(Dated: March 5, 2018)

We consider the sub-gap physics of a hybrid double-quantum dot Cooper-pair splitter with large single-level spacings, in the presence of tunnelling between the dots and finite Coulomb intra- and inter-dot Coulomb repulsion. In the limit of a large superconducting gap, we treat the coupling of the dots to the superconductor exactly. We employ a generalized master-equation method which easily yields currents, noise and cross-correlators. In particular, for finite inter- and intra-dot Coulomb interaction, we investigate how the transport properties are determined by the interplay between local and nonlocal tunneling processes between the superconductor and the dots. We examine the effect of inter-dot tunneling on the particle-hole symmetry of the currents with and without spin-orbit interaction. We show that spin-orbit interaction in combination with finite Coulomb energy opens the possibility to control the nonlocal entanglement and its symmetry (singlet/triplet). We demonstrate that the generation of nonlocal entanglement can be achieved even without any direct nonlocal coupling to the superconducting lead.

I. INTRODUCTION

Recent developments in quantum technologies have shown an enormous potential for applications. Quantum key distributions in quantum cryptography have become almost a standard technology. This progress was mainly realized in optical systems. In order to enable the full potential of quantum technologies, spintronics and topotronics in solid state systems, it is crucial to be able to generate entangled states. A promising route to entanglement generation is offered by hybrid superconducting nanostructures. This type of system has very reach physics. For example, the possibility to emulate topological superconductors in low dimensions with, possibly, the creation of Majorana bound states has clearly shown a revolutionary potential. The enormous advancement in the production and control of nanotubes and nanowires opened up the possibility to couple nanosystems, in a very controlled way, to superconductors, taking advantage of their properties such as the spin-orbit (SO) interaction. Quantum phase transitions and anomalous current-phase relations have been studied in hybrid semiconductor-superconductor devices. SO interaction in the presence of superconducting correlations may lead to the generation of triplet ordering in nanowires or quantum wells.

Superconductors are a natural source of electron-singlets (Cooper-pairs) which may provide nonlocal entangled electrons when split. Semiconductor-superconductor-hybrid devices have been the object of experimental studies investigating signatures of nonlocal transport in charge currents and cross-correlators.

Cooper-pair splitting has also been investigated in Josephson junctions. Spin entanglement and electron transport in hybrid systems have been theoretically studied using full counting statistics (FCS). Further studies have investigated the effects of external magnetic fields and thermal gradient on Cooper-pair splitting. Quantum dots increase the efficiency of Cooper-pair splitting since sufficiently large intradot Coulomb interaction suppresses local Cooper-pair tunneling. Alternatively, the efficiency can be improved using spin-filtering as in spin valves. Typically all these systems are investigated assuming a very strong on-site Coulomb interaction. In the present paper, we consider the possibility of a weak Coulomb interaction which complicates the analysis as it introduces additional transport channels. We find that this is not necessarily a limitation in the creation of nonlocal entanglement, instead it offers a different route to achieve nonlocal entanglement.

The model studied in this paper is a Cooper-pair splitter based on a double quantum dot (DQD) circuit that is tunnel coupled to one superconductor and to two normal leads, see Fig 1. This is an extension of the model studied by Eldridge et al., Ref. to finite interdot tunneling and SO interaction. In this work, we investigate the effect of both local and nonlocal Cooper-pair tunneling on the current and conductance in the presence of finite Coulomb energies. Finally, we will discuss how interdot tunneling with or without SO interaction affects the generation of nonlocal entanglement.

This work is organized as follows. In section [I] we introduce the model and the formalism employed for our calculations. In Section [II] we provide an overview of the transport properties in the absence of inter-dot tunneling. The effect of interdot tunneling and SO interaction is discussed in section [IV]. Finally, section [V] is devoted to conclusions.
the other energy scales. In this limit, for \( k \) particle level spacings in the dots are large compared to nanodevices. The model Hamiltonian, Eq. (1), gives the annihilation operator for an electron with spin \( n \), the number operator and interdot Coulomb interaction, respectively. We define the annihilation operator for an electron with spin \( n \)

\[
H_{\text{DQD}} = \sum_{\alpha} \epsilon_\alpha n_\alpha + \sum_{\alpha} U_\alpha n_\alpha^\dagger n_\alpha^\uparrow + U \sum_{\sigma,\sigma'} n_{L\sigma} n_{R\sigma'} \nonumber \\
+ \left( \frac{t}{2} \sum_{\sigma} e^{i\phi} n_{L\sigma}^\dagger d_{R\sigma}^\dagger + \text{H.c.} \right), \tag{1}
\]

where \( \alpha = L, R \) labels the left and right dot, respectively, and \( \sigma = \uparrow, \downarrow \) denotes the spin. The orbital levels \( \epsilon_\alpha \) are spin degenerate, and \( U_\alpha \) and \( U \) denote the intra- and interdot Coulomb interaction, respectively. The quantum dots are coupled to the normal leads and superconductor via the Hamiltonian, \( H_{\text{DQD-leads}} = \sum_{\eta} H_{\eta \text{tunnel}} \), where the coupling of dot \( \alpha \) with lead \( \eta = L, R, S \) is described by the standard tunneling Hamiltonian

\[
H_{\eta \text{tunnel}} = \sum_{k\sigma} \left( V_{\eta\alpha} c_{k\sigma}^\dagger d_{\alpha\sigma} + \text{H.c.} \right). \tag{3}
\]

Here, \( V_{LR} = V_{RL} = 0 \) since the left (right) dot is not directly coupled to the right (left) lead. The effective tunneling rates are \( \Gamma_{\eta\alpha} = (2\pi/|V_{\eta\alpha}|) \rho_\eta \), with the density of states \( \rho_\eta \) in lead \( \eta \) assumed to be energy independent in the energy window relevant for the transport. For a better readability we introduce \( \Gamma_{\perp,\alpha} \equiv \Gamma_{\alpha} \) to emphasize the coupling to the normal leads with a subscript \( N \).

As we are interested in Cooper-pair splitting and in general sub-gap transport, we assume the superconducting gap to be the largest energy scale in the system. In this limit the quasi-particles in the superconductor are inaccessible and the superconducting lead can be traced out exactly. Thus, the system dynamics reduces to the effective Hamiltonian

\[
H_S = H_{\text{DQD}} - \sum_{\alpha=L,R} \frac{\Gamma_{\alpha}}{2} (d_{\alpha\uparrow}^\dagger d_{\alpha\downarrow} + \text{H.c.}) \nonumber \\
- \frac{\Gamma_S}{2} \delta_{\alpha,\perp} (d_{L\uparrow}^\dagger d_{L\downarrow}^\dagger + d_{R\uparrow}^\dagger d_{R\downarrow}) + \text{H.c.} \tag{4}
\]

where \( \Gamma_S \) describes the nonlocal proximity effect. This nonlocal coupling decays with the interdot distance \( l \), as \( \Gamma_S \sim \sqrt{T_{S\perp} T_{SR}} e^{-l/\xi} \), with \( \xi \) being the coherence length of the Cooper-pairs. So, only values \( 0 \leq \Gamma_S \leq \sqrt{T_{S\perp} T_{SR}} \) are physically admissible. The second term describes the local Andreev reflection (LAR) processes where Cooper pairs tunnel locally from the superconductor to dot \( \alpha \). The last term describes cross-Andreev reflection (CAR), that is a nonlocal Cooper-pair tunneling process where Cooper-pairs split into the two dots. Due to CAR, electrons leaving the system through opposite normal leads are potentially entangled. On the contrary, the LAR process does not contribute to the nonlocal entanglement production. The LAR process is usually attenuated by large interdot couplings, \( U_\alpha \).

Albeit the effective Hamiltonian, Eq. (4), no longer preserves the total particle number for the double-dot

![Double quantum dot circuit](image)
system it still preserves the parity of the total occupation, \( \sum_{\alpha\sigma} n_{\alpha\sigma} \). A decomposition, \( H_S = H_S^{\text{even}} \oplus H_S^{\text{odd}} \), of the system Hamiltonian into an even and an odd parity sector is provided in Appendix A. In conclusion the Hilbert space for the proximized double-dot system has the dimension 16. A generalization to include more charge states, to treat for instance smaller level spacings or higher temperatures, is straightforward and can be treated within the master-equation approach presented below. Lowest order corrections in \( 1/\Delta \) can be also included in the system Hamiltonian according to Ref. 61.

In the following, we consider the case of the quantum dots weakly coupled to the normal leads in comparison to the superconducting one, \( \Gamma_{\alpha\sigma} \gg \Gamma_{\alpha'\sigma'} \). In this limit quantum transport is mainly characterized by the transitions between the eigenstates of \( H_S \), the Andreev bound states.\(^{62,63}\) Those tunneling events with the normal leads \( \alpha \) and \( \sigma \) denote the Fermi function of normal lead \( \alpha \).

B. Master-equation and transport coefficients

We calculate the stationary transport properties, such as the current and the conductance, by means of the master-equation formalism using standard FCS techniques. All the relevant transport properties can be related to the Taylor coefficients of the cumulant generating function\(^{22,23}\) and obtained in an iterative scheme.\(^{24,25}\) In this work, we limit our analysis to the current and the differential conductance, however, also higher cumulants, such as noise and cross-correlations, can be easily obtained.

Here, we consider the regime \( \Gamma_{\alpha\sigma} \ll k_B T \), for which the tunnel couplings to the normal leads can be treated in first order. The tunnel couplings to the superconductor, the charging energies, and the interdot tunneling are treated exactly within the model under consideration. This leads to the master-equation \( \dot{P}_\alpha = \sum_{a'} \left( w_{a\rightarrow a'} P_{a'} - w_{a'\rightarrow a} P_a \right) \) for the occupation probabilities \( P_a \) of the eigenstates \( |a\rangle \) of the system Hamiltonian, where \( w_{a\rightarrow a'} \) are Fermi golden rate rules. The tunneling rates for the tunneling-in contribution read

\[
\gamma_{\alpha\sigma}^\text{in}(\chi) = e^{-\chi} \Gamma_{\alpha\sigma}^{\text{even}} f_\alpha(E_a - E_{a'}) \langle |a| d_{a\alpha}^\dagger |a'\sigma\rangle^2. \tag{5}
\]

Here, \( E_a \) and \( |a\rangle \) refer to the eigenenergies and the eigenstates of \( H_S \), and \( f_\alpha(\epsilon) = \{1 + \exp[(\epsilon - \mu_\alpha)/k_B T]\}^{-1} \). The Fermi function of normal lead \( \alpha \) with chemical potential \( \mu_\alpha \) and temperature \( T \). We only attach\(^{22,23}\) counting variables to the normal leads, \( \chi = (\chi_L, \chi_R) \).

The stationary current through the superconductor \( I_S \), can be easily expressed in terms of the currents through the left and right leads, \( I_S = -I_L - I_R \). The tunneling-out contribution can be obtained from the substitution \( \{d_{a\sigma}^\dagger f_\alpha, \chi_\alpha\} \rightarrow \{d_{a\sigma} f_\alpha(-\epsilon), -\chi_\alpha\} \), where \( f_\alpha(\epsilon) = 1 - f_\alpha(-\epsilon) \). Summation over the spin and lead indices yields the full rates \( w_{a\rightarrow a'} = \sum_{\alpha\sigma} (\gamma_{\alpha\sigma}^\text{in} + \gamma_{\alpha\sigma}^\text{out}) \).

Single electron tunneling changes the parity of the system. So, the only transitions that occur are between the eigenstates \( |e_i\rangle \) of \( H_S \) with even occupation number and those with odd occupation numbers, \( |o_j\rangle \). Here, the

\[
\begin{align*}
|0\rangle & \quad \text{empty state} \\
|S\rangle & = \frac{1}{\sqrt{2}} (d_{1L}^\dagger d_{1L} - d_{1R}^\dagger d_{1R}) |0\rangle \quad \text{singlet state} \\
|\alpha\rangle & = \frac{1}{\sqrt{2}} (d_{1L}^\dagger d_{1L} + d_{1R}^\dagger d_{1R}) |0\rangle \quad \text{doubly occupied states} \\
|\sigma\rangle & = \frac{1}{\sqrt{2}} (d_{1L}^\dagger d_{1L} d_{1R}^\dagger d_{1R}) |0\rangle \quad \text{quadruply occupied state} \\
|T\rangle & = d_{1L}^\dagger d_{1L} |0\rangle \quad \text{polarized triplet state} \\
|\alpha\sigma\rangle & = d_{1L}^\dagger d_{1R}^\dagger |0\rangle \quad \text{singly occupied states} \\
|\sigma\alpha\rangle & = d_{1L}^\dagger d_{1R}^\dagger |0\rangle \quad \text{triply occupied states}
\end{align*}
\]

Here, \( i, j = 1 \ldots 8 \) label the eigenstates of the even and odd parity sector, respectively. We can write the eigenstates of the even sector in the basis of Table I

\[
|e_i\rangle = e_{i,0}|0\rangle + e_{i,S}|S\rangle + \sum_\alpha e_{i,\alpha} |\alpha\rangle \quad + e_{i,dd}|dd\rangle + e_{i,T0}|T0\rangle + \sum_\sigma e_{i,T\sigma}|T\sigma\rangle. \tag{6}
\]

Similarly the eigenstates of the odd sector can be expressed as

\[
|o_j\rangle = \sum_\alpha (o_{j,\alpha\sigma}|\alpha\sigma\rangle + o_{j,tao\sigma}|tao\rangle). \tag{7}
\]

Finally we can evaluate the matrix elements of the fermionic operators, \( \langle o_{j,\alpha\sigma}|e_i\rangle \), and therewith express the transitions from the state \( |e_i\rangle \) to the state \( |o_j\rangle \) as

\[
\begin{align*}
\omega_{e_i\rightarrow o_j} = \sum_\alpha \Gamma_{\alpha\sigma}^{\text{even}} f_\alpha(E_{e_i} - E_{o_j}) e^{i\chi_\alpha} \left| o_{j,\alpha\sigma}^* e_{i,\alpha} + o_{j,tao,\alpha\sigma}^* e_{i,dd} \right|^2 & + \frac{1}{\sqrt{2}} [o_{j,\sigma}^* \alpha e_{i,S} - \alpha e_{i,T0}] - \alpha \sigma o_{j,\alpha\sigma}^* e_{i,\alpha} e_{i,\sigma} \left| \alpha \sigma o_{j,\alpha\sigma}^* e_{i,\sigma} e_{i,\alpha} \right|^2 \\
& + \frac{1}{\sqrt{2}} [\Gamma_{\alpha\sigma}^{\text{even}} f_\alpha(E_{o_j} - E_{e_i}) e^{-i\chi_\alpha} \left| o_{j,\alpha\sigma}^* e_{i,\alpha} + o_{j,tao,\alpha\sigma}^* e_{i,dd} \right|^2 & - \frac{1}{\sqrt{2}} [o_{j,\sigma}^* \alpha e_{i,S} + \alpha e_{i,T0}] - \alpha \sigma o_{j,\alpha\sigma}^* e_{i,\sigma} e_{i,\alpha} \left| \alpha \sigma o_{j,\alpha\sigma}^* e_{i,\alpha} e_{i,\sigma} \right|^2 \tag{8}
\end{align*}
\]

with the coefficients \( e_{i,\alpha} = \langle a|e_i\rangle \) and \( o_{j,\alpha} = \langle a|o_j\rangle \) and \( E_{e_i} (E_{o_j}) \) the eigenenergy corresponding to \( |e_i\rangle \) (|o_j\rangle). The bar on the indices indicates their complement, i.e. \( \bar{L} = R, \bar{r} = \bar{l} \), and so forth. The rate for the inverse transition \( w_{o_j\rightarrow e_i} \) follows straightforwardly.

From the cumulant generating function, \( Z(\chi, \mu) = \lim_{t \to \infty} \frac{1}{2} \ln \text{tr} P(\chi, \mu) \), we can obtain the stationary current \( I_\alpha = \partial Z/\partial \chi_\alpha \mid_{\chi = 0} \) in the normal lead \( \alpha = L, R \)
and the corresponding differential conductance $G_{\alpha,\beta} = -\partial^2 Z/\partial \epsilon \partial \mu|_{\epsilon=0}$. Both the current \cite{27,28} and the conductance \cite{29} can be calculated in the usual iterative scheme.

III. TRANSPORT IN ABSENCE OF INTERDOT TUNNELING

In this section, we give an overview of how the local and nonlocal proximation affects quantum transport in absence of interdot tunneling. In particular, we start discussing the two limits $\Gamma_{S\alpha} \gg U$ and $U \gg \Gamma_{S\alpha}$. Both limits feature a resonant current originating from the CAR process. The former case of weak interdot Coulomb energy is typically realized in experiments\cite{29}. The limit of strong interdot Coulomb energy additionally permits to study resonant currents which are entirely characterized by LAR. Throughout this work, we consider identical quantum dots, i.e. $U_L = U_R \equiv U_C$, $\Gamma_{SL} = \Gamma_{SR} \equiv \Gamma_{S\alpha}$, and $\Gamma_N \equiv \Gamma_{NL} = \Gamma_{NR}$. We limit to the case of equal orbital levels in the two quantum dots, $\epsilon \equiv \epsilon_L = \epsilon_R$, and equal chemical potentials $\mu \equiv \mu_L = \mu_R$.

A. Weak interdot Coulomb energy, $U \approx 0$

In Fig. 2(a), we show a density plot of the current $I_R(\epsilon, \mu)$ as a function of the dots’ level $\epsilon$, which can be tuned by gate voltages, and the chemical potential $\mu$ of the normal leads. We notice that the current in the normal leads obeys the symmetry $I_\alpha(\epsilon, \mu) = -I_\alpha(2\epsilon_0 - \epsilon, -\mu)$ with $\epsilon_0 = -(U_C/2 + U)$. This symmetry is due the particle-hole (PH) symmetry of the Hamiltonian Eq. \cite{4} in the absence of interdot tunneling.

We focus on the situation $\mu < 0$ which corresponds to the transport of Cooper pairs from the superconductor to the double-dot system. Two resonances can be seen in Fig. 2(a): one at $\epsilon = \epsilon_{\text{CAR}} = -U/2$ that is caused only by CAR and another at $\epsilon = \epsilon_0$ which originates from both CAR and LAR. The current is asymmetrical with respect to the chemical potentials $\mu$. The bias asymmetry of the CAR peak is due to the triplet blockade: for $\mu > 0$ tunneling of electrons from the leads can bring the
Fig. 3. (a) Current $I_R$ through the right lead as a function of the gate voltage $\epsilon \equiv \epsilon_L = \epsilon_R$, and the chemical potential $\mu \equiv \mu_L = \mu_R$ for finite $U = 0.25 U_C$ and $\Gamma_S = \Gamma_{S\alpha}/3$. Other parameters are as in Fig. 2. (b) Corresponding slices at constant $\mu = -(U_C + U)/2$ (dashed line), and $\mu = -U_C$ (solid line). The slice at $\mu = -(U_C + U)/2$ is indicated in panel (a) by a dotted line. (c) Current $I_R$ at constant $\mu = -(U_C + U)/2$ for various values of $\Gamma_S$. (d) Corresponding population probabilities as a function of the gate voltage $\epsilon$ at fixed $\mu = -U_C$.

Along the level position axis, the CAR resonance is centered at $\epsilon_{\text{CAR}}$ and its broadening is $\sqrt{2}\Gamma_S$. This can be seen in panel (b) of Fig. 2, which shows the current at constant $\mu = -U_C$ for two different values of the nonlocal coupling: $\Gamma_S = \sqrt{\Gamma_{SL}\Gamma_{SR}}/3$ (dashed line) and $\Gamma_S = \sqrt{\Gamma_{SL}\Gamma_{SR}}$ (solid line). The CAR broadening is proportional to the nonlocal coupling $\Gamma_S$ but its height does not depend on it. The CAR resonance instead follows the singlet population, i.e. $h^2 R_C^\text{CAR}/e_0 N_{NR} \approx 2 P_S$, as can be seen in panel (d). The states involved in the CAR process are $|0\rangle, |\alpha\rangle, |S\rangle$ and in fact one only observes the corresponding populations, $P_0 + \sum_{\alpha} P_{\alpha \sigma} + P_S \approx 1$. On the contrary, the resonance at $\epsilon = -U_C/2$ is mainly due to the LAR, but involves also CAR as indicated by the non-vanishing singlet population at the LAR resonance [see panel (d)].

We will discuss now that strong superconducting coupling may also generate negative differential conductance (NDC) when single electron tunneling events with the normal leads are accompanied by a simultaneous exchange of a Cooper-pair. For instance if one of the dots is doubly occupied, while the other is singly occupied, it can occur that an electron leaves the system through a normal-metal lead and the two remaining electrons tunnel (locally or nonlocally) to the superconductor. If the process is energetically admissible the total current is reduced instead of increased by the opening of the new resonance and NDC is observed.

This is indeed observed in panel (c) of Fig. 2, having defined the conductance as $G_S = dI_S/dV$. We show $G_S$ as function of the chemical potential, for a fixed level position $\epsilon = \epsilon_0 - 0.125 U_C$. The differential conductance becomes negative around $\mu \approx 3\epsilon + U_C$ (leftmost peak). This extra resonance corresponds energetically to the transition from the triply occupied states to the empty state, $|\alpha\sigma\rangle \rightarrow |0\rangle$, where two electrons tunnel in the superconductor and the remaining electron tunnels in one of the normal leads. This involves only the exchange of a nonlocal Cooper pair and is no longer present in the absence of nonlocal coupling [dot-dashed line in panel (c) of Fig. 2]. In order to increase the visibility of the NDC we have chosen a stronger nonlocal coupling $\Gamma_S$ (by increasing $\Gamma_{S\alpha}$) to obtain a higher peak value and slightly higher temperatures to increase the linewidth of this resonance in comparison to other figures.
B. Finite interdot Coulomb energy, \( U \gtrsim \Gamma_{S\alpha} \)

For finite interdot Coulomb energy the LAR dominated resonance in Fig. 2(a) splits into two resonances at gate voltages \( \epsilon_{\text{LAR}} = -U_C/2 \) and \( \epsilon_0 = \epsilon_{\text{LAR}} - U \) as can be seen in panel (a) of Fig. 3. The former current resonance is purely affected by LAR involving the states \(|0\), \(|a\sigma\), \(|da\). In fact, in panel (d) one observes that only the corresponding populations are non vanishing, i.e. \( P_0 + \sum_n P_{a\sigma} + \sum_n P_{da} \approx 1 \) and that the current is proportional the population of the doubly occupied state, \( hI_R^{\text{LAR}}/e \approx 4P_{da} \). We still observe the asymmetry of the nonlocal-current resonances in the chemical potential due to the triplet blockade. Additionally, one notices an asymmetry of the LAR resonances, which can be explained partly by the triplet blockade mechanism and partly by energy considerations.

The central resonance at \( \epsilon_0 = \epsilon_{\text{LAR}} - U \) is affected both by the LAR and the CAR processes. For an intermediate value of the chemical potentials [see dashed line in panel (b) of Fig. 3] its width is roughly proportional to \( \Gamma_S \Gamma_{SR} \) and vanishes if \( \Gamma_S \) becomes maximal. In panel (c) we demonstrate the effect of the nonlocal Cooper-pair tunneling on the current resonances, for an intermediate value of the chemical potentials and for different values of the nonlocal coupling \( \Gamma_S \). The dashed line corresponds to the dashed line in panel (b). When \( \Gamma_S \) approaches its maximum, the width of the central resonance (left peak) tends to zero while its height remains unaffected. We suspect that the behavior of the width of this central resonance is due to the mutual exclusion of the local Cooper-pair tunneling process and the nonlocal one, and originates from a destructive interference of the two channels (see also later). On the contrary, if both processes were independent, the linewidth would be the sum of both contributions. In conclusion this regime of finite interdot Coulomb energy can be helpful to assess the strength of the nonlocal coupling \( \Gamma_S \) in comparison to the local terms.

IV. INFLUENCE OF INTERDOT TUNNELING AND SPIN-ORBIT INTERACTION

In this section, we consider the effect of finite interdot tunneling and SO interaction on the current \( I_R \). For the sake of simplicity we consider in the following only the case \( \phi = 0 \) (no SO coupling) and \( \phi = \pm \pi/2 \) (finite SO coupling with \( k_{SOI} = \pi/2 \)). Let us first focus on the general behavior of the current as a function of the level position and chemical potential as shown in the density plots of Fig. 4. For simplicity we consider the case without interdot Coulomb energy, \( U = 0 \), which describes well the situation of \( \Gamma_{S\alpha} \gg U \). Finally, in order to see stronger signatures of the interdot tunneling term we generally consider \( U_C \gg t \gg \Gamma_S, \Gamma_{S\alpha} \).

In the top panel we show the case of finite interdot tunneling in the absence of SO coupling, i.e. \( \phi = 0 \), which can be directly compared with the density plot of Fig. 2(a) where the interdot tunneling was absent. One immediately sees that the Andreev resonant lines (black solid lines) are generally split in comparison to the case without interdot tunneling, giving rise to an even richer Andreev-bound-state spectrum. The most general observation is that the PH symmetry of the transport properties, as discussed in section III, is broken, i.e. \( I_a(\mu, \epsilon) \neq -I_a(-\epsilon, -\mu) \) with \( \epsilon_0 = -U_C/2 + U \). The breaking of the PH symmetry in transport is observed if both the quantities \( \Gamma_S, \Gamma_{S\alpha} \neq 0 \). On the other hand if one of these quantities vanishes the PH symmetry is restored. We discuss PH-symmetry breaking in more detail in Sec. IV A.

In the bottom panel of Figure 4 instead, we show how the current is affected by tunneling in the presence of the SO coupling, for the case \( \phi = \pm \pi/2 \). We see that in this case the PH symmetry is again restored for any value of \( \phi = \pm \pi/2 \). Note that the Andreev addition

![Figure 4](image-url)

**FIG. 4.** (a) Current \( I_R \) through the right lead as a function of the gate voltage \( \epsilon = \epsilon_L = \epsilon_R \) and chemical potential \( \mu = \mu_R = \mu_L \) for finite interdot tunneling with \( t = 0.4U_C \) and the SO angle \( \phi = 0 \). Other parameters are \( U = 0 \), \( \Gamma_S = \Gamma_{S\alpha} = 7.5 \times 10^{-2}U_C \), \( \Gamma_{N\alpha} = 2.5 \times 10^{-4}U_C \) and \( k_B T = 2.5 \times 10^{-5}U_C \). (b) Current \( I_R \) for the same parameters as in panel (a) but for finite SO interaction with an SO angle of \( \phi = \pm \pi/2 \).
energies spectrum becomes also quite intricate and it is not so useful to enter in the details of the behavior of any resonant line. In general one can see that in comparison to the top panel crossings and avoided crossings occur between different pairs of Andreev levels. This is a natural consequence of the different symmetry of the tunnel coupling between the two dots in the two cases. Finally, for $\Gamma_S, \Gamma_S' \neq 0$, the CAR peaks are split along the level-position axis and an extra resonance appears. We will discuss in detail the nature of this extra resonance in Sec. IV B.

A. Interdot tunneling and breaking of PH

To investigate the PH symmetry breaking, we apply the PH transformation $d_{\alpha\sigma} \rightarrow d_{\alpha'-\sigma}'$ to Eq. (4). It is easy to check that indeed this transformation leaves obviously unaffected the local and nonlocal pairing terms but is equivalent to a change of sign of the interdot tunneling term, i.e. $t \rightarrow -t$. Therefore, the symmetry obeyed by the current is $I_{\alpha}(\epsilon, \mu, t) \rightarrow -I_{\alpha}(2\epsilon_0 - \epsilon, -\mu, -t)$ which we have numerically verified. Notice that the sign of $t$ in the tunneling Hamiltonian cannot be gauged away only if both the local and nonlocal pairing terms are present in Eq. (4). Finally, we notice that for $|\phi| = \pi/2$ the sign of $t$ is unessential due to Kramer's degeneracy and therefore the PH symmetry is restored in this special case.

It remains the question why the sign and more generally a phase of $t$ is detectable in the transport properties of the system. This is essentially due to the interference between two paths connecting the empty state with the singlet state. One path is the nonlocal Andreev tunneling with rate $\Gamma_S$ while the other is the process where a Cooper-pair virtually tunnels into one of the dots bringing it in the doubly occupied state and subsequently this
state is converted into a singlet state by interdot tunneling. The interference between the two paths is clearly affected by the phase (not only the sign) of \( t \). In order to observe this interference effect the doubly occupied state of a single dot needs to be accessible. We have verified that, for \( U_C \to \infty \), an overall phase of \( t \) does not affect the transport properties of the system.

**B. Weak interdot Coulomb energy, \( \Gamma_{Sa} \gg U \)**

We focus on the effect of the interdot tunneling on the CAR resonance. In Fig. 5(a)-(c) we show the evolution of the CAR current peak for different values of \( |t| \) for \( \phi = 0 \). For increasing strength of the interdot tunneling, the position of the CAR resonance shifts to the right and at the same time the resonance linewidth changes. The peak shift is \( \delta \epsilon_{\text{CAR}}/U_C \approx (1/2) (t/U_C)^2 \) for \( t \ll U_C \). This is shown in the panel Fig. 5(d) where the position of the CAR peak maximum \( \epsilon_{\text{max}} \) is plotted as a function of \( \tau = t/U_C \). For different values of the nonlocal coupling \( \Gamma_S \) [different point styles in panel (d)] the peak position follows the same universal function of \( \tau \) (solid line). Instead the linewidths, shown in Fig. 5(e)-(f), exhibit quite different behaviors depending on the value of \( \Gamma_S \), the strength of \( t \) and also its sign.

These observations can be explained by making use of a reduced Hilbert space which describes well the system in the vicinity of the CAR resonance. This simplified model is sketched in Fig. 6. The relevant states for the CAR resonance are the empty state \( |0\rangle \), the singlet state \( |S\rangle \), and the singly occupied states \( |\alpha \sigma \rangle \). The states in the even sector \( |0\rangle \) and \( |S\rangle \) are connected via the nonlocal term \( \Gamma_S \), and they are connected to the singly occupied states \( |\alpha \sigma \rangle \) via the tunneling rate to the normal lead, \( \Gamma_N \). In the absence of interdot tunneling the CAR resonance linewidth is only determined by the nonlocal term \( \Gamma_S \), see section III. However, for finite intradot Coulomb energy in the presence of local terms \( \Gamma_{Sa} \) and strong interdot tunneling \( t \) (with \( \phi = 0 \)), we need to consider also an additional possibility: when the quantum-dots are in the empty state a Cooper pair can be virtually transferred by means of the local term \( \Gamma_{Sa} \) in the doubly occupied state \( |d\alpha \rangle \) which is converted to the singlet state via the interdot tunneling. One can see in Eq. (A1) that the tunneling amplitude \( (t/\sqrt{2}) \cos(\phi) \) couples the \( |d\alpha\rangle \) states with the singlet state \( |S\rangle \). We will quantitatively show that the interference of this alternative channel with the standard nonlocal process fully determines the observed behavior of the CAR peak.

When \( \Gamma_S \ll t \), the peak shift can be understood in terms of the level repulsion of the singlet state with the doubly occupied state. We first note that the interdot coupling removes the degeneracy of the double occupancies and yields the states \( |d\pm\rangle = (|dR\rangle \pm |dL\rangle)/\sqrt{2} \). Only the symmetric state \( |d+\rangle \) is affected by the level repulsion with \( |S\rangle \). In this model the hybridized states \( |\pm\rangle \approx \alpha |S\rangle \pm \beta |d+\rangle \) with \( \alpha, \beta \) c-numbers have the energies

\[
\epsilon_{\pm} = \frac{1 + 4\epsilon/\epsilon_{\text{CAR}} \pm \sqrt{1 + 4\tau^2}}{2},
\]

where \( \tau = t/U_C \). The position of the CAR resonance is the solution of equation \( \epsilon_{\pm}(\epsilon_{\text{CAR}}) = 0 \), the resonance condition between \( |\pm\rangle \) and the empty state \( |0\rangle \). The peak position is \( \epsilon_{\text{CAR}} = (\sqrt{1 + 4\tau^2} - 1)U_C/4 \), which fits well the shifting of the peak position [see solid line in Fig. 5(d)]. In the limit \( U_C \to \infty \) (\( \tau \to 0 \)) the doubly occupied states are unaccessible, even virtually, and the transport becomes independent of the interdot tunneling.

Finite interdot tunneling also modifies the linewidth of the CAR peak as can be seen in Fig. 5(a)-(c) and more clearly in Fig. 5(e)-(f) where we show the linewidth \( \epsilon_{\text{CAR}} \) of the CAR resonance. For \( \Gamma_S = \sqrt{\Gamma SL tin_{SR}} \) (black circles) the width is roughly proportional to the nonlocal coupling while for \( \Gamma_S = 0 \) (red triangles) it increases with \( \tau \). Intriguingly, for an intermediate value of \( \Gamma_S \) (blue small circles) and \( \tau > 0 \), the linewidth almost vanishes for a specific value of \( \tau \) [see Fig. 5(e)]). This behavior is not seen for \( \tau < 0 \) [see Fig. 5(f)].

We can explain these results by making use again of the simplified model shown in Fig. 6. In the absence of the interdot tunneling the linewidth of the CAR peak is only determined by the strength of the coupling between the empty state \( |0\rangle \) and the singlet state \( |S\rangle \). Essentially, it is given by the off-diagonal matrix element \( w_{\text{CAR}} = 2 |\langle 0 |H_S|S\rangle| = \sqrt{2}\Gamma_S \). Any additional process that contributes to that coupling between \( |0\rangle \) and \( |S\rangle \), also through a virtual high energy state, will affect the linewidth. This correction may be obtained considering the effective Hamiltonian \( H_S = H_0 + V \), which represents the model shown in Fig. 6, with \( H_0 = \sum_i E_i |i\rangle \langle i| - \langle \Gamma_S/\sqrt{2}|(0\langle S + |S\rangle\langle 0|) \) for \( i = 0, S, d+, d- \) and the per-
we show the behavior of the CAR peak with increasing values of $t$ for constant values of $U_C$ and $\Gamma_S$. First we notice that for $\Gamma_S = 0$ (dashed lines) the CAR peak does not split but it shifts to the right for increasing values of $\tau$ and no resonance is present at $\epsilon \approx 0$. Instead, for $\Gamma_S \neq 0$, the resonance splits into two resonances, one fixed at $\epsilon \approx 0$ and the other right-shifted with $\delta \epsilon_{\text{rs}}/U_C \approx (1/2)(t/U_C)^2$. This demonstrates the connection with the nonlocal term $\Gamma_S$ of the CAR peak at $\epsilon \approx 0$.

We numerically observed that the current of the right-shifted peak follows the population of the unpolarized triplet state, $hI_{\text{rs}}/e_0 \Gamma_{NR} \approx 2P_{00}$. These observations suggest that a resonant mechanism involving the virtual occupation of the $|d+\rangle$ is established with the unpolarized triplet state $|T0\rangle$, as depicted schematically in Fig. 6. This mechanism is analogous to the one induced by the nonlocal singlet proximity in the case of interdot coupling where $\phi = 0$. We refer to this resonance as triplet CAR resonance, since it generates nonlocal entanglement with triplet symmetry. The position and linewidth of this right-shifted resonance are described by Eq. (9) and Eq. (11) setting $\Gamma_S = 0$, respectively. This is a consequence of the fact that a $s$-wave superconductor cannot induce directly triplet correlations. This shows how the presence of SO coupling can nevertheless induce nonlocal triplet superconducting correlations even when the only superconducting lead has $s$-wave pairing symmetry.

**V. CONCLUSIONS**

We have presented a comprehensive study of a Cooper-pair splitter based on a double-quantum dot. Employing a master-equation description, in the framework of FCS, we have calculated the current injected into the normal leads. We have considered a finite intra-dot interaction which allows the local transfer of Cooper-pairs from the superconductor to an individual quantum dot. We have studied the signatures of local and nonlocal Andreev reflection in the current injected in the normal leads. The interdot Coulomb interaction separates the local and nonlocal resonances. The effect of interdot tunneling both with and without SO coupling has been considered, too. In particular, we find that the interdot tunneling can induce nonlocal entanglement starting from local Andreev reflection. Furthermore, a process including the virtual doubly-occupied states of the individual dots leads to modifications of the position and linewidth of the current resonances. For the case with SO coupling, we find that a nonlocal triplet pair amplitude can be generated in the system. This mechanism involving the virtual occupation of the doubly occupied states is active only for finite intradot Coulomb interaction.

Appendix A: Matrix representation of the system Hamiltonian

In this section we provide the decomposition of the system Hamiltonian \( H_S = H_S^{\text{even}} \oplus H_S^{\text{odd}} \) into sectors with even and odd parity. We assume the single particle level spacing in the quantum dot to be large compared to \( U \), \( U_\alpha \) and the interdot tunneling \( t \), so the total dimension of the system Hilbert space reduces to 16 states (8 even + 8 odd). Here, we express Eq. (4) in the even sector basis \( \{ |0\rangle, |S\rangle, |dL\rangle, |dR\rangle, |dd\rangle, |T0\rangle, |T\uparrow\rangle, |T\downarrow\rangle \} \) stated in Table I. The Hamiltonian for the even charge sector reads

\[
H_S^{\text{even}} = \begin{pmatrix}
0 & -\frac{1}{\sqrt{2}} \Gamma_S & -\frac{1}{2} \Gamma_{SL} & -\frac{1}{2} \Gamma_{SR} & 0 & 0 & 0 & 0 \\
-\frac{1}{\sqrt{2}} \Gamma_S & \epsilon_L + \epsilon_R + U & \frac{1}{\sqrt{2}} \cos(\phi) & \frac{1}{\sqrt{2}} \cos(\phi) & +\frac{1}{\sqrt{2}} \Gamma_S & 0 & 0 & 0 \\
-\frac{1}{2} \Gamma_{SL} & \frac{1}{\sqrt{2}} \cos(\phi) & 2 \epsilon_L + U_L & 0 & -\frac{1}{2} \Gamma_{SR} & i \frac{\sqrt{2}}{2} \sin(\phi) & 0 & 0 \\
-\frac{1}{2} \Gamma_{SR} & -\frac{1}{2} \Gamma_{SL} & 0 & 2 \epsilon_R + U_R & -\frac{1}{2} \Gamma_{SL} & i \frac{\sqrt{2}}{2} \sin(\phi) & 0 & 0 \\
0 & +\frac{1}{\sqrt{2}} \Gamma_S & -\frac{1}{2} \Gamma_{SR} & -\frac{1}{2} \Gamma_{SL} & 2(\epsilon_R + \epsilon_L) + U_R + U_L + 4U & 0 & 0 & 0 \\
0 & 0 & -i \frac{\Gamma_L}{2} \sin(\phi) & -i \frac{\Gamma_R}{2} \sin(\phi) & 0 & \epsilon_L + \epsilon_R + U & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & \epsilon_L + \epsilon_R + U & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & \epsilon_L + \epsilon_R + U
\end{pmatrix}
\]

(A1)

Note that the interdot tunneling preserves the spin of the tunneling electrons (being time reversal invariant) and the total parity of the DQD. In absence of the SO interaction, \( \phi = 0 \), all triplet states \( |T\rangle \) are completely decoupled from the other even parity states. When \( \phi \neq \pi k \), where \( k \) integer, the unpolarized triplet state |\( T \rangle \rangle \) couples with the doubly occupied states |\( d\rangle \). The Hamiltonian for the odd charge sector, in the basis \( \{|R\rangle, |L\rangle, |L\rangle, |T\rangle, |dR\rangle, |dL\rangle, |T\uparrow\rangle, |T\downarrow\rangle \} \), is given by

\[
H_S^{\text{odd}} = \begin{pmatrix}
\epsilon_R & 0 & \frac{t}{2} e^{-i\phi} & 0 & -\frac{1}{2} \Gamma_{SL} & 0 & +\frac{1}{2} \Gamma_S & 0 \\
0 & \epsilon_R & 0 & \frac{t}{2} e^{+i\phi} & 0 & -\frac{1}{2} \Gamma_{SL} & 0 & +\frac{1}{2} \Gamma_S \\
\frac{t}{2} e^{+i\phi} & 0 & \epsilon_L & 0 & +\frac{1}{2} \Gamma_S & 0 & -\frac{1}{2} \Gamma_{SR} & 0 \\
0 & \frac{t}{2} e^{-i\phi} & 0 & \epsilon_L & 0 & +\frac{1}{2} \Gamma_S & 0 & -\frac{1}{2} \Gamma_{SR} \\
0 & -\frac{1}{2} \Gamma_{SL} & 0 & +\frac{1}{2} \Gamma_S & 0 & E_{LR\uparrow} & 0 & -\frac{t}{2} e^{-i\phi} \\
-\frac{1}{2} \Gamma_{SR} & 0 & -\frac{1}{2} \Gamma_{SL} & 0 & +\frac{1}{2} \Gamma_S & 0 & E_{LR\downarrow} & 0 \\
0 & +\frac{1}{2} \Gamma_S & 0 & -\frac{1}{2} \Gamma_{SR} & 0 & -\frac{t}{2} e^{+i\phi} & 0 & E_{dL\uparrow} \\
0 & 0 & +\frac{1}{2} \Gamma_S & 0 & -\frac{1}{2} \Gamma_{SR} & 0 & 0 & E_{dL\downarrow}
\end{pmatrix}
\]

(A2)

where \( E_{L\alpha\sigma} = 2\epsilon_\alpha + U_\alpha + \epsilon_\alpha + 2U \) with \( \alpha = R, L \) (\( \bar{\alpha} = L, R \)) and \( \sigma = \uparrow, \downarrow \).
