New application of low cost sensors for continuous CO2 flux measurements

Metrology for low cost CO2 sensors applications: the case of Steady-State-Through-Flow (SS-TF) chamber for CO2 fluxes observations

Abstract. Soil CO2 emissions are one of the largest contributions to the global carbon cycle, and a full understanding of processes generating them and how climate change may modify them is needed and still uncertain. Thus, a dense spatial and temporal network of CO2 flux measurements from soil could help reduce uncertainty in the global carbon budgets. In the present study, the design, assembling and calibration of low cost Air Enquirer kits, including CO2 and environmental parameters sensors, have been designed, built and applied. Different type of calibrations for the CO2 sensors and their associated errors are calculated. In addition, for the first time this type of sensors have been applied to design, develop and test a new Steady-State-Through-Flow (SS-TF) chamber for simultaneous measurements of CO2 fluxes in soil and CO2 concentrations in air. Sensor's responses were previously corrected for temperature, relative humidity, illumination and pressure conditions in order to reduce the uncertainty of measured CO2 values and of the following calculated CO2 fluxes. Based on SS-TF, CO2 soil fluxes measured by the proposed SS-TF and by a standard closed Non-Steady-State-Non-Through-Flow (NSS-NTF) chamber were shortly compared to ensure the reliability of the results. The use of a multi-parametric fitting reduced the total uncertainty of CO2 concentration measurements by 62% compared with one where only the uncertainty if a simple CO2 calibration was applied, and by a 90% when compared to the uncertainty declared by the manufacturer. The new SS-TF system allows continuous measurement of CO2 fluxes and CO2 ambient air with low cost (~1.2 k€), low energy demand (<5W) and low maintenance (twice per year due to sensor calibration requirements).
Global soils store at least twice as much carbon as Earth’s atmosphere (Oertel et al., 2016; Scharlemann et al., 2014), and act as sources and/or sinks for greenhouse gases (GHGs) such as carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O). The total global emission of CO₂ from soils is recognized as one of the largest contributions in the global carbon cycle and is, among others, temperature dependent (Bond-Lamberty and Thomson, 2010a). However, soil respiration is probably the least well constrained component of the terrestrial carbon cycle (Bond-Lamberty and Thomson, 2010b; Schlesinger and Andrews, 2000) and the degree to which climate change will stimulate soil-to-atmosphere CO₂ flux remains highly uncertain (Pritchard, 2011). Continuous measurements of soil fluxes are therefore essential to understand changes in soil respiration of ecosystems in relation to climate variables such as atmospheric temperature. A high temporal and spatial resolution monitoring of CO₂ fluxes at sensitive areas could offer useful data both for better understanding the processes at the sources and sinks and thus improving biogeochemical models (Agustí-Panareda et al., 2016; Randerson et al., 2009). In addition, a complete uncertainty budget of CO₂ flux measurements will be essential for the evaluation and correction of global flux models and their associated uncertainties.

Gas interchange between the soil and the lower atmosphere is generally measured as the quantity of gas exhaled from the soil per unit of surface and time (µmol m⁻² s⁻¹). It can be measured with different techniques, being the most common the Steady-State Through-Flow (SS-TF), also known as open dynamic chamber, and the Non-Steady-State Non-Through-Flow (NSS-NTF) or closed chamber (Pumpanen et al., 2004). In both cases, the CO₂ fluxes are measured using a chamber installed on the soil surface. NSS-NTF measurements are based on the rate of CO₂ concentration increase within the chamber, while in the SS-TF technique the CO₂ efflux is continuously calculated as the difference between the CO₂ concentration at the inlet and the outlet under determined hypothesis (Livingston and Hutchinson, 1995). In the case of NSS-NTF flux measurements, calibrated data is not strictly necessary as long as the sensor's calibration does not change during the measurement timespan because the flux is proportional to the slope of the CO₂ concentration increase within the chamber. SS-TF based results need high accurate calibration sensors because the absolute value of the measured CO₂ concentrations into the chamber are used. A literature survey suggests that generally NSS-NTF may underestimate CO₂ fluxes by 4–14%. This could be, probably, due to: i) advective fluxes forced by small pressure gradients between the air into the chamber and outside it; ii) setting configurations, such as the installation depth of the chamber into the soil; iii) the influences of environmental parameters such as wind, pressure, etc. No significant difference was observed when fluxes were measured using SS-TF chambers where no pressure gradients are created (Pumpanen et al., 2004; Rayment, 2000).

In recent years, Wireless Sensor Networks (WSN) are increasingly used for real time and high spatial resolution monitoring (Oliveira and Rodrigues, 2011). A WSN is composed of spatially distributed autonomous sensors to monitor physical, chemical or environmental conditions, and to cooperatively pass their data through the network to other locations. WSN can be used for local data recording for later analysis or for continuous transmission in real time to a remote laboratory for synchronous analysis.
Low-cost sensors for CO\textsubscript{2} atmospheric measurements have been largely used in industrial environments and for indoor air quality and ventilation rate studies (Fahlen et al., 1992; Mahyuddin and Awbi, 2012; Schell and Int-Hout, 2001). When low cost sensors are applied at high CO\textsubscript{2} concentration areas and/or spots where air concentrations observed are in the order of thousands of parts per million (ppm), the total uncertainty of the measurement does not affect the quality of the study of the concentration variability under different conditions and sources/sinks. However, in the last decade, the improvement in precision and cost decrease of Non Dispersive InfraRed (NDIR) CO\textsubscript{2} sensors have made them more readily available for multiple purposes (Yasuda et al., 2012). Their low weight and dimensions allow their utilization in a wide variety of applications, including Unmanned Aerial Vehicles (Kunz et al., 2018), CO\textsubscript{2} measurements network areas (Kim et al., 2018; Song et al., 2018) and for the study of the distribution of CO\textsubscript{2} in large regions, as in the case study of Switzerland (Müller et al., 2020). However, in order to be able to use these sensors in the outdoor atmosphere, a metrological effort is needed to: i) ensure a traceable and stable calibration; ii) evaluate and correct the influence of the environmental parameters, such as temperature, relative humidity and pressure, on the sensor response; iii) estimate the total uncertainty related with the sensors calibrations and corrections.

This work reports on the design and full characterization of presents a low cost Air Enquirer Kit, including NDIR CO\textsubscript{2} and environmental parameters sensors, and suggests new possible applications of it to reduce the cost and the maintenance of continuous CO\textsubscript{2} fluxes. The CO\textsubscript{2} sensor within the Kit was calibrated using a multiparametric approach. Manuscript presents the results of the comparison of different calibration methodologies for NDIR CO\textsubscript{2} sensors. Furthermore, a new SS-TF system, based on 5 multi-sensors portable Air Enquirer Kits, is presented, calibrated and tested here for the first time and shortly compared with a NSS-NTF system at a Spanish mountain site. The system has been designed and built to continuously monitor soil CO\textsubscript{2} fluxes from soil with high temporal resolution, high accuracy and low cost and maintenance. This new SS-FT system also allows continuous measurements of ambient CO\textsubscript{2} concentration. The system was previously the SS-TF is made by four Air Enquirer Kits fully characterized under laboratory conditions. Then, CO\textsubscript{2} fluxes based on SS-FT technique were shortly compared with observations based on the NSS-NTF method at a Spanish mountain site. In the present manuscript the Air Enquirer Kits, used within the SS-TF chamber, are presented together with the methodology used to calibrate the NDIR CO\textsubscript{2} sensors and to correct their response under different environmental conditions. The new prototype of the SS-FT chamber is also introduced after describing its theoretical basis as well as the NSS-NTF method. Finally, the results of the sensors calibrations and corrections and of the short NSS-NTF/SS-TF chambers comparison are presented and discussed, together with further research steps.
2 Methods

2.1 Air Enquirer Kit

A multi-sensor portable kit, named Air Enquirer (Morguí et al., 2016), was designed and built in the mark of an EduCaixa project (www.educaixa.org). The kit consists of 5 low cost sensors controlled by an Arduino DUE Rev3 microcontroller board that measure: i) NDIR CO2 concentration (in ppm); ii) relative humidity (%); iii) temperature (°C); iv) barometric pressure (hPa); and v) light intensity (lux). Data from sensors are automatically read and stored at a frequency of 0.2Hz in a microSD card. All sensors and the Arduino board controlling them are enclosed in a methacrylate box of 15x8x5 cm³ in size (Fig. 1).

Table 1 shows the main features of each sensor, following specifications provided by their respective manufacturers. The total cost of each Air Enquirer (AE) kit is about 200€.

2.2 Calibration and multi-parametric correction of the CO2 sensors of the Air Enquirer kit

Low-cost CO2 sensors are known to be temperature (T), humidity (H) and pressure (P) dependent (Arzoumanian et al., 2019; Martin et al., 2017). In this study, five Air Enquirer AE kits were calibrated using different methodologies from the literature and their responses were corrected under different climate conditions. The simultaneous use of the CO2 and the environmental parameters sensors allows a continuous correction of the response of the CO2 sensor under different conditions of T, P and absolute humidity (H). The absolute humidity was calculated from RH, P and T following Vaisala (Vaisala Oyj, 2013). CO2 sensors were then calibrated using a Picarro G2301 Cavity RingDown Spectroscopy Analyzer (CRDS) as a second reference standard of relative humidity (RH).

First of all, a theoretical correction of the CO2 data was applied taking into account: i) the change from ppm of CO2 in wet air to ppm of CO2 in dry air following Wagner and Prüß, (2002); ii) the conversion from ppm of CO2 measured under specific pressure to the declared using the ideal gas law equation.

The concentration of CO2 in dry air (CO₂Dry) was calculated by Eq. (1):

\[ CO₂_{Dry} = \frac{CO₂_{wet} \times 1013}{V_{Dry}} \]  (1)

being \( V_{Dry} \), the Volume of 1m³ of dry air at 1013 hPa after removing the water volume. \( V_{Dry} \) can be calculated from Eq. (2):

\[ V_{Dry} = \frac{P_0}{P - P_{w}} \]  (2)

being \( P_{w} \), the water vapour saturation directly calculated from Eq (3):

\[ P_{w} = A \cdot 10^{\frac{-mT}{T_0}} \]  (3)

\( A_{m} \) and \( T_0 \) are constants with values 6.1164, 7.5914 and 240.73 respectively.
In a second step, an experimental multiparametric calibration of the CO₂ sensors was done using the data of the environmental sensors and a reference CO₂ instrument. A Picarro G2301 Cavity RingDown Spectroscopy Analyzer (CRDS) was used as a second reference standard. This CRDS has a precision better than 0.03 ppm for CO₂ (Crosson, 2008; Richardson et al., 2012). The CRDS results were previously corrected for water vapour (Rella et al., 2013) and calibrated in the laboratory using six NOAA WMO-CO2-X2007 reference gases (primary standard) before and after each experiment following Tans et al. (2011). In order to calibrate the CO₂ sensors response for a wide range of temperature, pressure, humidity and CO₂ concentration, duplicate measurements were carried out using a temperature controlled box at two sites: i) at the Institut de Ciències del Clima laboratories (IC3), located at 20 meters above sea level (m.a.s.l.), in the city of Barcelona, Spain, and ii) at the Centre de Recerca d’Alta Muntanya laboratories (CRAM, mountain town of Vielha, Spain, at 1582 m.a.s.l.). Each experiment lasted 7 days and was carried out using the scheme in Fig. 2. In order to remove high frequency variability, the sampled air was homogenised in a sealed pre-chamber prior to entering in the calibration chamber. Then, the air was pumped to the calibration box at a flow rate of 0.4 L min⁻¹ and through the secondary standard reference instrument: CRDS. Both experiments were performed in a temperature range between 20 ºC and 42 ºC and a relative humidity with diurnal cycles between 10% and 50%. Temperature in the calibration box was set to be in increased in slopes of 10ºC, although at low temperatures it fluctuated with room temperature. The pressure ranged between 1004 hPa and 1012 hPa in the calibration at IC3 and between 838 hPa and 850 hPa in the calibration at CRAM. The two calibration experiments at the CRAM and at IC3 stations were carried out with one month difference.

CO₂ concentration values measured by each NDIR CO₂ sensor installed within each Air Enquirer kit and corrected for P and RH using Eq. (1) \((\text{CO}_2 \text{dry,kit})\), were calibrated by comparison with simultaneous CO₂ concentration measured by the CRDS \((\text{CO}_2 \text{CRDS})\) and considering the environmental conditions of T, absolute humidity \((H)\) and \(P\) using Eq. (14):

\[
\text{CO}_2 \text{corr} = \alpha + \beta \text{CO}_2 \text{CRDS} + \gamma T + \delta H + \varepsilon P
\]

A multiparametric fit of Eq. (14), yields the following calibrated/corrected CO₂ values: as reported in Eq. (5):

\[
\text{CO}_2 \text{corr} = \frac{\text{CO}_2 \text{dry,kit}}{p} + \frac{1}{p} \beta \text{CO}_2 \text{CRDS} \frac{1}{p} T - \frac{\delta}{p} H - \frac{\varepsilon}{p} P
\]

The \(\text{CO}_2 \text{corr}\) calibrated results were compared to those obtained with a simple bias correction using the averages of \(\text{CO}_2 \text{CRDS}\) and \(\text{CO}_2 \text{dry,kit}\) values and also to those obtained with a simple linear calibration of the \(\text{CO}_2 \text{dry,kit}\) values with the \(\text{CO}_2 \text{CRDS}\) values without taking in consideration the effect of T, P and H.
2.3 Steady-State Through-Flow chamber (SS-TF or Open Dynamic Chamber)

The prototype of the open SS-TF chamber consists of two methacrylate cells of 36 L, where two Air EnquirerAE kits are installed in each of the chambers in order to continuously monitor the CO₂ concentration and environmental variables. The duplicity of the Air EnquirerAE kits is used to ensure the reliability of the measurements. The Chamber dimensions were designed to avoid border effects and minimize measurement errors, as observed by Senevirathna et al. (2007). The first chamber is a hermetic closed chamber with a unique entry for ambient air (labelled here as Mixing chamber in Fig. 3). The second one (labelled here as Flux chamber), with an open base, is installed directly over the soil.

The Mixing chamber is used to mix the sampled air and to measure the CO₂ concentration background of the atmospheric air \( (C_{\text{mix}}) \) before it enters into the Flux chamber. It contains two Air EnquirerAE kits and a fan located at its top for mixing the sampled air. This chamber has only two openings for the inlet and outlet of atmospheric air at a flow of 0.46.5 L min⁻¹ (labelled 'q' in Fig. 3). Cable glands are used at the openings to prevent leakages. Using this configuration, high frequency variability of atmospheric air could be avoided and near steady-state conditions were reached.

The Flux chamber is bottomless and has to be positioned in the first 5 cm of the soil/vegetation layer where the soil fluxes are to be measured. Two Air EnquirerAE kits and a vent fan were installed at the top of this chamber as well. A constant flow \( q \) between the two chambers was achieved with a membrane KNF pump and a flowmeter (labelled as FM in Fig. 3). Low flows, in comparison with the chamber volume, are needed to maintain near steady-state conditions during measurements.

Using the system depicted in Fig. 3, CO₂ fluxes \( (f_{\text{CO}_2}) \) can be calculated for given time intervals within the Flux chamber using the mass balance in Eq. (36) (Gao and Yates, 1998), where, \( V \) and \( A \) are, respectively the volume of the Flux chamber and the emitted soil surface area, \( C_{\text{in}}(t) \) (μmol L⁻¹) is the spatially averaged concentration of target gas in the chamber headspace, \( C_{\text{out}}(t) \) (μmol L⁻¹) is the average CO₂ concentration of inlet air in the flux chamber, \( C_{\text{out}}(t) \) (μmol L⁻¹) is the outflow CO₂ concentration, \( J_g \) is the flux of the target gas at the enclosed soil surface and \( q_{\text{in}} \) and \( q_{\text{out}} \) are the inlet and outflow, respectively.

\[
dM(t) = VdC_{\text{in}}(t) = Af_g(t)dt + q_{\text{in}}C_{\text{in}}(t)dt - q_{\text{out}}C_{\text{out}}(t)dt
\]  

Assuming that for each measurement interval: i) the inflow and outflow rates are constant and equal (meaning no leakages present in the pneumatic circuit), thus \( q_{\text{in}} = q_{\text{out}} = q \); ii) chamber reach a steady state condition, thus \( C_{\text{in}}(t) = C_{\text{out}}(t) = C_{\text{out}} \), and \( dM(t) = 0 \), CO₂ flux can be calculated for each time interval from the simplified Eq. (47):

\[
f_{\text{CO}_2} = J_g = \frac{q}{A}(C_{\text{out}} - C_{\text{in}})
\]

Assuming that the fan completely mixes the air within the chamber and the CO₂ concentration at each of the boxes is homogeneous, outflow concentration is equal to Flux chamber concentration \( (C_{\text{out}}(t) = C_{\text{in}}(t)) \), measured by the two Air EnquirerAE kits within the flux chamber) and inflow concentration is equal to the mixing concentration \( (C_{\text{in}}(t) = C_{\text{mix}}(t)) \), measured by the two Air EnquirerAE kits within the Mixing chamber. The advantage of this system is that fluxes can be
measured continuously with a very small energy requirement (<5 W) and, even using duplicate sensors, with a relative low cost (~1.2k€) in comparison with other automatic commercial flux chambers, priced at roughly 12 k€. The new system described here enables the feasibility of a network of continuous measurements and a replication of experiments to cope with soil flux variability.

2.4 Non-Steady-State Non-Through-Flow chamber (NSS-NTF)

CO₂ fluxes using the NSS-NTF chamber, or closed static chamber, are measured on the basis of the so-called linear accumulation method (Livingston and Hutchinson, 1995), which uses the initial rate of concentration increase in an isolated chamber that has been placed on the soil surface for a known period of time. Assuming ideal gas behaviour, the slope of the CO₂ concentration during the accumulation interval can be used to determine the CO₂ flux (µmol·m⁻²·s⁻¹) following Eq. (58):

\[ f_{\text{CO}_2} = f_B = \frac{CO_{2\_slope} \cdot V}{A \cdot R} \]

where \( V \) (m³) and \( A \) (m²) are the volume of the chamber and the enclosed soil surface area respectively, \( CO_{2\_slope} \) (ppm·s⁻¹) is the slope of the linear increment of the CO₂ concentration during the early accumulation time, \( P \) and \( T \) are the atmospheric pressure and the environmental temperature within the chamber, and \( R \) (m³·Pa·K⁻¹·mol⁻¹) is the universal gas constant. It has been underlined that the linear approach of the accumulation method is only reliable for short time periods (Davidson et al., 2002; Grossi et al., 2012; Gutiérrez-Álvarez et al., 2020). Otherwise, gradients of environmental parameters between the inside and outside chamber could influence the measurement, probably yielding to leakages of unknown origin in the chamber. Luckily, high frequency measurements, as the ones performed by CO₂ sensors, allow to apply this method over a really short accumulation time (\( T = 5 \) min has been used in the present study), thus complying with the theoretical requirements. A necessary condition for the application of this method is that the initial CO₂ concentration within the chamber has to be equal to the atmospheric CO₂ concentration. Therefore, NSS-NTF chambers need to be ventilated after each measurement period (Davidson et al., 2002; Xu et al., 2006). This can be done manually or using automatic systems. In this study, a manual static chamber was used. A closed NSS-NTF chamber of methacrylate (25x25x25) cm³ was built at IC3 in order to perform a short campaign for the comparison of CO₂ fluxes measured by NSS-NTF and SS-TF systems. An Air Enquirer® (Ari03) and a fan were fastened at the top of the chamber. Both devices were run by a small external battery pack. An outer metallic sleeve was previously fixed onto the soil to avoid leaks and other disturbances. However, the systemic comparison between these two systems is beyond the scope of this study.
3 Results and discussion

3.1 Calibration and multi-parametric correction

Calibration and the 3.1 Comparison between different calibration/corrections approaches

The calibration and correction factors, following from Eq. (2), of the CO2 sensors installed in the five Air Enquirer AE kits are shown in Table 2. The average bias (in ppm CO2) between the AE kit CO2 value after and before applying the theoretical corrections for P and dry air is also shown. The last five columns of Table 2 present, for the different methodologic approaches, the calculated Residual Standard Root Mean Square Error (RSE) of the linear fit between the CO2_Kit and RMSE using Eq. (9):

\[
\text{RSE} = \sqrt{\frac{1}{n-1} \sum (x_i - \bar{x})^2}
\]

where \( n \) is the number of values, \( x_i \) are the CO2 values for each case: \( \text{CO2}_{uncalibrated} \); \( \text{CO2}_{corrected \ for \ P \ and \ dry \ air} \); \( \text{CO2}_{corrected \ for \ P \ and \ dry \ air \ and \ with \ the \ average \ bias \ from \ the \ CRDS \ data \ removed} \); \( \text{CO2}_{linear} \); \( \text{CO2}_{multi} \); \( \text{CO2}_{calibrated \ CRDS} \); \( \text{CO2}_{AE} \).

A single theoretical correction for P and RH is demonstrated that already reduces uncertainty by a factor of 5. However, this theoretical correction is not enough for applications where the absolute CO2 value is needed (e.g. for atmospheric composition or SS-TF measurements), as the bias value is extremely variable depending on the sensor unit and up to 50 ppm. When we remove the average bias between the sensor response corrected for P and RH and the CRDS CO2 reference value, the uncertainty is highly reduced and the RMSE of the corrected values ranges between 5.4 ppm and 10.8 ppm. This uncertainty, however, could still be too high for certain applications such as the measurements of small atmospheric variability or for small CO2 fluxes measurements both for the SS-TF and NSS-NTF chambers.

Calibrating these sensors through comparison with the CRDS secondary standard in the laboratory by linear fit allows reaching RMSE values between 2.72, 1.2 ppm and 10.4 ppm. However, when the influence of the environmental parameters in the response of the sensors is also taken into account, the RMSE values range is shifted to the interval between 1.39 and 5.82 ppm, 2.19 ppm and 5.92 ppm, the lowest ones. Figure 4 shows time series of the differences between the CO2 CRDS data and all CO2 sensors data after applying the simple calibration (CO2 simple) and the multiparametric regression (CO2 multi). Corresponding values of T and RH measured during the calibration experiments are also reported. Each CO2 sensor responses differently to the variations of T and RH, and so does the parametric coefficients. Therefore, a theoretical correction of the CO2 value for these variables won’t be applicable, and a specific multiparametric fitting is needed.

The response of the Figure 5 shows the relation between the reference CO2 values (CRDS) and the values measured by the CO2 sensors before and after for raw data than after the application of the different calibration and the multi-parametric
correction as IC3 as well as CRAM laboratories is shown in Fig. 4. Four sensors show RSE\textsubscript{multi} values of lower than 5 ppm, and just one of them (kit #04) greater than 5 ppm. Moreover, this last sensor shows negative correlation with the ambient temperature, unlike all the others where the CO\textsubscript{2} values increased as temperature went up. Despite this kit was lately installed within the CO\textsubscript{2} fluxes chamber for the second part of the experiment, results from it were not used for the calculation of the CO\textsubscript{2} fluxes.

A variance and covariance analysis were also performed to check the influence of meteorological parameters on the CO\textsubscript{2} sensor response. A clear influence of temperature (T), absolute humidity (H) and pressure (P) was observed on the CO\textsubscript{2} sensor's response (p-value: < 10^{-6} for all variables). No cross-correlation was observed among variables. It is important to remark that although the multiparametric calibration was done after applying the theoretical correction for P and RH, as explained previously, pressure conditions seem to have the highest influence on the sensor response. In fact, a reduction of 62% in the RSE\textsubscript{multi} was observed when pressure correction was applied. Moreover, parametric values for P diverge between sensors, so every sensor seems to be differently influenced by atmospheric pressure.

The two calibration/correction experiments at the CRAM and at IC3 stations were carried out with one month difference. Previous work with NDIR sensors has shown that a calibration minimum every six months may be necessary to keep accuracy between the desired range, as dust and soiling of mirrors may cause drift in the data results (Curcoll et al., 2019; Piedrahita et al., 2014).

3.2 Comparison between the NSS-NTF and SS-TF systems

The new prototype of the SS-TF system, described in section 2.2, was shortly tested in a grassland area of the Pyrenees, near CRAM, between the 1\textsuperscript{st} and the 2\textsuperscript{nd} of June of 2016 and compared with a manual NSS-NTF system. CO\textsubscript{2} fluxes (\textit{f}_{\textit{CO}_2}) were calculated for both SS-TF and NSS-NTF systems, using Eq. (47) and Eq. (58), respectively.

CO\textsubscript{2} concentrations from each of the sensors installed in the SS-TF chamber (upper panel) and the corresponding calculated \textit{f}_{\textit{CO}_2} time series (lower panel) are shown in Fig. 5. Ten minutes averages CO\textsubscript{2} concentration values were used for the SS-TF system in order to reduce the uncertainty associated with the CO\textsubscript{2} concentration mean. Ten minute average CO\textsubscript{2} concentration values are presented with an associated uncertainty of 2σ (95% of confidence). Using Eq. (4), the \textit{f}_{\textit{CO}_2} data are presented with 2*RSE\textsubscript{parametric} confidence interval, assuming as negligible the uncertainty over the flow and the box volume compared with CO\textsubscript{2} concentrations uncertainty. CO\textsubscript{2} flux values change from close to zero up to 8 µmol m\textsuperscript{-2} s\textsuperscript{-1}. The obtained \textit{f}_{\textit{CO}_2} values agree with CO\textsubscript{2} flux values observed in other studies in grasslands at a similar altitude, latitude and period of the year, where the range of night-time fluxes was reported to be between 2 and 4 µmol m\textsuperscript{-2} s\textsuperscript{-1} (Bahn et al., 2008; Gilmanov et al., 2007).

The differences between the ten minutes average of CO\textsubscript{2} concentrations measured by the two sensors within the Mixing chamber (AE Kits #1 and #2) were of 2.2 ±5.3 ppm. This difference is coherent with the RSE\textsubscript{multi} of both
sensors, and remains stable over time. The differences between the ten minutes average of CO₂ concentrations measured by the two sensors within the Flux chamber (AE Kits #3 and #4) were greater (20 ± 8 ppm). Furthermore, this difference was found to be temperature dependent with a significant correlation (p-value<10⁻¹⁰ and r²=0.95). One of the sensors used for this was #04 (Table 2). Data from this CO₂ values of kit was not taken in consideration for the CO₂ flux retrieval due to its lower precision and, as mentioned above, an apparently negative temperature dependence, as found in #4 were found to have a different behaviour during the calibration/connection experiments event and the RMSE (0.00) was greater than 5 ppm, values of this kit were discarded. Each value of flux has been calculated using Eq. (7) and averaging the calibrated CO₂ values of AE #1 and #2 for the mixing chamber and using the calibrated CO₂ values from AE #3 for the flux chamber. 10 min. averages were calculated from every minute calculated flux data. The variability of the flux within the 10 minutes averages is represented in Fig. 6 as an associated uncertainty of 2σ. The associated expanded uncertainty for each value has been calculated propagating the 2*RMSE_multi of the flux chamber CO₂ sensor.

CO₂ fluxes using the NSS-NTF chamber were calculated using the slope of the increase of the CO₂ concentration within the chamber and its associated uncertainty. Two examples of the CO₂ concentrations measured by the CO₂ sensor of kit #03 within the manual NSS-NTF chamber (see section 2.3) are shown in Fig. 6. Data of the first minute after manually closing the chamber were discarded during the fCO₂ calculations in order to remove installation noise. Concentration gradients were linear over the following 5 minutes, with a correlation coefficient R² >0.99 in all cases, as calculated with Eq. (5). Such correlation was positive for Positive fluxes were measured during the afternoon measurements and negative for the ones at morning measurements, due to as expected because of the photosynthesis phase of grassland plants.

The correlation between both NSS-NTF and SS-TF fCO₂ results during the parallel measurements carried out at CRAM soil during the 1st and the 2nd of June of 2016 is shown in Fig. 7. The results of a short comparison campaign are here presented in order to strengthen the data obtained from the new system presented in this work. Actually, the size of the comparison dataset does not allow robust statistic. Indeed, the main goal of the present manuscript is presenting a fully characterized automatic CO₂ flux system with high precision, low cost and low maintenance. However, an agreement is observed between the results of the two systems when positive CO₂ fluxes are observed while differences between the two systems are observed for negative CO₂ fluxes. The correlation between both NSS-NTF and SS-TF fCO₂ results during the co-measurements carried out at CRAM grasslands during the 1st and the 2nd of June of 2016 is shown in Figure 8. CO₂ flux values change from close to zero up to 8 µmol m⁻² s⁻¹. The obtained fCO₂ values agree with CO₂ flux values observed in other studies in grasslands at a similar altitude, latitude and period of the year, where the range of night-time fluxes was reported to be between 2 and 4 µmol m⁻² s⁻¹ (Bahn et al., 2008; Gilmanov et al., 2007). Although the short duration of this first comparison experiment, results help to strengthen the reliability of the new SS-TF chamber based on low cost sensors. However, the size of the comparison dataset does not allow a robust statistic and further long-term comparison should be carried out to fully characterize this new system. Indeed, the main goal of the present manuscript is not characterized the new SS-TF chamber but to offer a robust metrology for low
CO2 sensors and AE kits which can be easily applied for continuous CO2 flux measurements with high precision, low cost and low maintenance.

CO2 fluxes observations from NSS-NTF and SS-TF chambers agree for positive CO2 fluxes while they do not for negative CO2 fluxes. A plausible cause of this mismatch may be the different degree of opacity of the two systems’ chambers which influence the sink effect of the soil during the sunlight hours. Measurements uncertainties have been reported as 2 times the standard deviation of the 10 minutes average measurements. In fact, the NSS-NTF chamber was completely translucent while in the SS-TF chamber the top side was opaque.

3.3 Calibration and recalibration strategy

According to the RMSE results shown in Table 2, the multiparametric correction reduces the uncertainty of CO2 measurements by a factor of 10 compared to those where only a theoretical correction for RH and P was applied and by a factor of 3 compared to a lineal calibration for CO2. In the SS-TF, the flux calculation depends on the difference between the absolute concentrations values of different sensors in two chambers, and a bias between them of e.g. 10 ppm will cause, in this system, a fixed bias of 0.32 μmol·m⁻²·s⁻¹ in the flux calculus. Therefore, the multiparametric correction of sensors for this application is strongly recommended, together with a periodical recalibration of the CO2 sensors. Previous works with NDIR sensors have shown that at least every 6-months may be necessary to calibrate the sensors in order to take into account possible effects due to dust and soiling on their internal mirrors (Curcoll et al., 2019; Piedrahita et al., 2014) or the degradation of the IR light (CO2Meters, 2013). A mobile second reference standard could be displayed to perform in situ calibration of the low cost sensors. However, a periodical full calibration and calculation of correction factors for all environmental parameters could be difficult to carry out at field sites, and may even cause large errors if the range of temperature, humidity and pressure used is not large enough. For those cases where a full multiparametric recalibration couldn’t be performed each six months, a bias correction should be performed at least every six months. This could be done by placing CO2 sensors in a mixing chamber at the same time and introducing air from a reference tank with known CO2 concentration. Thus, taking in consideration the Eq. 4, this calibration will only adjust the 𝛼 parameter, considering the effects of P, T and RH constant over the time.

For NSS-NTF applications, where only the slope of the CO2 concentration is used, the bias has no effect on the calculus of the soil flux. Therefore, for this last case periodical corrections for the low cost sensors are not needed although they are advisable to improve the quality of the measurements. Finally, when no calibrations are possible, the recommendation is to calculate the CO2 concentration in dry air and compensate for pressure. Actually, comparing NSS-NTF based flux data, only a difference of about 4% is observed when theoretical correction for P and RH or multiparametric calibration data are compared. However, when using the CO2 AE kits values without any correction this difference rises up to a 23 %.
4 Conclusions

A new application of low Nowadays the improvement in precision and cost decrease of Non Dispersive InfraRed (NDIR) CO₂ sensors have made them more readily available for continuous multiple purposes. However, in order to apply them for atmospheric measurements where low CO₂ flux is presented here. In order to achieve concentrations or small CO₂ variability is observed a reliable performance, CO₂ sensors were calibrated. Robust metrology is still needed to: i) ensure a traceable calibration; ii) evaluate and correct the influence of the environmental parameters on the sensor response; iii) estimate the total uncertainty related with the measurements.

In this study an analysis of different calibration methods is carried out for NDIR low cost CO₂ sensors using Air Enquirer kits, designed and built, including also environmental sensors. In addition, a new application of these sensors is presented to continuously measure CO₂ fluxes on soil with a dynamic chamber.

The lowest uncertainty for the CO₂ sensors was obtained by calibrating them using a secondary standard reference (Picarro CDRS/CRDS monitor) and data correcting the sensor's response was continuously corrected for synchronous measurements under different temperature, humidity and barometric pressure conditions. A multiparametric fitting was applied to calibrate and correct the sensor's responses, achieving a drastic reduction of 90% in the uncertainty of measured CO₂ concentrations.

The new SS-TF chamber presented in this study will ensure the highest quality of the data and it will be advisable for SS-TF based CO₂ flux measurements or CO₂ atmospheric concentrations. For NSS-NTF based CO₂ flux measurements, a correction for P and RH of the CO₂ sensors will already give reliable results, although calibrating the sensors with a portable second reference standard is recommended.

The presented SS-TF chamber based on Air Enquirer kits allows continuous measurement of CO₂ fluxes from soil and continuous ambient air CO₂ concentration with low uncertainty, low cost (~1.2 k€), low energy demand and low maintenance (twice per year). This system will help future development of high spatial and temporal resolution CO₂ flux networks needed to understand soil respiration and productivity mechanisms at sensitive areas. This system could be a good tool for creating CO₂ flux dense networks. In the present study it has only been shortly compared with a NSS-NTF chamber at Pyrenees area, showing CO₂ fluxes comparable between them and in agreement with the literature. However, a full characterization of this system needs to be carried out in the future by long-term comparison with commercial CO₂ flux systems.

Code availability

The software code for this paper is available from the corresponding author.

Data availability

The data for this paper are available from the corresponding author.
Author contributions

Josep Anton Morguí coordinated the design and manufacture of the Air EnquirerAE kits, and promoted the building of the new low cost SS-TF chamber for CO2 fluxes. Lidia Cañas collaborated in the mounting and tuning of the Air EnquirerAE kits. Armand Karrang, during his bachelor degree project, participated in the laboratory and field campaigns. Roger Curcoll and Claudia Grossi, performed the laboratory and field experiments, analysed the data and coordinated the manuscript writing. Arturo Vargas participated in the development theoretical approach of the SS-TF methodology for gas fluxes. All authors participated in the data analysis, discussion of the results and writing of the manuscript.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

The design of the Air EnquirerAE kits, as well as the calibration experiments of the CO2 sensors, were funded by an EduCaixa grant from the CaixaBank Foundation (Principal Investigator (PI): Josep Anton Morguí). The open SS-TF chamber prototype was designed and build at the IC3 in the framework of the project ‘Methane interchange over the Iberian Peninsula’ and funded by the Retos 2013 grant #CGL2013-46186-R, from the Spanish Ministry of Economy and Competitiveness (PI: Claudia Grossi). The analysis of the data and the preparation of the manuscript was possible thanks to the funding of the Project 19ENV01 traceRadon. This project has received funding from the EMPIR programme co-financed by the Participating States and from the European Union Horizon 2020 research and innovation programme.

Authors would like to thank the Universitat de Barcelona for the use of the CRAM facilities and the team of the Climadat Project (CaixaBank Foundation) at IC3 for support during the laboratory experiments.
