Factors, and Mortality of Infectious Causes of Chronic Meningitis Within Our Healthcare System. Our Aim for This Study Was to Evaluate the Epidemiology, Risk Factors, and Mortality of Infectious Causes of Chronic Meningitis Within Our Healthcare System. Our aim for this study was to evaluate the epidemiology, risk factors, and mortality of infectious causes of chronic meningitis within our healthcare system.

Methods. A total of 59 cases were identified through a systematic retrospective review from our electronic medical record database from 2004 to 2018 and were identified by having the presence of two consecutive lumbar punctures with a white blood cell count in CSF >5 WBC/mL in a 4-week period, or by having 4 weeks of meningitis symptoms with one lumbar puncture with >5 WBC/mL. All cases were manually reviewed. We excluded patients with a history of Epstein-Barr virus (HIV) infection. We included a review of comorbidities that could impair the immune system such as diabetes mellitus, alcohol use, chronic kidney disease (CKD) stage III or greater use of chemotherapy, immunotherapy, or chronic use of steroids and previous transplant recipients. The study was approved by the institutional review board.

Results. 59 cases of chronic meningitis attributable to an infectious etiology were identified. The most common pathogens were Borrelia burgdorferi (37%), Cryptococcus sp. (27%), and Candida sp. (10%). Other etiologies which were less common included viral etiologies (13%). Finally, there were two cases secondary to Taenia solium meningoencephalitis. Regarding the total number of patients with the comorbidities studied, 13 (22%) had diabetes, 12 (20%) had CKD, 12 (20%) were under some form of chemotherapy or immunotherapy including chronic steroid use and 3 (5%) of patients were transplant recipients.

Conclusion. Our study identified common infectious pathogens causing chronic meningitis in a rural, HIV-negative population. Our findings indicate that cryptococcosis should be considered even within HIV-negative individuals, and Lyme disease should be considered in all endemic areas. Mortality was significant among patients with cryptococcal meningitis, where patients with Lyme meningitis did very well.

1405. Infectious Causes of Chronic Meningitis in HIV-Negative Patients: A Case Series

Jose E. Rivera, MD; Eunice H. Bae, Medical Doctor; Tyler Crissinger; Kelly Baldwin, MD; Geisinger Medical Center, Danville, Pennsylvania; Geisinger Commonwealth School of Medicine, Danville, Pennsylvania; Neuro-ID, Danville, Pennsylvania

Session: 155. CNS Infections
Friday, October 4, 2019: 12:15 PM

Background. Chronic meningitis can be defined as inflammation of the cerebrospinal fluid (CSF) with the presence of >5 white blood cells/mm³ of CSF for 4 weeks. There is little literature available on defining the infectious causes or risk factors of chronic meningitis, and there are no studies that have looked at mortality in this group of patients. Our aim for this study was to evaluate the epidemiology, risk factors, and mortality of infectious causes of chronic meningitis within our healthcare system.

Methods. Three patients with complicated NCC followed at a single tertiary care center are described in this study: Patient 1 with subarachnoid NCC (age 64, female), patient 2 with subarachnoid and intraventricular NCC (age 48, male) and patient 3 with parenchymal NCC (age 43, male). Patients 1–3 were followed clinically and radiographically for 8, 1.5 and 3 years, respectively. Patient 1 was treated with antihelminthic therapy and steroids for 24 months. She was transitioned to MTX for 1 month, graphically for 8, 1.5 and 3 years, respectively. Patient 1 was treated with antihelminthic therapy for 12 months of antihelminthic therapy and steroids with resolution of a previously positive NCC (age 43, male). Patients 1–3 were followed clinically and radiographically for 8, 1.5 and 3 years, respectively. Patient 1 was treated with antihelminthic therapy and steroids for 12 months. She was transitioned to MTX for 1 month, graphically for 8, 1.5 and 3 years, respectively. Patient 1 was treated with antihelminthic therapy and steroids for 12 months.

Results. Chronic meningitis is a condition that can occur due to the inflammatory response against degenerating cysts of the Taenia solium tapeworm. Inflammation can occur when cysts lose their ability to evade the host immune response during their natural life cycle or result from antihelminthic therapy. A subset can develop chronic perilesional edema requiring immunosuppressive therapy. Although guidelines recommend methotrexate (MTX) as an alternative to long-term steroids, limited information is available regarding when to start a steroid-sparing agent (SSA) and alternative SSAs in case of MTX failure or intolerance.

Methods. Retrospective chart review.

Results. Three patients with complicated NCC followed at a single tertiary care center are described in this study: Patient 1 with subarachnoid NCC (age 64, female), patient 2 with subarachnoid and intraventricular NCC (age 48, male) and patient 3 with parenchymal NCC (age 43, male). Patients 1–3 were followed clinically and radiographically for 8, 1.5 and 3 years, respectively. Patient 1 was treated with antihelminthic therapy and steroids for 24 months. She was transitioned to MTX for 1 month, but developed ulcerative stomatitis, leukopenia and transaminitis. She completed a treatment course of steroids, complicated by osteoporosis. Patient 2 was treated with 12 months of antihelminthic therapy and steroids with resolution of a previously positive cysticercal antigen in spinal fluid. Imaging revealed persistent inflammation in spite of adequate antihelminthic therapy. He was started on MTX and has remained on this medication for 5 months. Patient 3 was treated with 2 courses of antihelminthic therapy. He developed perilesional edema despite treatment with steroids and MTX. He was switched to a steroid-sparing agent (SSA) and a combination of MTX and SSA was continued for 12 months. He developed osteoporosis and had a rapid radiographic resolution of edema and clinical improvement in seizures. His seizures returned during an interruption in his adalimumab treatment and again resolved with re-initiation of this medication.

Background. Clinical manifestations of neurocysticercosis (NCC) are primarily due to the inflammatory response against degenerating cysts of the Taenia solium tapeworm. Inflammation can occur when cysts lose their ability to evade the host immune response during their natural life cycle or result from antihelminthic therapy. A subset can develop chronic perilesional edema requiring immunosuppressive therapy. Although guidelines recommend methotrexate (MTX) as an alternative to long-term steroids, limited information is available regarding when to start a steroid-sparing agent (SSA) and alternative SSAs in case of MTX failure or intolerance.

Methods. Retrospective chart review.

Results. Three patients with complicated NCC followed at a single tertiary care center are described in this study: Patient 1 with subarachnoid NCC (age 64, female), patient 2 with subarachnoid and intraventricular NCC (age 48, male) and patient 3 with parenchymal NCC (age 43, male). Patients 1–3 were followed clinically and radiographically for 8, 1.5 and 3 years, respectively. Patient 1 was treated with antihelminthic therapy and steroids for 24 months. She was transitioned to MTX for 1 month, but developed ulcerative stomatitis, leukopenia and transaminitis. She completed a treatment course of steroids, complicated by osteoporosis. Patient 2 was treated with 12 months of antihelminthic therapy and steroids with resolution of a previously positive cysticercal antigen in spinal fluid. He developed osteoporosis and had a rapid radiographic resolution of edema and clinical improvement in seizures. His seizures returned during an interruption in his adalimumab treatment and again resolved with re-initiation of this medication.

Disclosures. All authors: No reported disclosures.
**Conclusion.** SSAs are beneficial in the long-term treatment of patients with subarachnoid NCC or chronic perilesional edema. The formulation of guidelines that include multiple options for SSAs will be essential in guiding management of complicated NCC.

1407. Potential Impact of the Biofire® FilmArray Meningitis and Encephalitis (ME) Panel in Reducing Repeat Lumbar Punctures in Patients with Meningitis and Encephalitis

Elizabeth A. Aguilera, MD; Shelby Simar, MPH; Susan H. Wootten, MD; Rodrigo Hasbun, MD, MPH. 1The University of Texas Health Science Center at Houston, Houston, Texas; 2The University of Texas Health Science Center at Houston, School of Public Health, Houston, Texas; 3McGovern Medical School at the University of Texas Health Science Center at Houston, Houston, Texas

Session: 155. CNS Infections
Friday, October 4, 2019: 12:15 PM

**Background.** The Biofire® FilmArray Meningitis Encephalitis (FAME) is a multiplex polymerase chain reaction (PCR) test that can rapidly detect up to 14 pathogens that cause meningitis and encephalitis. The impact on preventing repeat lumbar punctures to obtain more diagnostic studies is currently unknown.

**Methods.** Patients admitted to Memorial Hermann Hospital (MHH) between July 2018-February 2019 with community-acquired symptoms of meningitis or encephalitis, CSF with white blood cell count >5 cells/mm³, and with leftover CSF at the MHH microbiology laboratory were eligible for the study. Testing FAME was performed after discharge for specimens that had not been centrifuged, had a volume of ≥200 μL, were appropriately stored, and were collected by lumbar puncture (LP) for evaluation of suspected meningitis/encephalitis.

**Results.** Of 1,382 CSF specimens screened, 70 (5.0%) met the criteria and were tested with FAME. The majority was adults (72.8%), non-Caucasian (68.6%), male (60%), immunocompetent (75.7%), and had meningitis presentation (75.7%). Mean age was 36.9 years (1 mo-89 years). The mean duration between CSF collection and any PCR result done in the hospital was 60 hours. Fifteen patients (21.4%) required 25 repeat LPs [13 (86.6%) for additional testing (7 (53.8%) pediatric patients) and 2 (13.3%) for cryptococcal meningitis assessment]. The FAME could have prevented repeat LPs in 86.6% of patients. Five of the 13 repeat LP (38.4%) FA ME showed a pathogen [VZV (2), HSV 1 (1), HHSV-6 (1), Neisseria meningitidis (1)]. Of 46 tests with negative FA ME, acyclovir therapy was started in 22 (47.8%) with a mean of 6 doses dispensed. 38 (26.6%) patients were discharged with an unknown etiology of whom FA ME was positive in 8 (21%) [HSV2 (37.5%), VZV (25%), Enterovirus (25%) and HSV1 (12.5%)]. PCR was ordered in the hospital for only 4 (50%) of these patients.

**Conclusion.** The FAME identified an etiology in 21% of patients with meningitis and encephalitis symptoms discharged with an unknown etiology. A total of 18.5% of patients required a repeat LP for additional testing. FAME testing offers an avenue for reducing the burden of repeat LPs and duration of unnecessary anti-infective therapy while increasing diagnostic yield.

1408. *Treponema pallidum*-Specific Antibody Testing in the Evaluation of Neurosyphilis, a Prospective Trial

Travis M. Larsen; Natalie Campen; Robert Larsen, MD; LAC+USC, Los Angeles, California

Session: 155. CNS Infections
Friday, October 4, 2019: 12:15 PM

**Background.** The therapeutic challenges of neurosyphilis are rooted in its diagnosis and management, with potential for complications arising from asymptomatic, unrecognized, or under-treated disease. Currently, the non-treponemal VDRL testing of cerebrospinal fluid (CSF) samples is used to predict those with CNS invasion by *T. pallidum*. However, more extensive evaluation of those at any stage of infection demonstrates both that the incidence of CNS invasion is much greater than predicted, and there exists a large proportion of false positives from VDRL testing alone.
