi_i^s z), \quad t \geq 0,$$

with $\pi^{vel}$ and $\alpha^i$ respectively the unique solution and unique bounded solution of

$$\frac{d\pi_i^s}{dt} = (2a_i^s + \delta)\pi_i^s + \frac{(b_i)^2}{r}(\pi_i^s)^2 - q^{nl}_i - q^{ro},$$

$$\frac{d\alpha_i}{dt} = (a_i^s + \delta + \frac{(b_i)^2}{r}\pi_i^s)\alpha_i - (a_i^s \pi_i^s - q^{ro})(x_i^0 - z).$$

The calculation of the unknown $q^{nl}_i$, $t \geq 0$, is obtained by requiring that $q^{nl}_i$ be such that when individual agents implement their associated best responses, they collectively replicate the posited $q^p$, trajectory. This fixed point requirement leads to the specification below of the collective target tracking MF equation system. In the remainder of this paper a superscript $s$ refers to a heater of type $s$.

**Definition 1** Collective Target Tracking (CTT) MF Equation System refers to the following coupled system of integro-differential equations on $t \in [0, \infty)$:

$$q^{nl}_i = \left| \int_0^t g(x_i - y)dt \right|,$$

$$\frac{d\pi_i^s}{dt} = (2a_i^s + \delta)\pi_i^s + \frac{(b_i)^2}{r}(\pi_i^s)^2 - q^{nl}_i - q^{ro},$$

$$\frac{d\alpha_i^s}{dt} = (a_i^s + \delta + \frac{(b_i)^2}{r}\pi_i^s)\alpha_i^s - (a_i^s \pi_i^s - q^{ro})(x_i^0 - z).$$

$1 \leq s \leq m$, where $n_s$ is defined below Assumption 1.

Equation (11) is the Riccati equation that corresponds to the LQG optimal tracking problem solved by an agent of type $s$. The solution of the collective target tracking (CTT) MF equation system (10)-(14) is obtained offline locally by each agent only based on statistical information $P_0 = (n_1,\ldots,n_m)$ and $P_0$, assumed available at the start of the control horizon. In theory, the control scheme is fully decentralized; i.e., no communication needs to take place among the controllers throughout the horizon. In practice however, because of the anticipated prediction error accumulations over time, it is more advisable to readjust periodically the control laws over long intervals based on aggregate system measurements based on a limited set of randomly sampled agents (see Fig. 2). As we shall see in Section 5, this also helps robustifying the control performance against mismodeling.

Note that the MF Equations for this model are significantly different from (4.6)-(4.9) in [19] which is amenable to analysis within a linear systems framework, while uniqueness of the fixed point is obtained via a sufficient contraction condition. In contrast, system (10)-(14) is fundamentally nonlinear (because of the form of $q^{nl}_i$), and $q^{nl}_i$ itself could indeed become unbounded. Special arguments have to be developed for the analysis.
We now tackle the fixed point analysis for (10)-(14). We consider the case $y \leq \bar{x}_0$, i.e. when the target temperature set by the aggregator is less than or equal to the initial mean temperature of the population. The analysis is very similar for the case $\bar{x}_0$. We will be omitted. Note that for $y \leq \bar{x}_0$, $z$ is set to be less than $y$; i.e., $z = l \leq y \leq \bar{x}_0 \leq h$, so that the agents collectively decrease their temperatures by moving towards that target (see Fig. 3).

### 3.1 CTT MF Equation System

Considering the CTT MF Equation System (10)-(14), we introduce in the following the operators $\Delta$ and $T^s$, $1 \leq s \leq m$, where $\mathcal{M} \triangleq \sum_{s=1}^{m} n_s T^s \circ \Delta$, $\mathcal{M}(\bar{x}) : \mathbb{C}_b[0, \infty) \rightarrow \mathbb{C}[0, \infty)$, characterizes the complete equation system. We define the operator $\Delta : \mathbb{C}_b[0, \infty) \rightarrow \mathbb{C}_b[0, \infty)$:

$$q_t^y = \left| \int_0^t g(\bar{x}_r-y)d\tau \right| \triangleq \Delta(\bar{x}_r; \tau \in [0; \infty))(t).$$  \hspace{1cm} (15)

Hereon, for notational convenience, the value at time $t$ of the function to the extreme right-hand side of (15), will be denoted $\Delta(\bar{x}_r)(t)$. Next for each $1 \leq s \leq m$, we define $T^s : \mathbb{C}_b[0, \infty) \rightarrow \mathbb{C}[0, \infty)$ for the equation system (11)-(13) with input $q_t^y$ and output $\bar{x}_t^s$, which is equivalent to

$$\bar{x}_t^s \triangleq (T^s q)(t).$$  \hspace{1cm} (16)

Hence, one can write the MF equation system for CTT as

$$\bar{x}_t = \left( \sum_{s=1}^{m} n_s T^s \circ \Delta \right)(\bar{x})(t) \triangleq (\mathcal{M} \bar{x})(t).$$  \hspace{1cm} (17)

### Remark 2

It should be noted that the image by $T^s \circ q$, $T^s(q)$, is the optimal state of the following deterministic LQR tracking optimal control problem,

$$J(u) = \int_0^{\infty} e^{-\delta t} \left( \frac{q^2}{2}(x_t - \bar{x}_0)^2 + \frac{q^2}{2}(x_t - \bar{x}_0)^2 + \frac{r}{2}u^2 \right) dt$$

s.t. $\frac{d}{dt} x = -a^*(x - \bar{x}_0) + b^*u$, $x(0) = \bar{x}_0$. \hspace{1cm} (18)

We need to restrict the operator $\mathcal{M}$ on an invariant subset of a Banach Space over which it is continuous. This allows us to apply a fixed point theorem, such as Schauder’s theorem [33], and show the existence of a solution to the CTT MF equations. As shown later, the image of $\mathcal{M}$ is included in the set $\mathcal{G} := \{ x : x \in \mathbb{C}_b[0, \infty), \; z \leq x(t) \leq x_0 \}$. Hence, one of the candidate subsets is $\mathcal{G} \subset (\mathbb{C}_b[0, \infty), \| \cdot \|_{\infty})$. Indeed, the Banach space $(\mathbb{C}_b[0, \infty), \| \cdot \|_{\infty})$ was used in the classical LQG MFG theory. We give however in the following subsection, an example where the continuity of $\mathcal{M}$ fails to hold on $\mathcal{G} \subset (\mathbb{C}_b[0, \infty), \| \cdot \|_{\infty})$. As a result, existence of a fixed point is not guaranteed. Instead here, we propose a suitable norm that weakens the topology and enlarges the space in order to force continuity. This paves the way in Subsection 3.3 for our proof of the existence of a fixed point.

#### 3.2 Failure of continuity under the sup-norm and suitable Banach space

We start by giving an explicit formula for the operator $T^s \circ \Delta$. Solving equation (12), and replacing the solution in (13) give for all $\bar{x} \in \mathcal{G}$,

$$(T^s \circ \Delta)(\bar{x})(t) = \phi^s(t, 0)\bar{x}_0 + \frac{(b^s)^2}{r} \int_0^t \phi^s(t, \eta) \pi^s_\eta d\eta + a^s \bar{x}_0 \int_0^t \psi^s(t, \eta)(-a^s \pi^s_\eta + q^s_\eta)d\eta d\tau,$$

with

$$\phi^s(t, \eta) = \exp \left( -\int_t^\eta (a^s + b^s \pi^s_\eta r^{-1}) d\tau \right)$$

and

$$\psi^s(t, \eta) = \exp \left( -\int_t^\eta (a^s + \delta + (b^s)^2 \pi^s_\eta r^{-1}) d\tau \right).$$

Using the fact that $(b^s)^2 \pi^s_\eta r^{-1}$ is the derivative w.r.t. $t$ of...
where \( C^* = ((b^*)^2 r^{-1} q^0 + (a^*)^2 + a^* \delta) (\bar{x}_0 - z) \). The proof of the following lemma is given in Appendix A.

**Lemma 3** Consider \( g(x) = x, \bar{x}_0 = 1, y = 0 \) and \( z = -1 \). The operator \( \mathcal{M} : \mathcal{G} \subset (C_b[0,\infty],\|\|\|_\infty) \to (C_b[0,\infty],\|\|\|_\infty) \) is not continuous.

In the proof of Lemma 3 it is shown that the continuity of \( \mathcal{M} \) does not hold because of the way the sup-norm evaluates the magnitude of a function. Indeed, the sup-norm assigns a non-negligible value to any function with a non-negligible value at the tail, \( \mathcal{M}(\bar{x}^n) \) does not converge to \( \mathcal{M}(y) \) under this norm. Thus, we need a norm that suppresses the value of a function at the tail. A good candidate is the norm \( \|x\|_k := \sup_{t \in [0,\infty)} |e^{-kt} x_t| \). We also need to enlarge the space \( C_b[0,\infty) \) to get a Banach space under this new norm. Thus, we define the following function space,

\[
C_k[0,\infty) = \{ x : x \in C[0,\infty] \sup_{t \in [0,\infty)} |e^{-kt} x_t| < \infty \},
\]

where \( k > 0 \). We establish in Lemma 7 of Appendix A some properties of the spaces \( C_k[0,\infty) \), which are used in the remainder of this paper.

### 3.3 Fixed Point Theorem

Following the preliminary results, we present our fixed point existence theorem, where the proof is given in Appendix B. We make the following technical assumption.

**A2:** We assume that the function \( g \) is Lipschitz continuous on compact subsets.

**Theorem 4** Fix \( 0 < k < \min a^* + \delta \). Under **A2**, the following statements hold:

i. for all \( \bar{x}' \) and \( \bar{x}'' \) in \( \mathcal{G} \), \( \| \mathcal{M}(\bar{x}') - \mathcal{M}(\bar{x}'') \|_k \leq \lambda R_k \| \bar{x}' - \bar{x}'' \|_k \), where \( R_k \) is a positive constant that depends on \( k \), and \( \lambda \) is the Lipschitz constant of \( g \) on \( [-\bar{x}_0 - y, \bar{x}_0 - y] \).

ii. the map \( \mathcal{M} : \mathcal{G} \subset (C_k[0,\infty],\|\|\|_k) \to \mathcal{G} \subset (C_k[0,\infty],\|\|\|_k) \) has at least one fixed point.

**Remark 5** If \( k \) is small enough, then the operator \( \mathcal{M} \) is a contraction, and there exists a unique fixed point \( \bar{x} \in \mathcal{G} \). The existence of a fixed point for (10)-(14) in essence implies the existence of a Nash equilibrium for an infinite population game. At the equilibrium, the prescribed control actions are the best responses for infinitesimal agents, and there is no unilateral profitable deviation.

Finally, we establish that the infinite population Nash equilibrium of Theorem 4 is in fact an \( \epsilon \)-Nash equilibrium when applied to the practical case of a large but finite population. The proof of this result is similar to the proof of Theorem 5.6 in [19], and is therefore omitted.

**Theorem 6** CTT MF Stochastic Control Theorem: Assume that **A1** and **A2** hold. Then, the set \( \{(u^i)^\circ ; 1 \leq N < \infty \} \) where \( (u^i)^\circ \) is defined in (7) for a fixed point \( \bar{x} \) of \( \mathcal{M} \), yields an \( \epsilon \)-Nash equilibrium in the sense that, for all \( \epsilon > 0 \), there exists \( N(\epsilon) \) such that for all \( N \geq N(\epsilon) \)

\[
J_i((u^i)^\circ, (u^{-i})^\circ) - \epsilon \leq \inf_{u_i \in U_i} J_i(u^i, (u^{-i})^\circ).
\]

### 4 DESIRABLE NEAR FIXED POINT ALGORITHM

Theorem 4 states that there exists at least one fixed point of \( \mathcal{M} \). However, it does not guarantee the existence of a practically useful fixed point. A fixed point which is desirable in practice is a sustainable mean trajectory (i.e. replicated as the mean of best responses to the associated pressure field), such that its steady-state value is equal to the target temperature \( y \). In the following, we propose an algorithm that generates desirable approximate fixed points in case (i) \( g(x) = \mu x \), and (ii) \( g \) is a continuous function equal to \( \mu(e^{\beta x} - 1) \) when restricted to \( [z - y, \bar{x}_0 - y] \), and constant outside this interval. Here \( \beta \) and \( \mu \) are positive scalars. In both cases, the function \( g \) satisfies \( |g(x)| \leq C(1 + |x|) \), for some \( C > 0 \), under Assumption **A2**. In the second case, the part of \( g \) that is actually involved in determining the fixed points is \( \mu(e^{\beta x} - 1) \), since a fixed point always belongs to the set \( \mathcal{G} \). The extension of \( g \) by a constant function outside the interval \( [z - y, \bar{x}_0 - y] \) is to force the inequality \( |g(x)| \leq C(1 + |x|) \) to hold everywhere. In the following, we denote the operators \( \mathcal{M} \) and \( \Delta \) by \( \mathcal{M}_\mu \) and \( \Delta_\mu \), to emphasize their dependence on \( \mu \). We consider only the uniform case, i.e. a population with only one type of space heater. Thus, we omit the superscript \( s \) in this section.

The idea of the algorithm is to construct a family of mean trajectories indexed by \( \mu \), \( \{ \bar{x}(\mu) \}_\mu \), such that \( \lim_{\mu \to \infty} \bar{x}(\mu) = \lim_{\mu \to \infty} \mathcal{M}_\mu(\bar{x}(\mu)) = y \). Subsequently, we look for a \( \mu_\ast \) that minimizes \( \| \bar{x}(\mu) - \mathcal{M}_\mu(\bar{x}(\mu)) \|_2 \). As a result, the mean trajectory \( \bar{x}(\mu_\ast) \) is approximately a fixed point, i.e. a near Nash equilibrium of the infinite population limit. Moreover, when the infinite population optimally responds to this mean, its mean \( \mathcal{M}_\mu(\bar{x}(\mu_\ast)) \) is guaranteed to converge to \( y \) as \( t \to \infty \).
In order to get $\lim M_\mu(\bar{x}(\mu)) = y$, the cost coefficient trajectory $q^\mu y(\mu) = \Delta_\mu(\bar{x}(\mu))$ must converge to $q^\mu_y^*$, satisfying the following algebraic equations:

$$
\begin{align*}
0 &= (-2a - \delta)\pi_\infty - b^2 r^{-1} s^2 + q^\infty x + q^\infty y, \\
0 &= (-a - \delta - b^2 \pi_\infty r^{-1}) s_\infty + (a^2 r - q^\infty)(\bar{x}_0 - z), \\
0 &= (-a - b^2 \pi_\infty r^{-1}) y - b^2 r^{-1}(s_\infty - \pi_\infty s_0) + a\bar{x}_0,
\end{align*}
$$

where $\pi_\infty$, $s_\infty$ denote the steady state values for Riccati and offset equations respectively. Solving the equation system for $q^\infty_y$ yields the unique solution:

$$
q^\mu_y^* = \frac{a(a + \delta)r + q^\infty b^2}{b^2} \left( \bar{x}_0 - y \right) / \left( y - z \right).
$$

(21)

Thus, it remains to find a family of mean trajectories $\{\bar{x}(\mu)\}_\mu$ that converge to $y$ as $t \to \infty$, and such that their corresponding cost coefficient trajectories converge to $q^\mu_y^*$ as $t \to \infty$. Indeed, the near Nash desired mean trajectory will be sought for within that family. We construct the family as follows. We start by applying the cost coefficient trajectory $q^\mu_t = n_1 q^\infty_y^*$ for $t \in [0, t_0]$ and $q^\mu_t = q^\mu_y^*$ for $t > t_0$, for some $n_1 > 1$ and $t_0 > 0$. This cost coefficient trajectory generates a mean trajectory $\bar{x}^{sup} = \mathcal{T}(q^\mu_y^*)$ which will constitute an upper boundary of our search set. Clearly, $\bar{x}^{sup}$ converges to $y$, in fact exponentially so, since the $q^\mu_y^*$ that generates it becomes constant after finite time $t_0$. Similarly, we get $\bar{x}^{inf}$, the lower boundary of the search set, by applying the same cost coefficient where we replace $n_1$ by a larger number $n_2$. $\bar{x}^{sup}$ is greater than $\bar{x}^{inf}$ since it is generated by a cost coefficient lower than that of $\bar{x}^{inf}$, thus corresponding to a lower pressure field [7]. Afterward, we define $\mu_{sup} = q^\mu_y^*/\lim \Delta_1(\bar{x}^{sup})$, with the integral in the denominator guaranteed to remain finite, because of the exponential convergence of the mean to the target. Thus, by construction, $q^{sup} = \Delta_{\mu_{sup}}(\bar{x}^{sup})$ converges to $q^\mu_y^*$.

Similarly, we define $\mu_{inf}$, such that $q^{inf} = \Delta_{\mu_{inf}}(\bar{x}^{inf})$ converges to $q^\mu_y^*$. If we choose $t_0$ small, $n_1$ and $n_2$ close to one, then $\bar{x}^{inf}$ and $\bar{x}^{sup}$ undershoot the target temperature $y$ for a small interval of time and climb back to $y$. As a result, the negative parts of the integrals $\int_0^\infty g(\bar{x}^{inf} - y)dt$ and $\int_0^\infty g(\bar{x}^{sup} - y)dt$ do not outweigh the positive parts. In this way, for any $\mu > 0$, if $\bar{x}^{inf} \leq \bar{x} \leq \bar{x}^{sup}$, then $\lim \Delta_\mu(\bar{x}) = \lim \Delta_\mu(\bar{x})$. In particular, $\mu_{sup} < \mu_{inf}$. Hence, for each $\mu_{sup} < \mu < \mu_{inf}$, $\Delta_\mu(\bar{x}^{inf})$ converges to a value greater than $q^\mu_y^*$, while $\Delta_\mu(\bar{x}^{sup})$ to a value lower than $q^\mu_y^*$. We define for each $f \in [0, 1]$ the trajectory $\bar{x}_f = (1 - f)\bar{x}^{inf} + f\bar{x}^{sup}$. Using the continuity of $\lim \Delta_\mu(\bar{x}_f)$ with respect to $f$, one can use the dichotomy method to find for each $\mu_{sup} < \mu < \mu_{inf}$, a $f^\mu \in [0, 1]$, equivalently, a convex combination $\bar{x}(\mu) = f^\mu \bar{x}^{sup} + \bar{x}^{inf}$, such that $\Delta_\mu(\bar{x}(\mu))$ converges to $q^\mu_y^*$. This gives the desired family of mean trajectories. We summarize the numerical scheme in Algorithm 1.

**Algorithm 1** Desirable near fixed point algorithm

1. Initiate $n_2 > n_1 > 1$, $t_0$, $d\mu$, $e_1$, $e_2$, $\gamma$
2. procedure GENERATION OF $\bar{x}^{sup}$ AND $\bar{x}^{inf}$
3. Apply $q^\mu_t = n_1 q^\infty_y^*$ for $t \in [0, t_0]$ and $q^\mu_t = q^\mu_y^*$ for $t > t_0$, and generate $\bar{x}^{sup} = \mathcal{T}(q^\mu_t)$.
4. Apply $q^\mu_t = n_2 q^\mu_y^*$ for $t \in [0, t_0]$ and $q^\mu_t = q^\mu_y^*$ for $t > t_0$, and generate $\bar{x}^{inf} = \mathcal{T}(q^\mu_t)$.
5. $\mu_{sup} = \lim_{t \to \infty} \Delta_1(\bar{x}^{sup})$ and $\mu_{inf} = \lim_{t \to \infty} \Delta_1(\bar{x}^{inf})$
6. end procedure
7. Initiate $\mu$ between $\mu_{sup}$ and $\mu_{inf}$
8. procedure GRADIENT DESCENT TO COMPUTE $\mu$
9. while $err_1 > e_1$ do
10. for $i = \mu$ and $i = \mu + d\mu$ do
11. $f^m = 0$, $f^M = 1$, $\bar{x}^{inf} = \bar{x}^{sup}$, $\bar{X}^M = \bar{X}^{sup}$
12. procedure COMPUTATION OF $\bar{x}(i)$
13. while $err_2 > e_2$ do
14. $f = (f^m + f^M)/2$
15. $\bar{x}(i) = f\bar{x}^{inf} + (1 - f)\bar{X}^M$
16. if $\lim_{t \to \infty} \Delta_1(\bar{x}_f(i)) \geq q^\mu_y^*$ then
17. $f^m = f$, $\bar{x}^{inf} = \bar{x}(i)$
18. else
19. $f^M = f$, $\bar{X}^M = \bar{x}(i)$
20. end if
21. $err_2 = \|\bar{x}(i) - q^\mu_y^*\|$
22. end while
23. end procedure
24. end for
25. $\nabla = (\|\bar{x}(\mu + d\mu) - M_\mu + d\mu(\bar{x}(\mu + d\mu))\|_2 - \|\bar{x}(\mu) - M_\mu(\bar{x}(\mu))\|_2)/d\mu$
26. $\mu = \mu - \gamma \nabla$
27. end while
28. $err_2 = |G|$
29. end procedure
30. Output: $\mu = \mu$ and $\bar{x}(\mu)$ a desirable near fixed point

**5 SIMULATIONS**

For our numerical experiments we simulate a population of 200 space heaters. We consider a uniform population of heaters; adopt a single layer ETP model as given in (1), where the capacitance ($C_a$) and conductance ($U_a$) parameters [4] are chosen to be 0.57 kWh/°C and 0.27 kW/°C respectively, the ambient temperature is set to -10 °C, and the volatility parameter is set to 0.15 °C/√h. The initial temperatures of the heaters are drawn from a Gaussian distribution with a mean of 21°C and a variance of 1. The cost function parameters $\delta$, $q^\infty$ and $r$ are uniformly chosen to be 0.001, 200 and 10 respectively. We consider two scenarios. In the first scenario the heaters are controlled by the mean-field controllers (7), while in the second scenario they apply, for comparison purposes, the LQG controllers of Section 2.2. We
limit the size of computations by considering a finite time horizon of length $T = 3$ hours. For the mean field game based controller, we use the function $g(x) = \mu_* x$, where $\mu_* = 1484$ is computed using the algorithm of Section 4.

Fig. 4 shows the Near Nash Trajectory (NNT), i.e., near fixed point desirable temperature trajectory $\bar{x}$ generated by the algorithm of Section 4, the resulting Theoretical Output Mean Trajectory (TOMT) $\mathcal{M}(\bar{x})$ and the Empirical Average Temperature (EAT) of the 200 space heaters when they optimally respond to $\bar{x}$ by applying the mean-field controllers (7). As shown in the figure, the three trajectories are approximately identical and converge to the target temperature $y = 20^\circ C$. This figure illustrates also the EAT under the LQG controllers. It should be noted that both approaches, MF and LQG, succeed in forcing the empirical average space heater temperatures to converge to the target temperature. But, as shown in Fig. 5 the user disturbance is much greater in the LQG case than it is in the mean field case. Indeed, this figure, which reports the temperature profiles of 10 heaters when they apply respectively the mean field and LQG controllers, shows that all the temperatures must move to $y$ in the LQG case, while in the mean field case the temperatures stay close to their initial values, and individual devices contribution is in direct relation with their initial energy content.

Next, we consider the case where $g(x) = \mu_*(e^{3x} - 1)$, with $\mu_* = 218$ is determined by the algorithm of Section 4. As shown in Fig. 6, the TOMT reaches for the first time the target faster than the case with linear $g$, but needs more time to resettle on $y$. This is due to the fact that when $\bar{x} > y$, the dominant part of $g$ is the exponential. This creates a high pressure field towards $y$. When $\bar{x}$ undershoots $y$, the linear part of $g$, the scalar $-1$, becomes the dominant part, and the mean climbs slowly towards $y$.

Finally, we consider the case where the heaters have biased a priori estimates of the initial mean and ambient temperatures. We assume that the estimates are respectively equal to $21^\circ C$ and $-10^\circ C$, while the actual values are respectively equal to $21.5^\circ C$ and $-11^\circ C$. If the heaters apply the mean field controllers with linear $g$, which are computed based on the estimates, then the EAT will not converge to the target temperature $y = 20^\circ C$. To compensate the estimation error, the heaters apply at the beginning the mean field controllers. When the EAT reaches a steady state, the controllers switch to the steady-state mean field controllers, i.e., (7) where the coefficient $q_0^*$ is replaced by a constant equal to the current $q_0$ computed using the EAT. This constant is updated continuously, and the controller recomputed at each instant. The results are illustrated in Fig. 7. The mean field controllers are applied between $t = 0$ and $t = 0.75$ hours. Because of the biased mean and ambient temperatures estimates, the EAT reaches a steady-state value equal to $20.5^\circ C$ at $t = 0.75$ hours. At this instant, the heaters switch to the steady-state mean field controllers. As a result, the controllers compensate the estimation error and force the EAT to converge to $y = 20^\circ C$.

6 CONCLUDING REMARKS

In this paper, the power of MFG based control methodologies has been applied to the problem of modulating the aggregate load of vast numbers of energy storage associated devices in power systems, in particular electric space heaters (or air conditioners), acting as a buffer against the intermittency of renewable energy sources such as solar and wind, or as a virtual battery coordinated by an aggregator entity on the energy markets. The MFG framework combines the ability of bottom up modeling approaches to answer “what if” types of questions arising in demand response or load dispatch schemes, with the decentralized control theoretic potential of game theory. From technically challenging in terms of complexity of control and monitoring needs, the
changing perturbations can be rejected, but also disturbances whereby not only piecewise constant slowly robustness to uncertainties in the elemental device model.

The mean field based integral control formulation adds the mean dwelling temperature converges to the target. Agents contribute according to their current abilities, yet may not be desirable (i.e. converging to target). An algo-

target following problems is defined. The corresponding solutions, as well as the impact of saturation constraints on the synthesis of control laws.

A Preliminary results

Proof of Lemma 3 The idea for finding a counterexample to continuity in the sup norm is to construct a sequence of mean trajectories \( \{\tilde{x}^{(n)}\}_n \in \mathcal{G} \) (recall that \( \mathcal{G} := \{x : x \in C_b[0,\infty), z \leq x(t) \leq x_0\} \) that converges uniformly to \( y \), in a way that the corresponding coefficients \( q_y^{(n)} \) increase to infinity as \( t \to \infty \), for each \( n \geq 0 \). Based on Remark 2 in Section 3.1, we expect that \( \lim_{t \to \infty} \mathcal{M}(\tilde{x}^{(n)})(t) = z \), for each \( n \). Moreover, \( \mathcal{M}(y)(t) = \bar{x}_0 \). Hence, \( \|\mathcal{M}(\tilde{x}^{(n)}) - \mathcal{M}(y)\|_{\infty} \) does not converge to zero as \( n \to \infty \). In particular, consider the sequence \( \tilde{x}^{(n)} = y + 0.5^n \). We have \( \lim_{n \to \infty} \|x^{(n)} - y\|_{\infty} = 0 \).

The coefficients \( q^y \) that correspond to \( \tilde{x}^{(n)} \) and \( y \) are respectively \( \Delta(\tilde{x}^{(n)}) = q_y^{(n)} = 0.5^n t \) and \( \Delta(y) = 0 \), and the corresponding Riccati equations are \( (\pi^y)^{(n)} \) and \( \pi^y_t \). Since \( q_y^{(n)} = 0.5^n t \) increases to infinity as \( t \to \infty \), one can show that the corresponding Riccati solution \( (\pi^y)^{(n)} \) also increases with \( t \) to infinity. We have \( \mathcal{M}(y)(t) = \bar{x}_0 \). Define \( A_n^s(\tau) = a^s + \delta + (b^s)^2(\pi^y)^{(n)}(n)_{\tau}^{-1} \) and \( f_n^s(\eta) = \int_{\eta}^{\infty} \exp\left(-\int_{\tau}^{\infty} A_n^s(\tau) d\tau\right) d\tau \). \( f_n^s \) is the unique bounded solution of \( df_n^s/d\eta = A_n^s(\eta)f_n^s - 1 \).

Since \( f_n^s \) is bounded, \( (\pi^y)^{(n)}(\eta) \) is increasing in \( \eta \) and \( A_n^s(\eta) > 0 \), one can show that \( 0 \leq f_n^s(\eta) \leq 1/A_n^s(\eta) \). Thus, \( f_n^s \) is decreasing with time and it converges to zero as \( t \to \infty \). Now define the function \( g_n^s(t) = f_0^s \exp\left(-\int_{\eta}^{\infty} (A_n^s(\tau) - \delta) d\tau\right) f_n^s(\eta) d\eta \). \( g_n^s \) is the unique solution of \( dg_n^s/dt = -(A_n^s(t) - \delta) g_n^s(t) + f_n^s(t) \), with \( g_n^s(0) = 0 \). \( A_n^s(t) - \delta > 0 \), thus one can show that \( \lim_{t \to \infty} g_n^s(t) = 0 \).

In view of (20), we get \( \lim_{t \to \infty} \mathcal{M}(\tilde{x}^{(n)})(t) = z \) for \( 1 \leq s \leq m \), which gives \( \lim_{t \to \infty} \mathcal{M}(\tilde{x}^{(n)})(t) = z \). This implies that \( \|\mathcal{M}(\tilde{x}^{(n)}) - \mathcal{M}(y)(t)\|_{\infty} \geq |\bar{x}_0 - z| \), and \( \mathcal{M} \) is not continuous on \( \mathcal{G} \subset (C_b[0,\infty), \|\cdot\|_{\infty}) \).

Lemma 7 The following statements hold:

i. \( (C_b[0,\infty), \|\cdot\|_{k}) \) is a Banach space.

ii. \( \mathcal{G} \) is a nonempty bounded closed convex subset of \( (C_b[0,\infty), \|\cdot\|_{k}) \).

iii. If \( \mathcal{F} \subset \mathcal{G} \) is a family of equicontinuous functions w.r.t. the sup-norm \( \|\cdot\|_{\infty} \), then \( \mathcal{F} \) is a compact subset of \( (C_b[0,\infty), \|\cdot\|_{k}) \).
PROOF. i) $\mathbf{C}_k[0,\infty)$ is obviously a vector space. Let $x^{(n)}$ be a Cauchy sequence in $\mathbf{C}_k[0,\infty)$. Fix a $t \geq 0$. We have for all $n,m > 0$, $e^{-kt}|x^{(n)}_t - x^{(m)}_t| \leq \|x^{(n)} - x^{(m)}\|_k$. Hence, $x^{(n)}$ is a Cauchy sequence in $\mathbb{R}$. We define $x$ to be the pointwise limit of $x^{(n)}$. Fix $t \geq 0$ and $\epsilon > 0$. There exists $n_0(\epsilon)$, such for all $n > n_0$, $\|x^{(n)}_t - x^{(m)}_t\|_k < \epsilon$, for all $m > 0$. Thus for all $n > n_0$ and $m > 0$

e^{-kt}|x^{(n)}_t - x_t| \leq \|x^{(n)}_t - x^{(m)}_t\|_k + e^{-kt}|x^{(m)}_t - x_t| \
\leq \epsilon + e^{-kt}|x^{(m)}_t - x_t|

Hence, for all $t$, $e^{-kt}|x^{(n)}_t - x_t| \leq \epsilon + \lim_{m \to \infty} e^{-kt}|x^{(m)}_t - x_t|$. Therefore, $\|x^{(n)}_t - x_t\|_k \leq \epsilon$, which implies that $x^{(n)}$ converges to $x$ under $\|\cdot\|_k$. It remains to show that $x \in \mathbf{C}_k[0,\infty)$. In fact, $x^{(n)}$ converges to $x$ under the norm $\|\cdot\|_k$ means that the function $e^{-kt}x^{(n)}_t$ converges uniformly to $e^{-kt}x_t$. Thus, $e^{-kt}x_t$ is continuous and bounded, and as a result $x$ is continuous and $\sup |e^{-kt}x_t| < \epsilon$. This implies that $x \in \mathbf{C}_k[0,\infty)$ and $\mathbf{C}_k[0,\infty)$ is a Banach space.

ii) The proof of non-emptiness and convexity are straightforward. For the boundedness, it suffices to remark that $|e^{-kt}x_t| \leq |x_t|$. It remains to prove that $\mathcal{G}$ is closed. Let $x^{(n)} \in \mathcal{G}$ be a sequence that converges to $x$ in $\mathbf{C}_k[0,\infty)$. This implies that $x^{(n)}$ converges pointwise to $x$. Thus, for all $t \geq 0$, $z \leq x_t \leq \bar{x}_0$. Hence, $x \in \mathcal{G}$ and $\mathcal{G}$ is closed.

iii) $\mathcal{F}$ is a closed subset of the Banach space $\mathbf{C}_k[0,\infty)$. To prove the compactness, it is sufficient to show that $\mathcal{F}$ is totally bounded [33, Appendix A, Theorem 4], that is for every $\epsilon > 0$, $\mathcal{F}$ can be covered by a finite number of balls of radius $\epsilon$. Let $\epsilon > 0$, then, there exists a time $T(\epsilon) > 0$, such that $|e^{-kt}(\bar{x}_0 - z)| < \epsilon$ for all $t \geq T$. The set $\mathcal{F}_T = \{f\mid f(0) \leq \bar{x}_0\}$ is uniformly bounded and equicontinuous in $(C(0,T),\|\cdot\|_{0,T})$. Hence, by Arzela-Ascoli Theorem [33], it is totally bounded in $(C(0,T),\|\cdot\|_{0,T})$. Here, $C(0,T)$ denotes the set of continuous functions on $[0,T]$, $\|\cdot\|_{0,T}$ the corresponding sup-norm, and $f^{(j)}$ denotes the restriction of $f^{(j)}$ to $[0,T]$. Thus, there exist $f^{(i)}(0)_{i=1}^m \in \mathcal{F}_T$ such that $\mathcal{F}_T = \cup_{i=1}^m B(f^{(i)}(0),\epsilon)$, where the balls $B(f^{(i)}(0),\epsilon)$ are defined w.r.t. $(C(0,T),\|\cdot\|_{0,T})$. Let $f \in \mathcal{F}$, then there exists $1 \leq i \leq m$ such that $\sup_{t \in [0,T]} |f(t) - f^{(i)}(t)| < \epsilon$.

Hence, $\sup_{t \in [0,T]} |f(t) - f^{(i)}(t)| < \epsilon$ for all $t \geq T$. Therefore, $\sup_{t \in [0,T]} |f(t) - f^{(i)}(t)| < \epsilon$ for all $t \geq T$. Hence, $\|f - f^{(i)}\|_k < \epsilon$. Thus, $\mathcal{F} = \cup_{i=1}^m B(f^{(i)}(0),\epsilon)$, where the balls are now defined w.r.t. $(C_k[0,\infty),\|\cdot\|_k)$. This implies that $\mathcal{F}$ is totally bounded in $(C_k[0,\infty),\|\cdot\|_k)$.

B Proof of the fixed point existence theorem

Before showing the existence of a fixed point for $M$, we need the following preliminary results to apply Schauder’s Theorem.

Lemma 8 $\text{Im}(M) \subset \mathcal{G}$.

PROOF. As noted in Remark 2, $\bar{x}^s = T^s(\bar{y}_u)$, $1 \leq s \leq m$, is the optimal state of the optimal control problem (18). We denote by $u^*_s$ the optimal control law of (18).

At first, we show by contradiction that $\bar{x}^s \leq \bar{x}_0$. Suppose that there exists $t_0 > 0$ such $\bar{x}^s_{t_0} > \bar{x}_0$. Hence, there exist $t_1 < t_2$ such that $\bar{x}^s_{t_1} = \bar{x}_0$ and $\bar{x}^s_{t_2} = \bar{x}_0$ if $t_2 < \infty$, and such that $\bar{x}^s_{t_1} > \bar{x}_0$ for all $t \in (t_1, t_2)$. Let the control law $v$ be equal to $u^*_s$ on $[t_1, t_2]$, and to 0 on $[t_1, t_2]$. This means that the state that corresponds to $v$ is equal to $\bar{x}_0$ on $[t_1, t_2]$, and to the optimal state $\bar{x}^s$ otherwise. Hence, considering the cost in (18), $\inf J(u) > J(v)$, which is impossible. We now show the $\bar{z}$ lower bound inequality by contradiction. We assume without loss of generality that $\bar{x}_0 = 0$. Suppose that there exists $t_0 > 0$ such $\bar{x}^s_{t_0} < \bar{x}_0$. Hence, there exist $t_1 < t_2$ such that $\bar{x}^s_{t_1} = \bar{x}_0$ and $\bar{x}^s_{t_2} = \bar{x}_0$ if $t_2 < \infty$, and such that $\bar{x}^s_{t_1} < \bar{x}_0$ for all $t \in (t_1, t_2)$. We define the control law $v$ to be equal to $u^*_s$ on $[t_1, t_2]$, and to $a^*z/b^*$ otherwise. Hence, the state that corresponds to $v$ is equal to $z$ on $[t_1, t_2]$, and to $\bar{x}^s$ on $[t_1, t_2]$. We have,

$I_1 = \int_{t_1}^{t_2} e^{-\delta t}v^2 dt = \int_{t_1}^{t_2} e^{-\delta t}(\bar{u}^*_s)^2 (\bar{b}^* z)^2 dt$

$I_2 = \int_{t_1}^{t_2} e^{-\delta t}(\bar{u}^*_s)^2 dt = \int_{t_1}^{t_2} e^{-\delta t}\left((\bar{a}^*)^2 (\bar{b}^*)^2 (\bar{x}^s)^2 + \frac{1}{(\bar{b}^*)^2} \frac{d\bar{x}^s}{dt} + \frac{2\bar{a}_s}{(\bar{b}^*)^2} \bar{x}^s \frac{d\bar{x}^s}{dt}\right) dt$

$> I_1 + \frac{\bar{a}^*}{(\bar{b}^*)^2} \int_{t_1}^{t_2} e^{-\delta t} \bar{x}^s \frac{d\bar{x}^s}{dt} dt$

The inequality follows from the fact that $\bar{x}^s < \bar{z}$ on $[t_1, t_2]$ with $z < \bar{0}$ according to our assumption. Furthermore, using the integration by parts we get that

$\int_{t_1}^{t_2} e^{-\delta t} \bar{x}^s \frac{d\bar{x}^s}{dt} dt = \bar{z}^2 (e^{-\delta t_2} - e^{-\delta t_1}) + \int_{t_1}^{t_2} \delta e^{-\delta t} (\bar{x}^s)^2 dt$

$\geq \bar{z}^2 (e^{-\delta t_2} - e^{-\delta t_1}) + \int_{t_1}^{t_2} \delta e^{-\delta t} \bar{z}^2 dt = 0$

Hence, $\inf J(u) = J(u^*_s) > J(v)$, which is impossible. As a result $\bar{x}^s \in \mathcal{G}$, for $1 \leq s \leq m$, which implies that $\sum_{s=1}^m n_s \bar{x}^s \in \mathcal{G}$, and proves the result.

Lemma 9 Under A2, the following statements hold:
i. There exists $k_0 > 0$, such that $\forall \bar{x} \in \mathcal{G}$, $\Delta(\bar{x})(t) = q^0_t \leq k_0 t$.

ii. There exist $k_1 > 0$ and $k_2 > 0$, such that $\forall \bar{x} \in \mathcal{G}$, $\pi^*_t \leq k_1 t + k_2$. Here $\pi^*_t$ is the solution of the Riccati equation (11), with $q^0 = \Delta(\bar{x})$ (resp. $q^0 = q^0 := \Delta(\bar{x})$).

iii. Fix $0 < k < 2\min a^s + \delta$. There exists $k_3 > 0$, such that $\forall \bar{x}, \bar{x}' \in \mathcal{G}$, we have $\|\pi^s - (\pi^s)'\|_k \leq k_3\|\bar{x} - \bar{x}'\|_k$. Here $\pi^*_t$ and (resp. $(\pi^s)'$) is the solution of the Riccati equation (11), with $q^0 = q := \Delta(\bar{x})$ (resp. $q^0 = q' := \Delta(\bar{x}')$).

**Proof.** i) We have $\forall \bar{x} \in \mathcal{G}$, $\pi^*_t = \left|\int_0^t g(\bar{x}_r - y_r) d\tau\right| \leq \max_{|x| \leq 2|x_0 - z|} g(x)|t| \leq k_0 t$.

ii) $\forall \bar{x} \in \mathcal{G}$, $d\pi^*_t / dt = (2a^s + \delta + (b^r)^2 r^{-1} \pi^*_t) \pi^*_t - q^0_t - q^0_a$. Hence,

$$
\pi^*_t = \int_0^\infty \exp\left(-\int_0^\eta (2a^s + \delta + \frac{(b^r)^2}{r} \pi^*_t) d\eta\right) (q^0_t + q^0_a) d\eta \\
\leq \int_0^\infty (k_0 \eta + q^0_a) e^{-2a^s(\tau - t) d\eta} \\
\leq \frac{k_0}{2 \min a^s} t + \frac{k_0}{4 \min(a^s)^2} + \frac{q^0_a}{2 \min a^s} \leq k_1 t + k_2.
$$

iii) We have $\forall \bar{x}, \bar{x}' \in \mathcal{G}$,

$$
e^{-kt} q_{t} - q^0_t \leq e^{-kt} \int_0^t |g(\bar{x}_r - y_r) - g(\bar{x}'_r - y_r)| d\tau \\
\leq k e^{-kt} \int_0^t e^{-kT} |\bar{x}_r - \bar{x}'_r| d\tau \leq \frac{\lambda}{k} \|\bar{x} - \bar{x}'\|_k,
$$

where $\lambda$ is the Lipschitz constant of $g$ on the compact subset $[-|\bar{x}_0 - z|, |\bar{x}_0 - z|]$. We define $\tilde{\pi}^*_t = e^{-kt} \pi^*_t$, $\tilde{\pi}^*(\pi^*_t)' = e^{-kt} (\pi^*_t)'$, $\tilde{\pi}^* = \tilde{\pi}^*_t - (\tilde{\pi}^*_t)'$, $\tilde{q}_t = e^{-kt} (q_t - q^0_t)$ and $\tilde{A}^*_t = 2a^s + \delta - k + e^{kt} (b^r)^2 r^{-1} (\tilde{\pi}^*_t + (\tilde{\pi}^*_t)')$. We obtain that, $d\tilde{\pi}^*_t / dt = \tilde{A}^*_t \tilde{\pi}^*_t - \tilde{q}_t$. Therefore,

$$\tilde{\pi}^*_t = \int_0^\infty \tilde{q}_t \exp\left(-\int_t^\eta \tilde{A}^*_t d\eta\right) d\eta \\
\leq \frac{\lambda}{k(2 \min a^s + \delta - k)} \|\bar{x} - \bar{x}'\|_k \leq k_3\|\bar{x} - \bar{x}'\|_k.
$$

**Lemma 10** $\overline{\mathcal{M}(\mathcal{G})}$ is compact in $(C_k[0, \infty), \|\cdot\|_k)$.

**Proof.** Based on the third point of Lemma 7, it suffices to show that $\mathcal{M}(\mathcal{G})$ forms a family of equicontinuous functions w.r.t. the sup-norm. This can be done by showing that the family of derivatives of the functions in $\mathcal{M}(\mathcal{G})$ is uniformly bounded. We have for all $\bar{x} \in \mathcal{G}$,

$$
dT^s \circ \Delta(\bar{x})(t) = A^*_t \phi^s(t, 0)(\bar{x}_0 - z) + \\
C^s \int_0^t \int_0^\infty \psi^s(\tau, \eta) d\tau d\eta - C^s \int_0^t A^*_t \\
\times \phi^s(t, \eta) \int_0^\infty \psi^s(\tau, \eta) d\tau d\eta \leq \xi_1 + \xi_2 + \xi_3.
$$

where $A^*_t = a^s + (b^r)^2 r^{-1} \pi^*_t$ and $C^s$ is defined in (20). The function $\phi^s(t, 0)$ is the unique solution of the following differential equation, $d\phi^s(t, 0) / dt = -A^*_t \phi^s(t, 0)$ with $\phi^s(0, 0) = 1$. We show in the following that the product $\phi^s(t, 0)A^*_t$ is bounded. But $\phi^s(t, 0)A^*_t$ satisfies $d(\phi^s(t, 0)A^*_t) / dt = -A^*_t (\phi^s(t, 0)A^*_t) + A^*_t \phi^s(t, 0)$. Hence,

$$
\phi^s(t, 0)A^*_t = A^*_0 e^{-\int_0^t A^*_t d\tau} + \int_0^t e^{-\int_0^\tau A^*_t d\tau} A^*_t \phi^s(\tau, 0) d\tau.
$$

We have $|A^*_0| \leq a^s + (b^r)^2 r^{-1} k_2$ and $\|\phi^s(t, 0)\|_\infty \leq 1$, where $k_2$ is defined in the second point of Lemma 9. Fix $h \in \mathbb{R}$, and define the functions $\tilde{\pi}^*_t = \tilde{\pi}^*_t + h - \pi^*_t$ and $\tilde{q}_t = q^0_t + h - q^0_a$. We have

$$
d\tilde{\pi}^*_t / dt = -\left(2a^s + \delta + \frac{(b^r)^2}{r} (\pi^*_t + \pi^*_t + h)\right) \tilde{\pi}^*_t + \tilde{q}_t.
$$

Hence,

$$
\tilde{\pi}^*_t = \int_0^\infty \tilde{q}_t \exp\left(-\int_t^\eta \left(2a^s + \delta + \frac{(b^r)^2}{r} (\pi^*_t + \pi^*_t + h)\right) d\eta\right) d\tau.
$$

Thus, $|\tilde{\pi}^*_t| \leq h \max_{|x| \leq 2|x_0 - z|} |g(x)| / 2a^s$, which implies that

$$
\lim_{h \to 0} \frac{|\tilde{\pi}^*_t|}{|h|} \leq \max_{|x| \leq 2|x_0 - z|} |g(x)| / 2a^s
$$

and $d\pi^*_t / dt \leq \max_{|x| \leq 2|x_0 - z|} |g(x)| / 2a^s$. Hence recalling the definition of $A^*_t$ above, $A^*_t$ is uniformly bounded, and as a result $\phi^s(t, 0)A^*_t$ is uniformly bounded by $M^s > 0$. This implies that $|\xi_1| \leq M^s |\bar{x}_0 - z| \leq K^s$. Recalling the definition of $\psi^s(\tau, t)$ in Section 3.2 above, the second and third terms satisfy the following inequalities,

$$
|\xi_2| \leq C^s \int_0^\infty e^{-a^s \tau} d\tau \leq K^s \\
|\xi_3| \leq C^s \int_0^t A^*_t \phi^s(t, \eta) d\tau.
$$

We define on $[0, \infty)$, $f^*_t = \int_0^t \phi^s(t, \eta) d\tau$. $f^*_t$ is the unique solution of $df^*_t / dt = -A^*_t f^*_t + 1$, with $f^*_0 = 0$. Therefore,

$$
d(f^*_t A^*_t - 1) / dt = -A^*_t f^*_t A^*_t - 1 + A^*_t f^*_t.
$$

Solving this equation gives

$$
f^*_t A^*_t - 1 = -e^{-\int_0^t A^*_t d\tau} + \int_0^t e^{-\int_0^\tau A^*_t d\tau} A^*_t f^*_t d\tau.
$$
We have \( \|f^s_t\|_\infty \leq 1/a^s \). Hence, \( f^s_t A^s_t - 1 \) is uniformly bounded. Denote \( M^s_t \) the bound of \( f^s_t A^s_t \). We get that the third term \( |\xi_3| \leq C^s M^s_t/a^s \triangleq K^s_2 \). Finally, \( \|dM(\bar{x})/dt\|_\infty \leq \sum_{s=1}^3 n_s (K^s_1 + K^s_2 + K^s_3) \), where \( K^s_1, K^s_2 \) and \( K^s_3 \) do not depend on \( q^s \). This proves the result.

**Proof of Theorem 4** The second point follows from Lemmas 7, 8, 9, 10 (Lemma 8 guarantees that \( M \) stabilizes \( G \), Schauder’s fixed point Theorem [33], and the first point of this theorem, which we show in the remainder of this proof. Let \( \bar{x}' \) and \( \bar{x}'' \) belong to \( G \). We denote respectively by \( (\pi^s)' \) and \( (\pi^s)'' \) the corresponding Riccati solutions. We have,

\[
T^s \circ \Delta(\bar{x}')(t) - T^s \circ \Delta(\bar{x}'')(t) = \left( \phi^s_1(t, 0) - \phi^s_2(t, 0) \right) (\bar{x}_0 - z) + C^s \int_0^t \phi^s_1(t, \eta) \int_0^\infty (\psi^s_1(\tau, \eta) - \psi^s_2(\tau, \eta)) d\tau d\eta
\]

\[
+ C^s \int_0^t \phi^s_2(t, \eta) \int_\eta^\infty \psi^s_2(\tau, \eta) d\tau d\eta \triangleq \xi_1 + \xi_2 + \xi_3,
\]

where \( (\phi^s_1, \psi^s_1) \), and \( (\phi^s_2, \psi^s_2) \) are the \( (\phi^s, \psi^s) \) functions defined in (19), and that correspond respectively to \( (\pi^s)' \) and \( (\pi^s)'' \). \( C^s \) is defined in (20). Using the inequality, \( |e^{-x} - e^{-y}| \leq e^{-\min(x,y)} |x - y| \), for \( x \) and \( y \) positive, we obtain that

\[
|\xi_1| \leq |\bar{x}_0 - z| (b^s)^s \aleph^s \eta \| (\pi^s)' - (\pi^s)'' \|_k \| e^{kt} \|_k \leq \lambda \frac{|\bar{x}_0 - z| (b^s)^s}{r k^2 (2 \min_a a^s + \delta - k)} \| \bar{x}' - \bar{x}'' \|_k e^{kt},
\]

where the second inequality follows from the third point of Lemma 9 and the definition of the constant \( k_3 \) as developed in Appendix B. Hence,

\[
|\xi_1| \leq \lambda \frac{|\bar{x}_0 - z| (b^s)^s}{r k^2 (2 \min_a a^s + \delta - k)} \| \bar{x}' - \bar{x}'' \|_k \leq \lambda c^s \| \bar{x}' - \bar{x}'' \|_k.
\]

Using the same inequality as above, we get that

\[
|\xi_2| \leq \lambda \frac{(b^s)^s \aleph^s}{r k^2 (2 \min_a a^s + \delta - k)} \| \bar{x}' - \bar{x}'' \|_k \times
\]

\[
\int_0^t e^{-\alpha^s(t-\eta)} \int_\eta^\infty e^{-\alpha^s(\eta - \tau)} (e^{k^2} - e^{k^2}) d\tau d\eta
\]

\[
= \lambda \frac{L^s \| \bar{x}' - \bar{x}'' \|_k (e^{k^2} - e^{-\alpha^s t})}{(a^s + \delta - k)(a^s + \delta)},
\]

where \( L^s = (b^s)^s \aleph^s / r k (2 \min_a a^s + \delta - k)(a^s + \delta) \). Therefore,

\[
\|\xi_2\|_k \leq \lambda \frac{L^s \| \bar{x}' - \bar{x}'' \|_k}{(a^s + \delta - k)(a^s + \delta)} \approx \lambda \frac{c^s \| \bar{x}' - \bar{x}'' \|_k}{(a^s + \delta - k)(a^s + \delta)}.
\]

We have that,

\[
|\xi_3| \leq \lambda L^s \| \bar{x}' - \bar{x}'' \|_k \int_0^t e^{-\alpha^s(t-\eta)} (e^{k^2} - e^{k^2}) d\eta
\]

\[
\leq \lambda \frac{L^s \| \bar{x}' - \bar{x}'' \|_k e^{k^2}}{a^s}.
\]

Hence, \( R_k = \sum_{s=1}^3 \int s (c^s_k + c^s_k + c^s_k) \).
